Savannah River	9.4 x 10-3	4.5 x 10-2	4.5 x 10-7
Hanford	2.8 x 10-3	1.6 x 10-2	1.6 x 10-7
Puget Sound	1.3	2.8 x 10-1	2.8 x 10-6
Pearl Harbor	6.7 x 10-1	6.0 x 10-1	6.0 x 10-6
Norfolk	2.7	3.5 x 10-1	3.5 x 10-6

Portsmouth	1.4	1.5 x 10-1	1.5 x 10-6
Kesselring	2.3 x 10-1	1.1 x 10-1	1.1 x 10-6
Nevada Test Site	2.0 x 10-2	7.0 x 10-4	7.0 x 10-9
Oak Ridge	4.7	8.8 x 10-2	8.8 x 10-7

The risk for this hypothetical accident is more severe at Navy shipyards than at the DOE sites. At all sites, this accident results in the second highest risk of the wet storage accidents evaluated.

For the hypothetical criticality accident scenario, the radioactive plume might cause contamination of the ground to a downwind distance of 0.25 mile. This would yield a total area impacted by the accident of approximately 8 acres. The calculated downwind distance would be contained within the boundaries of all sites under evaluation with the exception of Oak Ridge and Norfolk.

F.1.4.2.1.3 Mechanical Damage from Operator Error, Crane Failure, or Similar Accidents

F.1.4.2.1.3.1 Description of Conditions. Accidental mechanical damage to spent fuel was evaluated. The hypothetical accident included damage to one fuel unit, allowing fission products within the elements to escape through the clad failures. All gas and some volatile and solid nuclides were calculated to be released to the pool. The release fractions are consistent with severe accident analyses and Regulatory Guide 1.4. Due to the presence of pool water, no solids would be released into the air inside the facility.

F.1.4.2.1.3.2 Source Term. Conditions used in developing the source term are as follows:

- One fuel unit is damaged because only one fuel unit would be handled at a time and the storage facility design prevents damage to stored units from such events.
- One percent of the fuel is damaged and those fission products are available for release.
- All (100%) of the noble gases are released to the environment.
- Approximately 25% of the halogens are released to the pool and 90% of these fission products are absorbed in the water as they rise through the pool water. Therefore, 2.5% of the halogens are released to the air inside the facility.
- Due to the gaseous nature of the released fission products, installed HEPA filters would not remove them once they are released to the air in the building.
- The release to the environment occurs at a constant rate over a 15-minute period.
- There is no particulate fission product release to the atmosphere due to the presence of pool water.
- The following amounts of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclides	Curies

H-3	1.42
I-129	2.52 x 10-6
I-131	5.37 x 10-5

F.1.4.2.1.3.3 Results. The following table summarizes the public health risk to the general population that would result from the hypothetical mechanical damage accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. The probability of the occurrence of fuel damage is small based on the conservative fuel handling rules. At the INEL-ECF, it is recognized that the drop of a heavy container into a storage rack could crush the rack and the stored fuel and so heavy casks are never moved over the storage rack area. The heavy containers are brought only into an empty receiving area to discharge a single fuel unit. The spent fuel is removed from the receiving area before the next fuel unit is brought into the receiving area. Therefore, two errors must occur before damaged fuel is possible. The first is that fuel is improperly left in the discharge station while the heavy cask is moved over the discharge station. The second is that the cask must accidentally fall from the overhead crane or the crane must fail. The probability of failure associated with crane failure has been taken as 10-2 per year. Further, the crane failure must also occur in the right location and the drop must be high enough that sufficient energy is available to damage both the discharge station structurals and the fuel inside. An additional factor of 10-2 has been taken for this event, giving the total probability of 10-4 for the drop of the cask in the right location. Allowing a fuel unit to remain in the stand requires an operator error because fuel handling procedures call for the fuel unit to be removed from the stand and taken to an underwater storage location away from the receiving area. In addition, because independent overchecking is required for all fuel movement, an error by a verifier is also required. Therefore, based on operator error rates (Swain and Guttman 1983), the likelihood of this error is taken as 10-4 per year. Hence, the combined probability of cask drop on a fuel unit is taken as 10-8 per year per fuel movement. Then, taking an estimated rate of 1,000 fuel movements per year, the overall probability is taken as 10-5 events per year.

Wet Storage Mechanical Damage Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cance if accident occurs	Risk per year
INEL	2.6 x 10-6	5.3 x 10-6	5.3 x 10-11
Savannah River	2.2 x 10-6	2.0 x 10-5	2.0 x 10-10
Hanford	9.8 x 10-7	8.6 x 10-6	8.6 x 10-11
Puget Sound	1.7 x 10-4	7.2 x 10-5	7.2 x 10-10
Pearl Harbor	9.3 x 10-5	1.5 x 10-4	1.5 x 10-9
Norfolk	3.5 x 10-4	8.0 x 10-5	8.0 x 10-10
Portsmouth	1.9 x 10-4	5.6 x 10-5	5.6 x 10-10
Kesselring	3.6 x 10-5	6.0 x 10-5	6.0 x 10-10
Nevada Test Site	4.6 x 10-6	5.6 x 10-7	5.6 x 10-12
Oak Ridge	5.9 x 10-4	3.4 x 10-5	3.4 x 10-10

The risk for this hypothetical accident is generally more severe at Navy shipyards than at the DOE sites. At all sites, this accident results in the lowest or next to the lowest risk of the wet storage accidents evaluated.

For the hypothetical wet storage mechanical damage accident scenario, the radioactive plume might cause contamination of the ground to a downwind distance of less than 0.06 mile. This would yield a total area impacted by the accident of less than 0.5 acre. The calculated downwind distance would be contained within the boundaries of all sites under evaluation.

F.1.4.2.1.4 Airplane Crash.

F.1.4.2.1.4.1 Description of Conditions. Impact into water pools by aircraft with resulting

damage to the naval fuel units stored inside the pool was evaluated. Based on the probability of occurrence, as discussed in Section F.3, specific analyses were only performed for Savannah River, the Nevada Test Site, Oak Ridge, Pearl Harbor, Norfolk, and Kesselring locations. At other locations, the likelihood of occurrence is less than 10-7 per year. The hypothetical accident included damage to all fuel units stored at the water pool. Fission products and corrosion products are released from the fuel units into the water pool; however, the pool water is not released to the environment. An airplane crash into a water pool would not produce enough force to cause the pool to leak because the walls of the water pool are constructed of thick, reinforced concrete with earth surrounding them, making them very strong. In addition, it was judged unlikely that an airplane would impact the water pool at an angle steep enough to expose the floor of the pool or the walls of the pool below the water level to the direct impact. The presence of pool water results in only a release of gaseous fission products to the atmosphere.

F.1.4.2.1.4.2 Source Term. Conditions used in developing the source term are as follows:

- One percent of the fission products from each of the fuel units stored inside the pool is available for release.
- Of the available fission products, 100% of the noble gases and 25% of the halogens are released to the pool water. Due to the presence of pool water, a reduction of the halogen release by a factor of 10 prior to release to the atmosphere occurs.
- No solid fission products or corrosion products are released to the environment due to the continued presence of pool water.
- The release to the environment occurs at a constant rate over a 15-minute period.
- 300 naval fuel units would be in the water pool.
- No filtration by HEPA filters is assumed.
- The following amounts of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclide	Curies
I-129	7.59 x 10-4
I-131	1.61 x 10-2
H-3	4.28 x 102

F.1.4.2.1.4.3 Results. The following table summarizes the public health risk to the general

population that would result from the hypothetical airplane crash accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence.

Water Pool Airplane Crash Summary

Site	Probability of accident per year	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancers if accident occurs	Risk per year
Savannah River	2 x 10-6	6.4 x 10-4	6.1 x 10-3	1.2 x 10-8
Pearl Harbor	2 x 10-5	2.8 x 10-2	4.6 x 10-2	9.2 x 10-7
Norfolk	4 x 10-7	1.1 x 10-1	2.4 x 10-2	9.6 x 10-9
Kesselring	2 x 10-7	1.1 x 10-2	1.8 x 10-2	3.6 x 10-9
Nevada Test Site	4 x 10-7	1.3 x 10-3	1.7 x 10-4	6.8 x 10-11
Oak Ridge	1 x 10-6	1.8 x 10-1	1.0 x 10-2	1.0 x 10-8

The risk for this hypothetical accident is most severe at Pearl Harbor. For the sites with crash probabilities less than 10-7 per year, consequences were not calculated since it is expected that they would not substantially contribute to the risk.

For the hypothetical airplane crash into a wet storage facility accident scenario, the radioactive plume might result in contamination of the ground to a downwind distance of less than 0.06 mile. This would yield a total area impacted by the accident of less than 0.5 acre. The calculated downwind distance would be contained within the boundaries of all sites that are at risk for this accident.

F.1.4.2.1.5 HEPA Filter Fire.

F.1.4.2.1.5.1 Description of Conditions. In this hypothetical accident scenario, a fire in the

ECF High Efficiency Particulate Air (HEPA) filter banks is postulated. This accident could be initiated by the ignition of a flammable mixture released upstream of the system or by an external, unrelated fire that spreads to this system. Although the risks associated with this accident are relatively minor, it was analyzed to bound the higher probability, lower consequence type accident category. The airborne release fractions associated with this accident were conservatively chosen so that a HEPA filter failure by crushing or impact was also bounded.

F.1.4.2.1.5.2 Source Term. Conditions used in developing the source term are as follows:

- The original inventory of fission products in the filters is based on the total estimated unabated ECF releases over a 5-year period.
- One percent of the radionuclide inventory present on the filters becomes airborne during the fire. Release fractions for HEPA filters are small because the filters are constructed of material containing glass fibers which would melt during a fire and trap particles in the medium. Measurements from experiments show that one one-hundredth of 1% of the material in HEPA filters could be released during a fire, but 1% has been used in these analyses to allow for uncertainties in the final results of an individual fire.
- The release to the environment occurs at a constant rate over a 15-minute period.
- There is no increase in direct radiation due to this accident.
- The following amounts of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.
- No filtration by HEPA filters is assumed.

Nuclide	Curies	Nuclide	Curies
Cs-137	1.46 x 10-3	Co-60	2.09 x 10-3
Cs-134	2.04 x 10-4	Sr-90	8.90 x 10-4
Ba-137M	6.26 x 10-6	Y-90	8.90 x 10-4
Fe-55	2.32 x 10-3	Eu-154	9.80 x 10-5
Ni-63	2.98 x 10-3		

F.1.4.2.1.5.3 Results. The following table summarizes the public health risk to the general

population that would result from the hypothetical HEPA filter fire accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. The probability of a fire in a HEPA filter is estimated based on the probability of other fires spreading to the HEPA filter system. As discussed in section F.2.4.2, a probability of 5 x 10-3 is assigned to chemical fires. The probability of HEPA fires is considered less than a chemical fire since chemicals would not be stored in the immediate vicinity of the HEPA filter system. Additionally, HEPA filters are not inherently volatile or explosive. It is estimated that the probability for an existing chemical fire to spread to the HEPA filters is less than 0.1. This results in a probability of less than 5 x 10-4 for a HEPA filter fire. A value of 5 x 10-4 was used to develop the risk results in the table.

HEPA Filter Fire Summary

Site	Maximally exposed off-site individual (MOI)	No. of fatal cancer if accident occurs	Risk per year

	(rem)		
INEL	2.5 x 10-5	5.3 x 10-5	2.7 x 10-8
Savannah River	2.1 x 10-5	1.3 x 10-4	6.5 x 10-8
Hanford	7.0 x 10-6	5.3 x 10-5	2.7 x 10-8
Puget Sound	1.6 x 10-3	6.4 x 10-4	3.2 x 10-7
Pearl Harbor	8.7 x 10-4	1.2 x 10-3	6.0 x 10-7
Norfolk	3.3 x 10-3	6.9 x 10-4	3.5 x 10-7
Portsmouth	1.7 x 10-3	3.9 x 10-4	2.0 x 10-7
Kesselring	3.5 x 10-4	3.3 x 10-4	1.7 x 10-7
Nevada Test Site	4.3 x 10-5	5.7 x 10-6	2.9 x 10-9
Oak Ridge	5.7 x 10-3	2.2 x 10-4	1.1 x 10-7

The risk for this hypothetical accident is generally more severe at the Navy shipyards than at the DOE sites.

For the hypothetical HEPA filter fire accident scenario, the radioactive plume might cause contamination of the ground to a downwind distance of less than 0.06 mile. This would yield a total area impacted by the accident of less than 0.5 acre. The calculated downwind distance would be contained within the boundaries of all sites under evaluation.

F.1.4.2.1.6 Minor Water Pool Leakage.

F.1.4.2.1.6.1 Description of Conditions. In this hypothetical accident scenario, a minor leak develops in the water pool resulting in a gradual discharge to the environment. There is no danger of uncovering any spent nuclear fuel in the water pool, since the leak is so small that it is undetected and water level is maintained in the water pool. Since a strict accounting of water added to and removed from the water pool is maintained, the magnitude of this leak would be less than 4,400 gallons per year. The 4,400 gallons per year value is the maximum amount of water which might leak out of the water pool before periodic review of the water balance would detect a leak.

F.1.4.2.1.6.2 Source Term. There is no airborne release above normal levels in this hypothetical accident scenario. The radionuclide inventory in the leaking water is based on radioactivity analysis of ECF water pool water. The isotopes that were analyzed for but not detected could exist at the minimum detection limit.

Nuclide	Sample Results (-Ci/mL)	10CFR20 Effluent Limit (-Ci/mL)	Annual Releases (Ci/year)
H-3	2.0 x 10-4	1.0 x 10-3	3.3 x 10-3
Mn-54	2.5 x 10-8	3.0 x 10-5	4.1 x 10-7
Fe-55	1.0 x 10-8 *	1.0 x 10-4	1.6 x 10-7 *
Co-58	7.0 x 10-8	2.0 x 10-5	1.1 x 10-6
Co-60	1.6 x 10-5	3.0 x 10-6	2.6 x 10-5
Ni-63	2.3 x 10-7	1.0 x 10-4	3.8 x 10-6
Sr-90	4.0 x 10-9	5.0 x 10-7	6.5 x 10-8
Y-90	4.0 x 10-9	7.0 x 10-6	6.5 x 10-8
I-129	4.0 x 10-7 *	2.0 x 10-7	6.5 x 10-6 *
Cs-137	4.2 x 10-8	1.0 x 10-6	6.9 x 10-7

* These radionuclides were not detected in the ECF water. The numbers quoted reflect the detection limit of the analysis.

It should be noted that the sample results for the water pool indicate that the nuclide levels are all below the Code of Federal Regulations limits for liquid effluent in 10CFR20 with the exception of Co-60. The level of I-129 used in the calculations was based on the minimum detection limit of the sample. This level exceeds the effluent limit; however, I-129 was not actually detected in the water sample. Since Sr-90 has comparable water solubility to I-129 and exists in spent nuclear fuel at about a factor of 1.0 x 106 higher than I-129, it is inferred from the detected level of Sr-90 that the actual level of I-129 is well below the 10CFR20 effluent limit.

F.1.4.2.1.6.3 Results. The following table summarizes the public health risk to the general

population that might result from the hypothetical minor water pool leak at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. The probability of a leak developing is 10-1 per year.

Minor Water Pool Leakage Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancer if accident occurs	Risk per year
INEL	2.5 x 10-9	1.3 x 10-8	1.3 x 10-9
Savannah River	7.9 x 10-10	1.3 x 10-9	1.3 x 10-10
Hanford	9.9 x 10-12	1.7 x 10-10	1.7 x 10-11
Puget Sound	3.2 x 10-10	4.2 x 10-9	4.2 x 10-10
Pearl Harbor	1.3 x 10-10	4.6 x 10-10	4.6 x 10-11
Norfolk	2.7 x 10-10	1.8 x 10-9	1.8 x 10-10
Portsmouth	1.3 x 10-10	1.4 x 10-9	1.4 x 10-10
Kesselring	6.0 x 10-9	8.5 x 10-9	8.5 x 10-10
Nevada Test Site	2.5 x 10-9	1.4 x 10-9	1.4 x 10-10
Oak Ridge	1.5 x 10-9	3.9 x 10-9	3.9 x 10-10

At all sites except the Nevada Test Site, this accident results in the lowest or next to lowest risk of the wet storage accidents evaluated.

F.1.4.2.2 Dry Storage.

F.1.4.2.2.1 Wind-driven Missile Impact into Storage Casks with Mechanical

Damage.

F.1.4.2.2.1.1 Description of Conditions. In this hypothetical accident, no fuel damage

would result from any impact because of the strength of the containers used. Dry storage containers could experience a major wind storm or tornado which could propel a large object into a storage container causing the container seal to be breached. However, container analysis for this situation shows that the container is strong enough to prevent crushing of the spent nuclear fuel and release of fission products.

Winds produced by tornados are higher than hurricane winds and thus the impacting missile would be travelling with higher velocity and would have higher kinetic energy. Even at this higher velocity, analysis has shown that the missile would not penetrate the container. The probability of penetration at the lower velocity of a hurricane (212 miles per hour) would be even smaller than the probability of penetration for a missile propelled by the winds of a tornado (travelling at 360 mph). While hurricanes can have high winds, hurricane winds normally cannot generate the very large, very fast missiles analyzed for tornados. While hurricanes may occur more frequently than tornados, the overall risk from a hurricane is lower because the container would not be penetrated.

The analysis of wind damage using missiles propelled by the winds of tornados is the same as is done for design of nuclear power plants. Hurricanes very infrequently have winds that could generate such missiles, so the analyses provided for tornados provide an upper limit for the effects of hurricanes. Examination of damage caused by recent severe hurricanes shows that robust structures can withstand hurricanes.

F.1.4.2.2.1.2 Source Term. Conditions used in developing the source term are as follows:

- The source term is based on best estimate spent nuclear fuel corrosion products.
- One percent of the original corrosion products associated with the fuel could be released from the cask to the atmosphere. This is based on experimental measurements of the fraction of corrosion products loosened from naval spent nuclear fuel by shock and vibration and the fact that a wind-driven missile would not penetrate the container or damage the fuel inside. Only loose corrosion products would be available for release from the container, and any release from the container would have to occur via a convoluted path through the damaged seal.
- The release to the environment occurs at a constant rate over a 15-minute period.
- There is no increase in direct radiation due to this accident.
- The following amounts of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclide	Curies
Co-60	9.58 x 10-2
Fe-55	1.76 x 10-1
Co-58	3.54 x 10-2
Mn-54	5.98 x 10-3
Fe-59	5.11 x 10-4

F.1.4.2.2.1.3 Results. The following table summarizes the public health risk to the general

population that would result from the hypothetical wind-driven missile accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. The probability of container damage is small due to the very strong container design. The dry storage containers are expected to be designed as well as shipping containers so that they would not be penetrated by environmentally caused missiles and the fuel would not be affected. However, an analysis was performed for a case in which the impact of a tornado missile might topple a container on a railcar and cause unseating of the container seal and thus release radioactive material in the form of corrosion products.

The probability of the occurrence of a tornado was obtained using the data in document WASH-1300 (AEC 1974). The maximum likelihood of a tornado occurrence at all storage locations being evaluated in the continental United States is 10-3 per year. The probability of a missile generated by the tornado striking a container and causing the damage analyzed has been estimated to be less than 10-2. Thus, the total probability of a wind-driven missile damaging a container is less than 10-5, and a probability of 10-5 per year was used in the risk assessment.

Dry Storage Mechanical Damage Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancer if accident occurs	Risk per year
INEL	4.6 x 10-4	4.9 x 10-4	4.9 x 10-9
Savannah River	4.9 x 10-4	3.0 x 10-3	3.0 x 10-8
Hanford	1.7 x 10-4	1.3 x 10-3	1.3 x 10-8
Puget Sound	3.9 x 10-2	1.7 x 10-2	1.7 x 10-7
Pearl Harbor	2.1 x 10-2	3.0 x 10-2	3.0 x 10-7
Norfolk	8.1 x 10-2	1.8 x 10-2	1.8 x 10-7
Portsmouth	4.2 x 10-2	1.0 x 10-2	1.0 x 10-7
Kesselring	8.1 x 10-3	7.4 x 10-3	7.4 x 10-8
Nevada Test Site	8.8 x 10-4	5.3 x 10-5	5.3 x 10-10
Oak Ridge	1.4 x 10-1	5.1 x 10-3	5.1 x 10-8

The risk for this hypothetical accident is generally more severe at Navy shipyards than at the DOE sites. This accident results in the lowest risk of the two dry storage accidents evaluated.

For the hypothetical wind-driven missile accident scenario, the radioactive plume might cause contamination of the ground to a downwind distance of less than 0.06 mile. This would yield a total area impacted by the accident of less than 0.5 acre. The calculated downwind distance would be contained within the boundaries of all sites under evaluation.

F.1.4.2.2.2 Airplane Crash.

F.1.4.2.2.2.1 Description of Conditions. A hypothetical aircraft accident scenario was developed for the dry storage option. Based on the probability of occurrence, as discussed in Section F.3, specific analyses were only performed for Savannah River, Oak Ridge, Pearl Harbor, Norfolk, Portsmouth, and Kesselring locations. At other locations, the likelihood of occurrence is less than 10-7 per year. The accident is postulated to cause damage to a single storage cask. This is based on the fact that containers used to store naval spent nuclear fuel would be very rugged so that only the rotor shaft from one of an airliner's jet engines would be strong enough and possess enough energy to have a chance of penetrating a container. From analyses of existing container designs, the rotor of a large jet engine, including those from the largest aircraft such as a Boeing 777, Russian Antonov An-225, or a Lockheed C-5, would not penetrate a container during an airliner crash, but, for the purposes of evaluation, calculations were performed for one container damaged to the extent that fission products and corrosion products might be released. Due to the severity of the shock, the cask seal might be breached resulting in damage to the fuel. The severe mechanical shock results in the release of corrosion products to the environment. The release of fission products also occurs due to the impact and resultant fire. The fission product release factors are based on overheating testing performed on the naval fuel systems.

F.1.4.2.2.2.2 Source Term. Conditions used in developing the source term are as follows:

- One percent of all of the fuel units stored inside the cask are damaged either by the impact or the resultant fire and those fission products are available for release.
- Of the available fission products, 100% of the noble gases, 3% of the halogens, 1.1% of the cesium, and 0.1% of the remaining solids are released to the environment.
- The release to the environment occurs at a constant rate over a 15-minute period.
- Ten percent of the original corrosion products from the fuel units are released from the cask to the atmosphere.
- The following amount of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclide	Curies
Cs-134	2.57 x 101
Cs-137	3.56 x 101
Pu-238	5.90 x 10-2
Ba-137M	3.07
Sr-90	3.12
Ce-144	7.17
Nb-95	4.37
Y-90	3.12
Ru-106	6.11 x 10-1

F.1.4.2.2.2.3 Results. The following table summarizes the public health risk to the general population that would result from the hypothetical airplane crash accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence.

Dry Storage Airplane Crash Summary

Site	Probability of accident per year	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancers if accident occurs	Risk per year
Savannah River	3 x 10-7	4.7 x 10-1	2.8	8.4 x 10-7
Pearl Harbor	1 x 10-5	19	26	2.6 x 10-4
Norfolk	1 x 10-6	72	16	1.6 x 10-5
Portsmouth	1 x 10-7	38	9.0	9.0 x 10-7
Kesselring	1 x 10-7	7.7	7.5	7.5 x 10-7
Oak Ridge	3 x 10-7	120	4.7	1.4 x 10-6

The risk for this hypothetical accident is most severe at Pearl Harbor and Norfolk. It is also the highest risk for any hypothetical accident evaluated at Pearl Harbor and Norfolk. For the sites with crash probabilities less than 10-7 per year, consequences were not calculated since it is expected that they would not substantially contribute to the risk.

For the hypothetical airplane crash into a dry storage cask accident scenario, the radioactive plume might cause contamination of the ground to a downwind distance of approximately 0.9 mile. This would yield a total area impacted by the accident of about 106 acres. The calculated downwind distance would be contained within the boundaries of the Savannah River and Kesselring sites. The contaminated plume would extend beyond the boundaries of Oak Ridge and the shipyards that are at risk for this accident.

F.1.4.2.3 Dry Cell Operations.

F.1.4.2.3.1 Inadvertent Cutting into Fuel Region or Mechanical Damage.

F.1.4.2.3.1.1 Description of Conditions. Mechanical damage due to handling during

examination, such as accidentally cutting into the fuel region of an element, was assessed. This hypothetical accident results from inadvertent cutting across the fuel region when cropping off the Zircaloy ends of a fuel unit. All noble gas isotopes within the vicinity of the cut might be released to the facility building and escape to the environment. The majority of the volatile and solid nuclides are likely to be retained in the fuel or the facility exhaust filters. The resulting airborne release to the environment was evaluated. The possible exposure to the workers, individuals living on the site boundary, and the general population was evaluated.

F.1.4.2.3.1.2 Source Term. Conditions used in developing the source term are as follows:

- One percent of the fission products in the fuel element being handled are close enough to the cut site to be available for release.
- All (100%) of the noble gases available for release are released to the atmosphere.
- Twenty-five percent of the halogens available for release are released.
- One percent of the particulate fission products could be released and 99.9% of these are removed by normally installed HEPA filters.
- Cs and Ru would behave like particulate fission products.
- The release to the environment occurs at a constant rate over a 15-minute period.
- There is no increase in direct radiation due to this accident.
- The following amounts of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclide	Curies
Pu-238	7.2 x 10-5
Cs-134	2.9 x 10-3
Cs-137	4 x 10-3
I-129	2.5 x 10-5
Sr-90	3.9 x 10-3
Ce-144	9.0 x 10-3
Nb-95	5.4 x 10-3
I-131	5.4 x 10-4
H-3	1.42
Y-90	3.9 x 10-3
Ba-137m	3.8 x 10-3
Ru-106	7.6 x 10-4
Zr-95	2.9 x 10-3
Y-91	2.3 x 10-3
Eu-154	2.7 x 10-4

F.1.4.2.3.1.3 Results. The following table summarizes the public health risk to the general

population that would result from the hypothetical mechanical damage accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. The probability of damage to fuel during handling is small. The work on fuel at the INEL-ECF includes removal of the non-fueled portions at each end of the fuel unit. This is done in a sawing operation. To cut into the fuel, there must be operator error in positioning the spent fuel in the cutting apparatus and error in selecting the saw cut positioning gage. The combined operator and independent checker error probability for cutting of the fuel has been evaluated to be less than 10-7 per cut (Swain and Guttman 1983). Using a conservative number of 103 saw cut operations per year results in a fuel cutting probability of less than 10-4 per year which has been used in the risk evaluation.

Dry Cell Mechanical Damage Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cance if accident occurs	Risk per year
INEL	2.2 x 10-4	3.5 x 10-4	3.5 x 10-8
Savannah River	2.4 x 10-4	1.4 x 10-3	1.4 x 10-7
Hanford	7.1 x 10-5	5.3 x 10-4	5.3 x 10-8
Nevada Test Site	4.0 x 10-4	3.7 x 10-5	3.7 x 10-9
Oak Ridge	5.8 x 10-2	2.5 x 10-3	2.5 x 10-7

The risk for this hypothetical accident is roughly proportional to the surrounding population with Oak Ridge being the worst and the Nevada Test Site being the best.

For the hypothetical dry cell mechanical damage accident scenario, the radioactive plume might result in contamination of the ground to a downwind distance of less than 0.06 mile. This would yield a total area impacted by the accident of less than 0.5 acre. The calculated downwind distance would be contained within the boundaries of all DOE sites under evaluation.

F.1.4.2.3.2 Partial Loss of Shielding Due to Earthquake.

F.1.4.2.3.2.1 Description of Conditions. A hypothetical earthquake causes the proposed

Dry Cell Facility to lose some portion of its concrete shielding. Direct radiation exposure to the on-site work force and the general public has been calculated.

F.1.4.2.3.2.2 Source Term. The conditions used to calculate the dry cell direct radiation

levels are as follows:

- For calculational purposes, a total of 50% of the high-density concrete dry cell shielding might be removed due to the earthquake. More realistic damage from an earthquake would result in cracks or small openings in the shielding. This bounds anticipated damage to the facility.

- Building containment and ventilation systems remain in operation. Therefore, there is no airborne release to the environment. Calculations have already been performed in Section F.1.4.2.1.1 for a drained water pool hypothetical accident which bound any anticipated airborne releases from the dry cell facility should the building containment and ventilation systems fail.

F.1.4.2.3.2.3 Results. The following table summarizes the public health risk to the general

population that would result from the hypothetical loss of shielding accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. As discussed in Section F.1.4.2.1.1.3, the probability of this hypothetical accident is estimated to be 10-5 per year.

Dry Cell Partial Loss of Shielding Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cance if accident occurs	Risk per year
INEL	9.3 x 10-17	3.0 x 10-19	3.0 x 10-24
Savannah River	6.7 x 10-15	3.0 x 10-16	3.0 x 10-21
Hanford	3.3 x 10-23	4.9 x 10-24	4.9 x 10-29
Nevada Test Site	6.3 x 10-11	3.7 x 10-37	3.7 x 10-42
Oak Ridge	1.2 x 10-2	7.5 x 10-6	7.5 x 10-11

At all sites, the risks associated with this accident are the lowest of any accident evaluated.

F.1.4.2.3.3 Airplane Crash Into Dry Cell Facility.

F.1.4.2.3.3.1 Description of Conditions. A hypothetical aircraft accident scenario was developed for dry cell operations. Based on the probability of occurrence, as discussed in Section F.3, specific analysis was only performed for Savannah River, the Nevada Test Site, and Oak Ridge. The accident was postulated to cause major damage to the building, resulting in the loss of containment and filtered exhaust systems. The fuel units inside the dry cell could also be damaged due to mechanical impacts and potential fire. The fission products which might be released are based on factors derived from overheating testing performed on the naval fuel systems. The mechanical impact also could result in the release of corrosion products to the environment.

F.1.4.2.3.3.2 Source Term. The development of the radioactive source term for this scenario is based on the following:

- One percent of the fuel units stored inside of the dry cell might be damaged by either the impact or resultant fire and those fission products would be available for release.
- Of the fission products available for release, 100% of the noble gases, 3% of the halogens, 1.1% of the cesium, and 0.1% of the remaining solids could be released to the environment.
- The release to the environment would occur at a constant rate over a 15-minute period.
- 10% of the available corrosion products could be released to the environment.
- A portion of the concrete shielding is destroyed; however, the resultant rubble provides a minimum of 6 inches of concrete shielding.
- The following amount of radionuclides could be released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclide	Curies
Cs-134	4.5 x 101
Cs-137	6.23 x 101
Pu-238	1.03 x 10-1
BA-137M	5.37
Sr-90	5.46
Ce-144	1.25 x 101
Nb-95	7.65
Y-90	5.46
Ru-106	1.07

F.1.4.2.3.3.3 Results. The following table summarizes the public health risk to the general population that would result from the hypothetical airplane crash into the dry cell at the Savannah River Site. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence.

Site	Probability of accident per year	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancers if accident occurs	Risk per year
Savannah River	2 x 10-6	8.2 x 10-1	4.8	9.6 x 10-6
Nevada Test Site	4 x 10-7	1.6	1.8 x 10-1	7.2 x 10-8
Oak Ridge	1 x 10-6	350	8.4	8.4 x 10-6

This accident results in the highest risk for any hypothetical accident evaluated at Savannah River, the Nevada Test Site, and Oak Ridge.

For the hypothetical airplane crash into a dry cell accident scenario, the radioactive plume might cause contamination of the ground to a downwind distance of approximately 1.3 miles. This would yield a total area impacted by the accident of about 207 acres. The calculated downwind distance would be contained within the boundaries of Savannah River and the Nevada Test Site, but not Oak Ridge.

F.1.4.3 Impact of Accidents on Close-in Workers. An evaluation has been made of the impact to

close-in workers involved in naval spent nuclear fuel management that might occur due to the various radiological accidents postulated in spent fuel handling. This evaluation focused on the radiological consequences of the accident. Clearly, a limited number of fatalities may occur which are related to spent fuel handling only in a secondary manner; i.e., the worker who happened to be in the facility may be killed due to a plane crash, seismic event, crane failure, etc. These secondary effects are not discussed in the following. Rather, only radiological consequences are considered.

F.1.4.3.1 Wet Storage.

F.1.4.3.1.1 Drained Water Pool Due to Seismic Event. No fatalities to workers close to

the scene of the accident would be expected due to radiological consequences. This is because drainage of the large amount of water in a water pool is expected to take several days which provides ample time for workers to leave the facility.

F.1.4.3.1.2 Accidental Criticality in a Water Pool Due to Human Error. It is likely no

fatalities would occur. At most, two or three workers may receive some appreciable radiation exposure. This is because the criticality would occur under approximately 20 feet of water. Shielding by the water would be sufficient to prevent exposure of nearby workers. Expulsion of a cone of water above the criticality might lead to significant exposure to any workers who were directly above the location of the criticality.

F.1.4.3.1.3 Mechanical Damage to Fuel in a Water Pool Due to Operator Error or

Crane Failure. No fatalities to workers would be expected from radiological consequences. This is because the release of the source term is underwater. Attenuation by the water would occur for most products, but release of noble gases would cause a direct radiation exposure to workers in the area. Upon releases from the surface of the water pool, radiation alarms would sound requiring evacuation of nearby workers. Timely evacuation would prevent substantial radiation exposure.

F.1.4.3.1.4 Airplane Crash into Water Pool Storage. No fatalities to workers would be

expected from radiological consequences. This is because any release of radioactive products would be underwater and radiation alarms would sound requiring evacuation of nearby workers. Timely evacuation would prevent substantial radiation exposure.

F.1.4.3.2 Dry Storage.

F.1.4.3.2.1 Wind-driven Missile Impact on Storage Casks. It is likely there would be no

fatalities to workers from radiological consequences. This is because there usually would be no nearby workers except for brief periods when a container is being placed in the dry storage array. Since a wind-driven missile is not expected to penetrate a dry storage container, direct radiation exposures even to nearby workers would not be expected. The container seal could be breached and some airborne products released. At most, two or three nearby workers may receive some radiation exposure from inhalation of airborne radioactivity.

F.1.4.3.2.2 Airplane Crash into Dry Storage. It is not likely that any fatalities would occur

to nearby workers due to the radiological consequences of this accident. As in Section F.1.4.3.2.1 above, workers are usually not in the dry storage array except when a container is being placed into the array. At most, two or three nearby workers might receive significant radiation exposure from inhalation of airborne radioactivity since the container seal may be breached. The low probability of the airplane crash itself, coupled with the probability that workers would be close enough to be affected, coupled with the probability that the wind would be blowing in the direction of the workers, makes it very unlikely that any worker would receive substantial radiation exposure.

F.1.4.3.3 Dry Cell Operations.

F.1.4.3.3.1 Inadvertent Cutting into Fuel or Mechanical Damage. No fatalities to

workers would be expected from the radiological consequences of this accident. This is because the ventilation systems' exhaust from a dry cell is directed to the outside of the building in which a dry cell is constructed and away from nearby workers.

F.1.4.3.3.2 Partial Loss of Shielding of a Dry Cell. It is likely that no fatalities would

occur among nearby workers from the radiological consequences of this accident. This is because there is still substantial shielding of radiation from material inside the cell even with the assumed 50-percent loss of the high-density concrete. However, one or two nearby workers may receive some exposure from radiation streaming through a crack in the dry cell if this is the mode of failure. Workers are trained to evacuate quickly when radiation alarms sound.

F.1.4.3.4 Other Accidents.

F.1.4.3.4.1 HEPA Filter Fire. No fatalities would be expected among nearby workers from the

radiological consequences of a fire in a HEPA filter. This is because HEPA filters are not located in an area where workers are likely to be working. In addition, the release of radioactivity involved in a HEPA filter fire is not large.

F.1.4.3.4.2 Small Leaks from Water Pools. No fatalities are expected among nearby

workers from the radiological consequences of a small leak from a water pool. The leak would be expected to be into the ground through the water pathway. Drinking water supplies would not be immediately impacted. In addition, the typical concentration of radioactivity in the water is low.

F.1.4.4 Evaluation of Shipboard Fire Involving Shipping Containers.

F.1.4.4.1 Description of Conditions. In this hypothetical accident scenario, a fire onboard a

ship that is transporting naval spent nuclear fuel in shipping containers from Pearl Harbor to Puget Sound is postulated. This accident could be initiated by a collision with another ship. The collision and subsequent fire are postulated to occur in Puget Sound in the center of the shipping lane at a distance of approximately 2 miles from Seattle. The consequences of a similar accident at Pearl Harbor would be less because of the smaller population and the fact that Pearl Harbor is a restricted area and is very close to the sea on the south side, limiting the number of people who might be exposed. This section addresses the radiological consequences of this postulated accident scenario. The toxic chemical consequences related to the burning fuel oil are presented in Section F.2.4.2.2.

During shipment, the containers are well protected from direct mechanical damage should a ship collision occur. The rugged nature of the shipping container and the naval reactor's fuel system is demonstrated by the analysis of airplane crashes which showed that a jet engine rotor would not penetrate the container or rupture the fuel. A severe fire is necessary to potentially cause failure of the container seals and overheat the spent fuel sufficiently to release fission products. Collisions of this severity are extremely unlikely. During the hypothetical accident, the fire would need to burn intensely in the hold for several hours to cause release of fission products or corrosion products to the environment.

F.1.4.4.2 Source Term. Conditions used in developing the source term are as follows:

- Ten percent of all fuel unit cladding inside of two shipping containers is ruptured and the contained fission products are available to be released from the fuel units.
- Of the available fission products, 100% of the noble gases, 3% of the halogens, 1.1% of the cesium, and 0.1% of the remaining solid fission products are assumed to be released to the container.
- Ten percent of all fission products released to the container are released to the environment and the remainder are adherent on the fuel and cask surfaces.
- Ten percent of the original corrosion products from the fuel units are released from the cask to the environment.
- The following amount of radionuclides could be released to the environment. This listing includes nuclides from one container that result in at least 99% of the possible exposure.

Nuclide	Curies
Cs-134	2.57 x 101
Cs-137	3.56 x 101
Pu-238	5.90 x 10-2
Ba-137M	3.07
Sr-90	3.12
Ce-144	7.17
Nb-95	4.37
Y-90	3.12
Ru-106	6.11 x 10-1

F.1.4.4.3 Results. The following table summarizes the public health risk to the general population that would result from the hypothetical shipboard fire accident. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence.

The probability of occurrence of this hypothetical shipping accident is 6.7 x 10-8 per year or less, and was obtained as follows. The probability of a single port entry accident is 1.6 x 10-4 (DOE 1994). The probability of a fire, given the occurrence of an accident, is 8 x 10-4 (DOE 1994). Combining these two probabilities with the port entry frequency of 21 naval spent nuclear fuel shipments spread over 40 years results in a probability of 6.7 x 10-8 per year. Due to the rugged nature of the naval fuel and likely effectiveness of fire fighting over a several hour period, the probability of fission product release to the environment would be even less.

DOE guidance (DOE 1993b) provides that the consequence of an accident which has a probability of occurrence of less than 1 x 10-7 per year need not be calculated. However, in view of interest in this accident expressed in several public comments, the following table is provided listing both the consequence and the risk.

Shipboard Fire Involving Shipping Containers

In Puget Sound Shipping Lane	50% Meteorology		95% Meteorology	
Maximally Exposed Off-site Individual (MOI)	Total EDE (Rem)	Likelihood of Fatal Cancer	Total EDE (Rem)	Likelihood of Fatal Cancer
	9.3 x 10-1	4.7 x 10-4	1.8	9.2 x 10-4
General Population within 50-mile Radius	Exposure (Person-Rem)	Number of Fatal Cancers	Exposure (Person-Rem)	Number of Fatal Cancers
	2.27 x 104	11.4	1.03 x 105	51.5
Risk per year	7.6 x 10-7		3.5 x 10-6	

The risk for this hypothetical accident is slightly lower than that for the most severe facility accident analyzed at Puget Sound.

For the hypothetical shipboard fire accident, the radioactive plume might cause contamination to a downwind distance of less than 1 mile. However, since this area is entirely over water, the contamination would be quickly diluted by tidal flow and turbulence.

F.1.5 Analysis of Uncertainties

The analyses of the impacts of normal operations and hypothetical accidents associated with management of naval spent nuclear fuel presented in this Environmental Impact Statement (EIS) are based on conservative calculations. This is necessary because virtually all of the events analyzed have never occurred and most of the impacts of routine operations are so small that they cannot be measured. The use of calculations introduces the possibility that the actual impacts may differ from those calculated due to various kinds of uncertainties, such as differences between actual behavior and the theoretical models or equations and the variability of the values of factors used in the calculations. In order to portray the effects of such variability and uncertainty, the analyses performed for this appendix have been divided into four components: the probability that an event, such as an accident, could occur; the amount of radioactive material or radiation that might be released by the event; the calculation of the potential for exposure to human beings from the release; and the conversion of the radiation exposure to detrimental health effects. Each of these components is discussed separately in the following sections for both routine operations and accidents.

Each of these components has been analyzed for both routine operations and accidents. The discussion in the following sections focuses on accident analyses, but it should be understood that the analysis of uncertainties for routine operations is the same, with a few exceptions. First, routine operations are certain to occur, so the "probability" of such events is effectively 1.0. Second, the source terms used for the analyses of routine operations are based on monitoring of current operations at Naval Nuclear Propulsion Program facilities such as the Expended Core Facility at INEL. Consequently, the estimates of the amount of radiation or radioactivity involved are expected to be close to those which might actually occur under the alternatives evaluated in this EIS. It is possible that there would be some variations among facilities and that future efforts to keep exposures to workers as low as reasonably achievable might reduce the source terms further, but the values used in the analyses in this EIS are expected to be little different from those actually encountered. The effects of routine operations and accidents have been calculated using similar analytical methods and models for determination of radionuclide movement in the environment, pathways to humans, and conversion of exposure to health effects. Therefore, the discussion of uncertainties in Sections F.1.5.3 and F.1.5.4 applies to the results of analyses of routine operations, as well as to postulated accidents.

F.1.5.1 Probabilities of Events. The probability that an accident might occur has been determined for a number of events which might reasonably be postulated. These probabilities are used in this appendix to calculate the risk, defined as the product of the probability times the consequences, for each postulated accident.

The best methods available have been used to estimate the probabilities for the events selected for analysis. For example, a methodology developed by Sandia Laboratories (Sandia 1983) was used to compute the probability that an aircraft might crash into naval spent nuclear fuel facilities. This method uses actual aircraft crash statistics obtained from the Federal Aviation Administration and was developed by Sandia to reproduce the observed frequencies as closely as possible. Probabilities for seismic events were derived from published studies of the frequencies of seismic activity and represent the best available estimates, but these probabilities are subject to some uncertainty due to the relatively few events which have occurred at the sites evaluated under the alternatives in this EIS.

The probabilities of a range of accidents which might be caused by human error have also been included. Such events include accidental criticality caused by handling errors, dropping of fuel modules, improper operation of cranes, and incorrectly performing machining procedures. For human error, a probability of one error in one thousand operations (a frequency of 10-3 events per year) is used for operations performed by a single trained operator following a written procedure. If the procedure requires verification of the action by a second trained operator, this frequency is lowered to 10-4. These probabilities are derived from the methodology used by the Nuclear Regulatory Commission for assessment of human reliability (Swain 1983).

In many instances, the probabilities assigned to the events reflect the likelihood that a particular event, such as an earthquake or an aircraft crash, might occur. However, for the purpose of the analyses, the resulting accident was assumed to have quite severe consequences. The probability of such severe consequences is smaller than the probability that the initiating event might occur, with consequences as severe as used in the analyses possibly occurring only one time in 10 or 100 occurrences of the initiating event. The probabilities for most of the analyses in this appendix used only the probability of the initiating event and did not include the further reduction in the probability of the postulated severe consequences resulting from the severity used. This was done, in part, because the severe consequences assumed, and in some cases the initiating events themselves, occur very infrequently, or have never occurred, so little data on their frequency is available.

For example, one accident analyzed is the impact on a spent fuel container of a missile produced by a tornado or other high winds. The sequence of events analyzed included breaching the container seal in order to release radioactive material. In reality, the missile would have to be large enough and traveling at high enough speed to cause the postulated damage. Similarly, it would have to contact the container at the correct location and at the correct angle in order to damage the seal. The probability assigned to this accident is 10-5 per year, the probability that a wind-driven missile might strike a container, and does not include any factor to account for other elements in the sequence required to actually damage the seal. Therefore, the probability of the consequences calculated for this accident would be much smaller than the probability of 10-5 per year used in the analysis.

A second example is provided by the analysis of aircraft impact on shipping containers used for storage of naval spent nuclear fuel. In this accident analysis, the impact was assumed to cause a shipping container to be penetrated if the container were contacted by the aircraft. However, naval spent nuclear fuel shipping containers are of very rugged design, and structural analysis of the container showed that a naval shipping container is very unlikely to be penetrated by an aircraft crash, even by the hardest parts of the airplane. Consequently, the probability that the naval spent nuclear fuel could be damaged and that fission products might be released is much, much less than the crash probability alone, which is the probability assigned to these consequences in this appendix.

A third example is seen in the ship fire accident. In this analysis, it is assumed that if a ship carrying naval spent nuclear fuel shipping containers were involved in a very severe collision and a fire occurred, the fire would include the cargo hold where the naval spent nuclear fuel containers are carried, the fire would not be extinguished by the redundant systems provided, and it would burn long enough at sufficient intensity to damage the shipping container and the spent nuclear fuel inside and cause release of radioactive materials from the containment provided. Given that a severe collision occurred, the probability that all of the necessary conditions would occur and a fire of the required intensity and duration would occur in the cargo hold is clearly far less than the probability of the collision.

As can be see from these examples, the actual probability of the consequences resulting from the analyses are smaller than the values presented in this appendix, at least in part because these probabilities do not include an additional factor to reflect the accident severity used in the analyses. As a result, the risks stated in this appendix for most accidents are believed to be at least 10 to 100 times larger than what would actually occur. However, the same probabilities have been used in the evaluation of all of the alternatives considered and all of the risks are small, so the approach used is adequate for the purposes of this EIS.

F.1.5.2 Release of Radioactive Material or Radiation (Source Term). Since the source terms used in the accident analyses are typically for accidents which have never occurred, there is greater room for uncertainty. All of the accidents analyzed in this EIS are intended to be accidents which produce consequences which are unlikely to be exceeded by any reasonably foreseeable accident. As a result, the accidents themselves and the sequences of events during the accidents have been chosen to maximize the source term. For example, systems such as high efficiency particulate filters have been considered to be inoperative in all cases where the accident might have an opportunity to disable them.

The source terms for the hypothetical accident analyses are dependent upon a number of factors. For there to be an accidental release of radioactivity to the environment, there must be damage to the storage facility or containment structure. Furthermore, naval spent nuclear fuel must be damaged as well in order for there to be any release of fission products since all fission products are fully contained within naval nuclear fuel. The amount of damage to the external containment or the fuel is dependent upon the severity and the nature of the accident. In the accidents analyzed, there are assumptions concerning the containment or the extent of damage to the fuel units which were made to provide a conservative, bounding evaluation whose results would not be exceeded by reasonably postulated accidents of a similar type.

One example of this is the evaluation of the dry storage container impacted by a wind-driven missile. Damage to the container by the missile is not expected to occur, but for the analysis in this EIS, the seal is assumed to be damaged by the missile impact and corrosion products within the container are assumed to be released through the damaged seal. The uncertainty on the resultant release is one-sided since the probability of a release larger than in the calculation (resulting in a higher calculated dose) is essentially zero while the possibility of a release of less radioactive material is large (for example, no release if the container seal is not broken). The range of variation, or the uncertainty interval, in the source term for this accident is between +0% and -100%.

Another example is the plane crash into a dry processing facility for naval spent nuclear fuel. The dry processing facility includes a thick concrete shielded cell in which a few naval spent nuclear fuel units are processed at a time. The massive concrete shield is provided to protect operating personnel from radiation but it has the secondary benefit of protecting the fuel units being processed from missiles caused by natural or man-made phenomena. In the unlikely event that an airplane crashed into the facility, it is expected that no damage to the spent fuel would result. Even so, for evaluation of this accident in this EIS, it is assumed that 1% of the fuel in the dry cell could be damaged and that sufficient jet fuel could enter the dry cell to cause a fire which could cause the release of fission products from the damaged fuel and destroy the filtration system. Again, the uncertainty range is one-sided since no damage to fuel is expected, causing the variability or uncertainty to range from +0% to -100%.

All of the source terms used for the evaluation of the accidents were developed in a similar fashion. Thus, the expected outcome for all of the accidents is that a lower release to the environment is expected than is used in the analysis, representing a range of variation of +0% to -100%.

F.1.5.3 Exposure to Humans. Exposure to the individuals and the general population is evaluated by

integrated computer programs. The methods used model the movement of airborne, ground, and water contamination resulting from the postulated release using five types of pathways to the population. These pathways include exposure directly to the radiation from the material in the plume, direct exposure to radiation from contaminated soil or water, inhalation of air containing gases or particles, and ingestion of contaminated water or food. The analyses in this appendix used parameter values which were the best available estimates or, when best estimate values were not available, are conservative.

The Gaussian plume model used in these analyses to represent airborne movement of radioactive material is the standard used in virtually all evaluations of environmental effects. Comparison of distributions calculated using the Gaussian plume model with test data has shown that the results may differ by as much as a factor of 5 in some circumstances. In order to ensure that exposures would be as high as could occur under any set of conditions, in most of the analyses a ground level release was used and no reduction in the airborne concentrations was included for either turbulence caused by buildings or the effect of wind meander which occurs naturally at the low wind speeds accompanying the worst case meteorological conditions.

One intentional choice of parameters to ensure that the results would be conservative is the use of the worst case meteorological conditions in the tabulations of the risks and consequences for all alternatives provided in Chapters 3 and 5. The results for both the most likely meteorological conditions and for the worst case are provided in detailed tables in this attachment and show that the worst case meteorological conditions produce exposure estimates which are 2 to 10 times higher than those for the most likely conditions (depending upon local meteorological conditions). Overall, the net effect is that the Gaussian plume model might introduce an uncertainty of a factor of 5 or less in either direction, but the use of the worst case meteorological conditions would essentially offset any underestimation of effects.

The direct radiation from the cloud is calculated using a conservative representation of the plume as a finite cloud, and, as a result, little uncertainty is introduced in this part of the analysis. Direct radiation from contamination which results from particles from the plume deposited on the ground surface depends upon the deposition parameters which are input as best-estimate values. Faster deposition would result in more material on the ground and increased exposure to those closer to the accident location but less material on the ground and decreased exposure for those farther from the accident site. Any effects of uncertainty in this parameter would depend upon the population distribution around the postulated accident scene.

The possible exposure to direct radiation from material in surface water and associated sediments as a result of accidental release directly to the water or fallout from an airborne release was estimated for people involved in activities such as professional fishing, maritime operations, swimming, and boating. The calculations took no credit for dilution by river currents or tidal movement and the concentrations in the air were not reduced by the amount of material deposited in the water. Due to the conservative concentrations used in the calculations and an assumption that every member of the population in the area would be exposed to direct radiation from surface waters, exposure from this pathway is very likely overestimated.

The inhalation pathway evaluation is based on average breathing rates and uptake consistent with the recommendations by the ICRP (ICRP 1977 and ICRP 1979). Obviously, higher values for these parameters would increase the estimated exposures and lower values would decrease the estimates. There appears to be little controversy concerning these parameters and the same parameters are used for evaluation of all of the alternatives in this appendix.

The ingestion pathway includes meat, seafood, dairy and crop products, and drinking water. Best-estimate parameters are used to evaluate the contamination levels in food and water when ready for consumption. Consumption rates for individuals are based on observed eating habits. The analysis also includes the assumption that a conservative 10% of the entire diet of the affected population consists of contaminated products. The uncertainties associated with these pathways can obviously affect the estimated impacts, but the range of variation is not large and the same values for a given site were used for evaluation of all alternatives.

The drinking water contribution to the ingestion pathway was calculated by assuming that a portion of the radioactive material would become dissolved in the drinking water supply. At sites where fresh surface water provides drinking water, any contamination of the water was assumed to occur promptly and no decreases due to radioactive decay were used. At sites where aquifers are a source of drinking water, consumption of water from the aquifer was delayed for the time required for the contamination to reach the aquifer and then to reach the nearest drinking water source. As an example, for a postulated leak from the Expended Core Facility, it was assumed that 20 years would pass before water carrying the radioactive material would reach a well drawing from the aquifer and that 1 percent of material released would enter the aquifer each year. Maximum exposed individuals were conservatively assumed to drink only water from the contaminated source and to drink 2 liters of water per day. For the population in general, a conservative fraction of the population was assumed to drink 1 liter of water per day from affected sources. The concentrations in these calculations are considered to be higher than expected because no reduction of the concentration by dilution was included and the fraction of the population exposed to the affected drinking water is conservatively high.

At sites where irrigation is used, contamination of food crops, livestock, and local game was analyzed. The same concentration of radioactive material as in drinking water was used in the irrigation water. Affected crops, livestock, and game were assumed to receive all water from the contaminated water source and applicable biological accumulation factors were used. Human consumption rates for the crops, livestock, and game were used to calculate the exposure from this source. The uncertainty from this source is associated with the concentration of contaminants in the irrigation water, the amount of such foods consumed, and the fraction of the population which ingests the affected food.

The population used to determine the effects of postulated accidents in this appendix is the entire population within the 22.5-degree sector at each distance within 50 miles downwind of the accident. The spread of the plume for the worst case meteorology does not cover the entire sector. The result is that there is a conservatism of more than a factor of 2 in the application of the calculations to the evaluation of the dose to the population. The population data used were obtained from the 1990 U. S. census, so population growth or decreases in a region could introduce small changes, but the same population distributions were used for a specific site for evaluation of all alternatives.

Considering all of the factors which might have an appreciable effect on the results of the analyses, any tendency of the Gaussian plume model to underestimate concentrations would be offset by the use of other parameters which are known to be conservative. Examples of such conservative factors include the general use of the meteorological conditions which would produce the most severe effects and the use of the entire population of a 22.5-degree sector. Consequently, this portion of the analyses would appear to contribute little in the way of uncertainty which could cause the results to be greater than presented in this appendix.

F.1.5.4 Conversion of Exposure to Health Effects. The conversion of amounts of radiation or

radioactive material transmitted to an individual or to population groups requires the calculation of the exposure or dose received by humans caused by inhaling or ingesting radioactive material or by being in a radiation field. Such calculations are based on a number of factors, including the nature and rate of human metabolic processes, such as respiration or excretion, the type of radiation involved, the sensitivity of various organs, and the age of the individuals involved. The rates of human metabolic processes are well characterized at this time and the energies, half-lives, and similar properties of radioactive material or radiation have been measured extensively and are not subject to great debate. Consequently, these factors introduce little uncertainty into the calculations in this EIS.

However, the number of detrimental health effects which might result from exposure of a large group of people to low levels of radiation has been the subject of debate for many years. The National Academy of Sciences has conducted several investigations of this matter and its full commentary on page 181 of its latest study of the health effects of exposure to low levels of radiation, frequently identified as BEIR V (NAS 1990), states:

> Finally, it must be recognized that derivation of risk estimates for low doses and dose rates through the use of any type of risk model involves assumptions that remain to be validated. At low doses, a model dependent interpolation is involved between the spontaneous incidence and the incidence at the lowest doses for which data are available. Since the committee's preferred risk models are a linear function of dose, little uncertainty should be introduced on this account, but departure from linearity cannot be excluded at low doses below the range of observation. Such departures could be in the direction of either an increased or decreased risk. Moreover, epidemiologic data cannot rigorously exclude the existence of a threshold in the millisievert dose range. Thus, the possibility that there may be no risks from exposures comparable to external natural background radiation cannot be ruled out. At such low dose rates, it must be acknowledged that the lower limit of the range of uncertainty in the risk estimates extends to zero.

The National Academy of Sciences considers that the uncertainty in the lifetime total excess cancer mortality risk estimates calculated using the linear extrapolation, no threshold models it has designated as preferred, which is consistent with the model used in this EIS, is approximately a factor of 2 in either direction (an interval of 0.5 to 2 times the calculated estimates).

The calculations of health effects performed in this Environmental Impact Statement use the relation recommended by the International Council on Radiation Protection because it is well-documented and kept up to date by the Council. It is also consistent with the preferred model identified by the National Academy of Sciences in the BEIR V report and is widely accepted by the scientific community as representing a method which produces estimates of health effects which will not be exceeded. However, there are some who believe that exposure to low levels of radiation can produce more health effects than would be estimated using the International Council on Radiation Protection relation. On the other hand, a growing number of researchers believe that the International Council on Radiation Protection relation overestimates the number of detrimental health effects produced by low levels of radiation and, in fact, the possibility of no effect cannot be excluded (CIRRPC 1992).

Clearly, using a relation developed by one or the other of these groups would produce a larger or smaller estimate of the number of health effects than the values presented in this EIS, but a factor of 2 change in the small risks calculated for all of the alternatives would still leave them as small risks. All of the results of analyses of normal operations and hypothetical accidents in Appendix D include the calculated exposure in addition to the number of health effects in order to permit independent calculations using any relation between radiation exposure and health effects judged appropriate.

F.1.5.5 Summary of Uncertainties. As discussed in the preceding portions of this section, the calculations in this EIS have generally been performed in such a way that the estimates of risk provided are unlikely to be exceeded during either normal operations or in the event of an accident. For routine operations, the results of monitoring of actual operations provide clearly realistic source terms, which, when combined with conservative estimates of the effects of radiation, produce estimates of risk which are very unlikely to be exceeded. The effects for all alternatives have been calculated using the same source terms and other factors, so this EIS provides an appropriate means of comparing potential impacts on human health and the environment.

The analyses of hypothetical accidents provide more opportunities for uncertainty, primarily because the calculations must be based on sequences of events and models of effects which have not occurred. In this appendix, the goal in selecting the hypothetical accidents analyzed has been to evaluate events which would produce effects which would be as severe or more severe than any other accidents which might reasonably be postulated. The models have attempted to provide estimates of the probabilities, source terms, pathways for dispersion and exposure, and the effects on human health and the environment which are as realistic as possible. However, in many cases, the very low probability of the accidents postulated has required the use of models or values for input which produce estimates of consequences and risks which are higher than would actually occur because of the desire to provide results which will not be exceeded. In summary, it is judged that the risks presented in this appendix are believed to be at least 10 to 100 times larger than what would actually occur.

The use of conservative analyses is not an important problem or disadvantage in this EIS since all of the alternatives have been evaluated using the same methods and data, allowing a fair comparison of all of the alternatives on the same basis. Furthermore, even using these conservative analytical methods, the risks for all of the alternatives are small, which greatly reduces the significance of any uncertainty analysis parameters.

F.2 TOXIC CHEMICAL ISSUES AT NAVAL SPENT NUCLEAR FUEL EXAMINATION AND STORAGE SITES

The INEL-ECF is a large laboratory facility used to receive, examine, and ship naval nuclear fuel and irradiated test specimen assemblies. In order to accomplish these tasks, some chemicals classified as toxic are involved in a variety of operations and thus a potential exists for releases of toxic chemicals due to human error and failure or malfunctioning of equipment.

This section provides the results of an evaluation of both normal operations and accidents that could result in toxic chemical releases. This section describes how facilities and operations were selected for analysis, discusses the computer codes used in the analysis, presents the weather conditions and atmospheric dispersion, defines the hypothetical accidents which would produce the most severe consequences, and estimates the potential health effects. Each alternate location's specific population and meteorology were used to produce estimated consequences for each operation and accident.

F.2.1 Toxic Chemical Inventory

Some chemicals classified as toxic are routinely used in a variety of operations at the INEL-ECF. Table F.2-1 provides the INEL-ECF Chemical Inventory. This inventory was developed from the Naval Reactors Facility Superfund Amendments and Reauthorization Act (SARA) Section 312 chemical inventory (INEL 1993). Those chemicals specifically stored and used at INEL-ECF as well as those used for facility support (e.g., fuel oil, diesel fuel, sulfuric acid, and sodium hydroxide) were included. Chemicals at INEL-ECF that were (a) in excess of 500 pounds, or (b) in excess of reportable quantities (usually 1 pound) on the EPA Title III List of Lists (EPA 1992a) were evaluated. The chemicals in the EPA Title III List of Lists are the hazardous chemicals defined in:

- SARA Section 302 Extremely Hazardous Substances (CFR 1992a)
- CERCLA Hazardous Substances (CFR 1992b)
- SARA Section 313 Toxic Chemicals (CFR 1992c)
- RCRA Hazardous Wastes (CFR 1992d)
- EPA list of 100 extremely hazardous chemicals (FR 1993).

Table F.2-1. INEL-ECF chemical inventory.

CAS No.	Chemical Name	Weight Total (pounds)	Weight Unit[1] (pounds)
Chemicals Used for Water Pool Operations			
60-00-4	Ethylenediaminetetraacetic Acid (EDTA) (reagent for water analyses)	46.3	1.1
75-71-8	Dichlorodifluoromethane (CFC-12) (refrigerant in coolers for pool water)	30.0	30.0
Chemicals Used for Examination Operations			
60-29-7	Ethyl Ether	5.7	5.7
67-63-0	Isopropyl Alcohol	100.6	6.6
123-31-9	Hydroquinone (photographic film developer)	65.5	3.3
144-55-8	Sodium Bicarbonate	198.0	99.0
302-01-2	Hydrazine	3.7	1.8
7664-41-7	Ammonia[2]	2.8	0.28
7727-37-9	Diatomic Nitrogen	643	125
Chemicals Used for Facility Support			
107-21-1	Ethylene Glycol (anti-freeze and paint additive)	516.1	514.0
115-07-1	Propylene (Propene)	0.01	0.005
1310-73-2	Sodium Hydroxide (boiler water pH control)	43260	43260
7664-93-9	Sulfuric Acid (boiler and cooling tower water pH control)	96427	96427
68476-33-5	Fuel Oil #5	776210	204270
68476-34-6	Diesel Fuel #2	14316	10735
72623-83-7	Hydrotreated Lubricating Oil	882.6	413
Chemical Used for Nuclear Poison			
1332-77-0	Potassium Tetraborate	17000	10

---

[1] The quantities in this column represent the amount of chemical stored in the largest single container as identified in the INEL-ECF chemical inventory.

[2] The ammonia is present as ammonium hydroxide.

In order to evaluate the alternate locations, the same inventory of chemicals at the INEL-ECF was used at the DOE sites; namely, the Savannah River Site, the Hanford Site, the Nevada Test Site, and the Oak Ridge Reservation. In addition, the Barnwell Nuclear Fuel Plant (hereafter referred to as the Barnwell Plant), which is adjacent to the Savannah River Site, was evaluated along with the DOE sites. Since the shipyards would not be involved with examination operations (except for Puget Sound), of the chemicals listed, only diesel fuel would be available in a substantial quantity, in the form of fuel stored at the shipyards. Although several of the chemicals listed in Table F.2-1 are water treatment chemicals associated with water pool operations and small water pools may be needed at the shipyards for fuel storage and inspection, the shipyard would already have on-hand similar water treatment chemicals for other operations at the shipyard. Therefore, an increase in the quantities or types of chemicals at the shipyards was considered to be very small and thus did not require evaluation. In addition, even though the Kenneth A. Kesselring Site is not a shipyard, this facility would also not be involved with examination operations. Therefore, this facility was evaluated in the same manner as the shipyards.

F.2.2 Computer Modeling to Estimate Toxic Chemical Exposures

Factors such as locations of affected persons, terrain, meteorological conditions, release conditions, and characteristics of the chemical inventory are required as input parameters for calculations to determine human exposure from airborne releases of toxic chemicals. This section describes the computer models used to perform exposure estimates. Specific input parameters used in the analyses are summarized in the appropriate subsection for normal operations and accident conditions. The EPIcode was used to evaluate toxic chemical releases resulting from accidents, and the ISC2 code was used to evaluate releases from normal operations.

F.2.2.1 EPIcode (tm). The Emergency Prediction Information Computer Code (EPIcode-) is the

computer code chosen for estimating airborne concentrations resulting from most releases of toxic chemicals (Homann 1988). Like RSAC, EPIcode uses the well-established Gaussian Plume Model to calculate the airborne toxic chemical concentrations usually at the same downwind locations as RSAC.

The EPIcode library contains information on over 600 toxic substances listed by the American Conference of Governmental Industrial Hygienists in the EPIcode Manual. EPIcode also allows user description of substances not included in the library. A step-by-step flow chart of the main EPIcode features (up to the output options) is shown in Figure F.2-1.

Figure F.2-1. Flow sheet for EPIcode (Homann 1988).

As shown in Figure F.2-1, the continuous release models require specification of the source term as an ambient concentration and a release rate. For releases over a specific time interval (i.e., term releases), the user specifies the release duration and the total quantity of material released.

Area continuous and area term releases are useful in calculating the effects of a release from pools of spilled volatile liquids. The user must enter the radius of the circle encompassing the spill area. Also entered is the temperature of the pool and ambient temperature to establish release rate from a liquid spill. An upwind virtual point source, which results in an initial lateral diffusion equal to the effective radius of the area source, is used to model an area release.

By specifying a release quantity, release duration, and release area, the user effectively proposes a release rate per unit spill area. The release quantity is defined as a source term (Q) or fraction of the material at risk. The concepts and defined terms are the same as for radiological calculations. EPIcode confirms that the volatility of the spilled substance can support such a release rate. If the proposed release rate exceeds the saturation conditions at the release temperature, EPIcode calculates a lower release rate and a corresponding longer release time.

In calculating effective release height, the actual plume height may not be the physical release height, e.g., the stack height. Plume rise can occur because of the velocity of a stack emission and the temperature differential between the stack effluent and the surrounding air. EPIcode calculates both the momentum plume rise and the buoyant plume rise and chooses the greater of the two results.

Since this effective increase in release height leads to lower concentrations at the ground level, the physical release heights were used to calculate the concentrations that the general public may be exposed to during accidental releases of toxic substances. This approach will always yield conservative estimates.

In this application, the standard terrain calculation of EPIcode is always used. Downwind concentrations were calculated using both 95% and 50% meteorological conditions (Section F.1.3.5). The elevation of the affected person is always ground level (0 meters) and, as in RSAC-5, the mixing layer height is always 400 meters (1320 feet). The deposition velocities used (Section F.2.4.2.1.3) are somewhat different than those of RSAC-5, but they are still conservatively low.

As described in its user manual (Homann 1988), EPIcode also includes the following steps:

- Treating a release as instantaneous vs. continuous depending upon the plume length at the specific downwind location being considered
- Correcting the concentration for sampling time
- Adjusting the wind speed for release height
- Depleting the plume as a function of downwind distance
- Adjusting the standard deviations of the crosswind and vertical concentrations for brief releases.

As output, EPIcode can generate data plots of mean toxic chemical concentration (during a specified averaging time) as a function of downwind distance. From these graphs and numerical output, the concentrations for the worker at 100 meters (330 feet) (the shortest distance for which EPIcode calculates), for the nearest public access (NPA), for the maximum off-site individual (MOI), and for nearby communities are determined and evaluated for health effects.

EPIcode was selected as the computer code for release analysis of chemicals amenable to Gaussian modeling after comparison with a number of codes, primarily CHARM and ARCHIE. It was judged more applicable for this application than either the CHARM code or the comparable ARCHIE code.

F.2.2.2 ISC2 Code. The Industrial Source Complex (ISC2) model is a widely used, publicly

available, and accepted EPA regulatory model which employs straight line (i.e., uniform wind field) Gaussian diffusion to estimate pollutant dispersion (EPA 1992b). ICS2 is an appropriate model for industrial complexes in rural or urban areas with transport distances less than 50 kilometers (30 miles). This model employs a standard meteorological data set requiring single point hourly wind speed, wind direction, ambient air temperature, atmospheric stability, and vertical mixing height values. Also, the ISC2 model is able to account for variations in pollutant concentrations due to the influence of nearby structures.

In addition to the ISC2 model, the MESOPUFF II model was also evaluated. MESOPUFF II is a regional (mesoscale) scale model that takes into account a varying wind field. Past trajectory analyses at the INEL have demonstrated that plumes may undergo many changes in direction due to the varying winds common to the INEL vicinity. The number of changes is partially dependent on release time and transport duration. The plume transport and estimation of pollutant concentration beyond 12 miles (20 kilometers) is best modeled using spatially varying wind data. Although not used as a basis for determining or enforcing compliance with regulations, it is used on a case-by-case basis. The model is also readily available to the public.

Upon review of the ISC2 and MESOPUFF II models, the decision was made to utilize ISC2 for the dispersion analysis of pollutants emitted from stationary sources. ISC2 is able to reasonably and accurately predict downwind pollutant concentrations within 30 miles (50 kilometers) by taking into account multiple point and area emission sources, evaluating hourly meteorological data, and determining the effects of nearby structures.

F.2.3 Health Effects

Toxic constituents dispersed during an accident could induce adverse health effects among exposed individuals. This possible impact is assessed by comparing the airborne concentrations of each substance at specified downwind locations to standard accident exposure guidelines for chemical toxicity.

Where available, Emergency Response Planning Guideline (ERPG) values are used for this comparison. ERPG values are estimates of airborne concentration thresholds above which one can reasonably anticipate observing adverse effects (Rusch 1993). ERPG values are specific for each substance, and are derived for each of three general severity levels:

- Exposure to concentrations greater than ERPG-1 values results in an unacceptable likelihood that one would experience mild transient adverse health effects, or perception of a clearly defined objectionable odor.
- Exposure to concentrations greater than ERPG-2 values results in an unacceptable likelihood that one would experience or develop irreversible or other serious health effects, or symptoms that could impair one's ability to take protective action.
- Exposure to concentrations greater than ERPG-3 values results in an unacceptable likelihood that one would experience or develop life-threatening health effects.

Where ERPG values have not been derived for a toxic substance, other chemical toxicity values are substituted, as follows:

- For ERPG-1, Threshold Limit Value, Time-Weighted Average (TLV-TWA) values (ACGIH 1993) are substituted: The TWA is the time-weighted average concentration for a normal 8-hour workday and a 40-hour workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect.
- For ERPG-2, Level of Concern values (equal to 0.1 of Immediately Dangerous to Life or Health) are substituted: Level of Concern is defined as the concentration of a hazardous substance in air, above which there may be serious irreversible health effects or death as a result of a single exposure for a relatively short period of time (EPA 1987).
- For ERPG-3, Immediately Dangerous to Life or Health (IDLH) values are substituted: IDLH is defined as the maximum concentration from which a person could escape within 30 minutes without a respirator and without experiencing any effects which would impair the ability to escape or irreversible side effects (NIOSH 1990).

Possible health effects associated with exceeding an ERPG-2 or -3 value are specific for each substance of concern, and must be characterized in that context. When concentrations are found to exceed an ERPG or substitute value, the specific toxicological effects for the chemicals of concern are considered in describing possible health effects associated with exceeding a threshold value.

ERPG values are based upon a 1-hour exposure of a member of the general population. In this EIS, exposures resulting from the release of toxic chemicals during an accident condition were postulated to occur over a period of 1 hour or less to allow for a direct comparison to the ERPG values. This approach provides an additional element of conservatism in the evaluation of accidents with releases that last much less than 1 hour.

In addition to comparing the airborne concentrations of each substance to standard accident exposure guidelines, each substance was evaluated to determine if it has the potential for future carcinogenic health impacts. If a particular substance has this potential, the Integrated Risk Information System (IRIS) (TOXnet 1993) was reviewed and if sufficient toxicological information was available, a future potential likelihood of developing cancer was determined. If sufficient information from IRIS was not available, alternative evaluation methods, including comparison to ambient air quality criteria, were substituted.

The impact of normal operations was also evaluated. This impact was assessed by comparing the airborne concentrations of each substance at specified downwind locations to the National Ambient Air Quality Standards (NAAQS) assigned for each substance. NAAQS consist of national primary and secondary ambient air quality standards (CFR 1991). National primary ambient air quality standards define levels of air quality which the EPA judges are necessary, with an adequate margin of safety, to protect the public health. National secondary ambient air quality standards define levels of air quality which the EPA judges are necessary to protect the public welfare from any known or anticipated adverse effects of a pollutant. As a result, the immediate as well as cumulative impact of normal operations was evaluated by comparing the airborne concentrations of each substance to the NAAQS.

F.2.4 Analysis Description and Results

The analysis results for both normal operations and accident conditions are reported for each location analyzed. Detailed estimated concentrations and ERPG levels, expressed in milligrams per cubic meter (mg/m3), are reported in tabular form for a worker, maximally exposed collocated worker (MCW), maximally exposed off-site individual (MOI), and maximally exposed individual at the nearest public access (NPA). A complete description of these individuals is provided in Section

F.1.3.2.

F.2.4.1 Normal Operations.

F.2.4.1.1 Source of Emissions. Emissions resulting from normal operations involving

toxic chemicals listed in Table F.2-1 were evaluated. It was determined that the burning of Number 5 fuel oil in the facility's boilers and the burning of Number 2 diesel fuel in the facility's emergency diesel generators represented the largest sources of emissions under normal operations and thus provide the conditions producing the most severe consequences for evaluation. These normal operations result in the release of oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide), sulfur dioxide, particulates (PM-10), lead, and volatile organic compounds (VOCs). The airborne release of these chemicals was evaluated for effects on the on-site workers, MCW, NPA, and MOI.

The emissions that occur due to normal operations at the INEL-ECF were evaluated using the ISC2 code. These releases were also used at the alternate locations (Hanford, Savannah River, Nevada Test Site, Barnwell Plant, and Oak Ridge) for evaluation purposes. Heating boilers and emergency diesel generators already exist at the alternate shipyard locations and thus selection of these alternate locations would not result in a measurable increase in emissions. Therefore, routine releases from shipyard locations were not considered.

F.2.4.1.2 Conditions and Key Parameters.

- Number 5 fuel oil was burned in facility boilers for space heating.
- Number 2 diesel fuel was burned in facility emergency diesel generators.
- Source term was based on the INEL report on routine yearly releases (NRF 1993) which included:
  - 1.02 tons per year of carbon monoxide released
  - 9.04 tons per year of oxides of nitrogen released
  - 33.7 tons per year of sulfur dioxide
  - 1.54 tons per year of particulates
  - 5.86 x 10-4 tons per year of lead
  - 0.18 tons per year of volatile organic compounds.
- Forty percent of the total boiler and emergency diesel generator use for the Naval Reactors Facility was attributed to the INEL-ECF.
- Three point sources (one representing boilers and two representing emergency diesel generators) were used.
- Stack diameters of 1.07 meters (3.5 feet) for boilers and 0.305 meter (1 foot) for emergency diesel generators were used.
- Stack gas exit velocities of 21.8 meters per second (72 feet per second) for boilers and 44.2 meters per second (145 feet per second) for emergency diesel generators were used.
- Stack gas exit temperatures of 505yK for boilers and 794yK for emergency diesel generators were used.
- Worker concentrations were based on 16 sector polar grids. Other affected locations were defined as discrete points.
- DOE site meteorological data were used for evaluations at the Naval Reactors Facility, Hanford, Nevada Test Site, and Oak Ridge. Meteorological data from the closest National Weather Service Station were used for evaluations at Savannah River and the Barnwell Plant.

F.2.4.1.3 Results. The airborne concentrations, averaged over the duration of each

exposure, were calculated by ISC2 for the worker, MCW, NPA, and MOI using normal meteorology. Tables F.2.4.1-1 through -6 list the downwind concentrations at various locations. The airborne concentrations were compared to respective NAAQS values where available. The NAAQS are as follows:

Carbon monoxide. The national primary ambient air quality standards for carbon monoxide are 10 mg/m3 for an 8-hour average concentration not to be exceeded more than once per year, and 40 mg/m3 for a 1-hour average concentration not to be exceeded more than once per year.

Sulfur oxides. The national primary ambient air quality standards for sulfur oxides that are measured as sulfur dioxide are 0.08 mg/m3 as an annual arithmetic mean and 0.365 mg/m3 as a maximum 24-hour concentration not to be exceeded more than once per year. The national secondary ambient air quality standards are 1.3 mg/m3 as a maximum 3-hour concentration not to be exceeded more than once per year.

Nitrogen dioxide. The national primary and secondary ambient air quality standard for nitrogen dioxide is 0.1 mg/m3 as an annual arithmetic mean.

Lead. The national primary and secondary ambient air quality standard for lead and its compounds that are measured as elemental lead is 1.5 x 10-3 mg/m3 as a maximum arithmetic mean averaged over a calendar quarter.

Particulate matter. The national primary and secondary ambient air quality standard for particulate matter is 0.05 mg/m3 as an annual arithmetic mean and 0.15 mg/m3 as a maximum 24-hour concentration.

A comparison of the downwind concentrations provided in Tables F.2.4.1-1 through -6 with the NAAQS identified above indicates that no NAAQS is exceeded for normal operations.

Table F.2.4.1-1. Summary of chemical concentrations for normal operations at the INEL Expended Core Facility.

	CHEMICAL CONCENTRATIONS mg/m3						
	Carbon Monoxide	Sulfur Dioxide	Nitric Oxide	Nitrogen Dioxide	Lead	VOC	PM-10
Worker	4.6 x 10-5	5.5 x 10-4	1.9 x 10-4	2.1 x 10-5	9.0 x 10-9	1.9 x 10-5	2.7 x 10-5
MCW	3.7 x 10-6	9.5 x 10-5	2.6 x 10-5	2.9 x 10-6	2.0 x 10-9	8.5 x 10-7	4.6 x 10-6
MOI	7.7 x 10-7	2.3 x 10-5	5.8 x 10-6	6.4 x 10-7	<1.0 x 10-9	1.6 x 10-7	1.1 x 10-6
NPA	7.7 x 10-7	2.3 x 10-5	5.8 x 10-6	6.4 x 10-7	<1.0 x 10-9	1.6 x 10-7	1.1 x 10-6

Table F.2.4.1-2. Summary of chemical concentrations for normal operations at Hanford.

	CHEMICAL CONCENTRATIONS mg/m3						
	Carbon Monoxide	Sulfur Dioxide	Nitric Oxide	Nitrogen Dioxide	Lead	VOC	PM-10
Worker	2.9 x 10-5	1.5 x 10-4	1.3 x 10-4	1.0 x 10-5	3.0 x 10-9	1.1 x 10-5	1.4 x 10-5
MCW	1.6 x 10-5	2.1 x 10-4	9.6 x 10-5	1.1 x 10-5	5.0 x 10-9	4.7 x 10-6	1.5 x 10-5
MOI (New ECF)*	1.0 x 10-6	3.2 x 10-5	8.0 x 10-6	8.9 x 10-7	1.0 x 10-9	2.0 x 10-7	1.5 x 10-6
MOI (FMEF)**	1.4 x 10-6	4.0 x 10-5	1.1 x 10-5	1.2 x 10-6	1.0 x 10-9	3.0 x 10-7	1.9 x 10-6
NPA	1.3 x 10-6	4.1 x 10-5	1.0 x 10-5	1.1 x 10-6	1.0 x 10-9	2.6 x 10-7	1.9 x 10-6

*MOI (New ECF) applies if spent fuel facility is constructed at the 200 Area on the Hanford Site.

**MOI (FMEF) applies if spent fuel facility is constructed at the Fuels and Materials Examination Facility.

Table F.2.4.1-3. Summary of chemical concentrations for normal operations at Savannah River.

	CHEMICAL CONCENTRATIONS mg/m3						
	Carbon Monoxide	Sulfur Dioxide	Nitric Oxide	Nitrogen Dioxide	Lead	VOC	PM-10
Worker	1.5 x 10-5	6.4 x 10-5	6.4 x 10-5	7.1 x 10-6	1.0 x 10-9	6.2 x 10-6	5.9 x 10-6
MCW	9.4 x 10-6	1.6 x 10-4	5.7 x 10-5	6.3 x 10-6	3.0 x 10-9	2.8 x 10-6	8.7 x 10-6
MOI	1.8 x 10-6	4.8 x 10-5	1.3 x 10-5	1.4 x 10-6	1.0 x 10-9	3.8 x 10-7	2.3 x 10-6
NPA	8.6 x 10-7	2.4 x 10-5	6.3 x 10-6	7.0 x 10-7	<1.0 x 10-9	1.9 x 10-7	1.1 x 10-6

Table F.2.4.1-4. Summary of chemical concentrations for normal operations at the Nevada Test Site.

	CHEMICAL CONCENTRATIONS mg/m3						
	Carbon Monoxide	Sulfur Dioxide	Nitric Oxide	Nitrogen Dioxide	Lead	VOC	PM-10
Worker	9.0 x 10-5	3.6 x 10-4	4.0 x 10-4	4.5 x 10-5	7.0 x 10-9	3.8 x 10-5	4.1 x 10-5
MCW	2.5 x 10-7	7.3 x 10-6	1.9 x 10-6	2.1 x 10-7	<1.0 x 10-9	5.2 x 10-8	3.5 x 10-7
MOI	7.9 x 10-7	2.3 x 10-5	5.9 x 10-6	6.6 x 10-7	<1.0 x 10-9	1.6 x 10-7	1.1 x 10-6

Table F.2.4.1-5. Summary of chemical concentrations for normal operations at Oak Ridge.

	CHEMICAL CONCENTRATIONS mg/m3						
	Carbon Monoxide	Sulfur Dioxide	Nitric Oxide	Nitrogen Dioxide	Lead	VOC	PM-10
Worker	6.4 x 10-5	3.0 x 10-4	2.8 x 10-4	3.1 x 10-5	5.0 x 10-9	2.6 x 10-5	2.7 x 10-5
MCW	1.6 x 10-6	2.6 x 10-5	9.6 x 10-6	1.1 x 10-6	<1.0 x 10-9	5.0 x 10-7	1.5 x 10-6
MOI	1.4 x 10-5	2.5 x 10-4	8.8 x 10-5	9.8 x 10-6	4.0 x 10-9	4.3 x 10-6	1.4 x 10-5
NPA	1.9 x 10-5	3.1 x 10-4	1.1 x 10-4	1.2 x 10-5	5.0 x 10-9	5.6 x 10-6	1.7 x 10-5

Table F.2.4.1-6. Summary of chemical concentrations for normal operations at the Barnwell Plant.

	CHEMICAL CONCENTRATIONS mg/m3						
	Carbon Monoxide	Sulfur Dioxide	Nitric Oxide	Nitrogen Dioxide	Lead	VOC	PM-10
Worker	1.5 x 10-5	6.5 x 10-5	6.4 x 10-5	7.1 x 10-6	1.0 x 10-9	6.2 x 10-6	5.9 x 10-6
MCW	1.9 x 10-6	4.7 x 10-5	1.3 x 10-5	1.5 x 10-6	1.0 x 10-9	4.5 x 10-7	2.3 x 10-6
MOI	5.9 x 10-6	1.4 x 10-4	4.0 x 10-5	4.5 x 10-6	2.0 x 10-9	1.5 x 10-6	7.0 x 10-6
NPA	5.9 x 10-6	1.4 x 10-4	4.0 x 10-5	4.5 x 10-6	2.0 x 10-9	1.5 x 10-6	7.0 x 10-6

F.2.4.2 Accidents. **Spillage of chemicals with a subsequent fire was evaluated for the bounding** accident involving toxic chemicals. The toxic chemicals that could be involved in the postulated accident are described in Section F.2.1. As was noted in that section, the extensive listing of chemicals provided in Table F.2-1 would be applicable only at sites involved with fuel examination.

The bounding accident evaluated for spent nuclear fuel storage in water pools at shipyard locations was a diesel fuel spill and fire. A diesel fuel fire involving spent nuclear fuel shipping containers aboard a ship at sea in Puget Sound was also evaluated.

Evaluation of the chemical spill with fire accident (excluding diesel fuel) at the alternate sites (INEL-ECF, Hanford, Savannah River, Nevada Test Site, Oak Ridge, and the Barnwell Plant) where naval spent nuclear fuel examinations may be conducted is presented in Section F.2.4.2.1. Evaluation of diesel fuel fires at shipyards and aboard ship in Puget Sound, as well as at INEL-ECF, Hanford, Savannah River, Nevada Test Site, Barnwell Plant, and Oak Ridge, is described in Section F.2.4.2.2.

These accidents incorporate spillage of the entire amount of a given chemical accompanied by a fire. The initiating event might be, for example, an airplane crash or ship collision. Such an accident bounds simpler chemical spills, such as handling accidents involving limited or unit (see Table F.2-1) amounts of a chemical, which were also considered. Consequently, only results for the fire accident are provided. The analyses utilize meteorological (see Section F.1.3.5) and demographic parameters specific to the evaluated location.

The toxic chemicals evaluated in the accident analyses would be used and stored in a number of different areas within the facility. Fuel oils, sulfuric acid, and sodium hydroxide would be expected to be located outside facility buildings in storage tanks. Other chemicals used for facility support and operation would likely be stored in a variety of locations within facility buildings such as tool rooms, laboratories, craft shops, equipment rooms, chemical mixing areas, hot cells, and flammable cabinets. The probability of releasing all or most of these chemicals in a single accident such as an airplane crash would be quite low, less than 10-7 per year, as supported in Section F.3.5. However, the probability of releasing an individual or limited number of chemicals is expected to be greater than this level and include a consideration of storage locations, types, sizes, and numbers of containers, and types and frequencies of initiating events. For accidents that could result in a toxic chemical release, a probability of 5 x 10-3 per year (Ganti and Krasner 1984) was considered to be a reasonable upper level. This level was based on the probability that a structurally damaging industrial fire could occur.

F.2.4.2.1 Chemical Spill and Fire.

F.2.4.2.1.1 Accident Description. **An accident might occur which caused toxic**

chemicals to spill, dispersed powdered toxic chemicals, and accelerated the vaporization of the toxic chemicals with a subsequent fire. The airborne release resulting from the involvement of the entire available amount of the toxic chemicals was evaluated with respect to the on-site workers, MCW, NPA, and MOI.

F.2.4.2.1.2 Source Term. The toxic chemicals involved in this hypothetical accident are provided in Table F.2-1. The entire amount of the toxic chemical might be involved due to the catastrophic nature of this accident.

F.2.4.2.1.3 Conditions and Key Parameters.

(1) Gases
  - 100% of the gas was released to the atmosphere.
  - Release period was 10 minutes.
  - Release was a point source.
  - Deposition velocity was 0.1 centimeter per second.

(2) Liquids
  - 100% of the liquid was released to the atmosphere.
  - The liquid was released into a pool of 0.1-inch depth.
  - The liquid was at its boiling point.
  - The release period was the longer of the calculated evaporation time or 10 minutes.
  - Release area was equal to the pool area.
  - Deposition velocity was 0.1 centimeter per second.

(3) Solids
  - 1% of the solid was dispersed into the atmosphere as PM-10.
  - Release period was 10 minutes.
  - Release was a point source.
  - Deposition velocity was 1.0 centimeter per second.

(4) Specific Chemicals
  - CFC-12 could break down at elevated temperatures into hydrochloric acid (10%) and phosgene (1%) with the remaining (89%) released as CFC-12.
  - The hypothetical sulfuric acid spill would be contained by a berm resulting in a pool release area of 443.2 square feet.
  - The hypothetical spill of sodium hydroxide was in the form of an aqueous solution and was contained by a berm resulting in a pool release area of 374 square feet. A 10-minute period was used for this release, and the sodium hydroxide was dispersed as a particulate.

(5) Meteorology
  - Wind speeds and atmospheric stability classifications used for the calculations were based on both 50% and 95% meteorology (Section F.1.3.5) to estimate downwind concentrations. The 95% meteorology included atmospheric stability classes A through F and wind speeds from 1.1 to 30 miles per hour.

(6) General
  - Standard rural terrain was used since this most closely resembles the sites being evaluated.
  - Release was calculated to occur at ground level.
  - No evacuation of downwind populations was included, in order to obtain maximum estimates of effects; therefore, exposures were not reduced to account for this action.
  - No credit was taken for building containment or filtration.
  - Biological effects of exposure to each chemical were treated separately. This was done to account for a lack of a current methodology to evaluate the effects resulting from simultaneous multiple chemical exposures.
  - To determine health impacts, the estimated concentrations were compared against the Emergency Response Planning Guidelines (ERPG) levels 1, 2, and 3 concentration limits or alternates.
  - To determine the likelihood of developing cancer from exposure to hydrazine, a slope factor of 1.7 x 101 per mg/kg-day obtained from IRIS (TOXnet 1993) was used. In addition, the exposure time was based on the duration of the release, and individual breathing rates and sizes were the same as those used in Section F.1 for radiological accident evaluations using the Radiological Safety Analysis Computer Program (RSAC-5) (Wenzel 1993).

F.2.4.2.1.4 Results. The airborne concentrations, averaged over the duration of each exposure, were calculated using EPIcode for the alternate locations for the worker, MCW, NPA, and MOI for both 50% and 95% meteorology. The airborne concentrations were compared to respective

ERPG values where available. However, ERPG values have not been derived for some of the chemicals. The effects of these substances were assessed by comparison with other appropriate values for toxic effects as discussed in Section F.2.3.3.

Tables F.2.4.2-1 through -12 list the downwind concentrations at various locations and corresponding ERPG values (or equivalent if TLV-TWA and IDLH concentrations are available). Hydrochloric acid and phosgene, from decomposition of CFC-12, sulfuric acid, and sodium hydroxide dominate the toxic chemical effects for on-site personnel. Concentrations of these chemicals above ERPG-3 levels might result in life-threatening effects. However, in no case is an ERPG-3 level exceeded for any member of the general public except for Oak Ridge where sulfuric acid concentrations could exceed ERPG-3 levels under both 50% and 95% meteorological conditions and sodium hydroxide concentrations could exceed ERPG-3 levels under 95% meteorological conditions. For the on-site workers, collocated workers, and any member of the general public that could be exposed to toxic chemicals at levels above ERPG-3, it is expected that actual toxic chemical exposures would be much less due to the mitigative measures that would be implemented (Section F.2.4.3).

Additional information on the toxic properties for the chemicals that dominate the toxic effects is provided below.

Hydrochloric acid is a irritant to the respiratory tract, skin, eyes, and mucous membranes. More severe exposures result in pulmonary edema, and often laryngeal spasm. A concentration of 53 mg/m3 causes irritation of the throat after short exposure. Concentrations of 75-150 mg/m3 are tolerable for 1 hour; concentrations of 1,500-3,000 mg/m3 are dangerous, even for brief exposures (TOXnet 1993).

Phosgene, also known as carbonyl chloride, is a highly toxic, corrosive liquid with a low boiling point. It is toxic from intakes by inhalation, ingestion, and dermal absorption. Effects from exposure may include contact burns to the skin and eyes, shortness of breath, chest pain, severe pulmonary edema, and death. At low vapor concentrations, it smells like musty hay. At higher concentrations, it has a sharp and pungent odor. It is a severe irritant to the eyes and respiratory tract and can be fatal if inhaled, even for short durations and at low concentrations. Exposure to 12 mg/cm3 can result in immediate irritation of the respiratory tract. 80 mg/m3 may cause lung injuries within 2 minutes; 100 mg/m3 for as little as 30 minutes is very dangerous; and 360 mg/m3 is rapidly fatal for exposures of 30 minutes or less (TOXnet 1993).

Sulfuric acid mist can be strongly irritating to the skin, eyes, mucous membranes, and respiratory tract. Odor may be detected at concentrations of 1 mg/m3; irritating effects may occur at concentrations of 1.1 mg/m3. Inhalation of concentrations near 3 mg/m3 may cause constriction of the air passage and choking sensations. At higher concentrations and durations of exposure, inhalation can cause pulmonary edema, emphysema, and permanent changes in pulmonary function (TOXnet 1993).

Sodium hydroxide dust can be irritating to the upper respiratory system. Irritating effects may occur at concentrations of 2 mg/m3. At higher concentrations and durations of exposure, inhalation can cause extreme irritation of the respiratory tract and permanent changes in pulmonary function (TOXnet 1993).

*IDLH concentrations are not available; therefore, corresponding ERPG-2 and -3 levels could not be determined.

In addition to comparing the airborne concentrations to their respective ERPG or other appropriate values, each substance was evaluated to determine if it has the potential for future carcinogenic health impacts. It was determined that exposure to hydrazine could result in an increased likelihood for developing cancer. Tables F.2.4.2-13 and F.2.4.2-14 provide the future potential likelihood for developing cancer from exposure to hydrazine for the worker, MCW, and MOI at the alternate locations under 50% and 95% meteorological conditions, respectively.

Table F.2.4.2-13. Future potential likelihood for developing cancer from hydrazine - 50% meteorology.

	INEL Expended Core Facilit	Savannah River	Hanford*	Nevada Test Site	Oak Ridge	Barnwell Plant
Worker	9.3 x 10-5	3.6 x 10-5	3.6 x 10-5	1.3 x 10-5	9.3 x 10-5	3.6 x 10-5
MCW	3.0 x 10-8	4.8 x 10-7	6.8 x 10-7	2.8 x 10-9	5.1 x 10-7	1.2 x 10-8
MOI	1.5 x 10-8	1.3 x 10-8	7.6 x 10-9	8.1 x 10-9	4.2 x 10-6	6.4 x 10-8

Table F.2.4.2-14. Future potential likelihood for developing cancer from hydrazine - 95% meteorology.

	INEL Expended Core Facilit	Savannah River	Hanford*	Nevada Test Site	Oak Ridge	Barnwell Plant
Worker	3.8 x 10-4	3.8 x 10-4	3.8 x 10-4	3.8 x 10-4	3.8 x 10-4	3.8 x 10-4
MCW	2.0 x 10-7	6.7 x 10-6	4.6 x 10-6	1.6 x 10-7	3.2 x 10-6	2.7 x 10-7
MOI	7.8 x 10-8	1.0 x 10-7	4.4 x 10-8	1.6 x 10-7	2.9 x 10-5	6.1 x 10-7

* MOI shown applies to new ECF if spent fuel facility is constructed at the 200 Area on the Hanford Site. A future potential carcinogenic risk of 1.1 x 10-8 (50% meteorology) and 1.2 x 10-7 (95% meteorology) applies to a spent fuel facility constructed at the Fuels and Materials Examination Facility.

F.2.4.2.2 Fire Involving Diesel Fuel.

F.2.4.2.2.1 Accident Description. A catastrophic failure of the diesel fuel storage tank

facility was postulated to occur. This could result in the spilling of the entire quantity of diesel fuel and a subsequent fire. The airborne release of toxic chemicals resulting from the fire was evaluated with respect to the on-site workers, MCW, NPA, and MOI as applicable for the accident site.

F.2.4.2.2.2 Source Term. The material involved in this accident was diesel fuel with the

fire generating the following toxic chemicals due to combustion:

- Carbon monoxide
- Oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide)
- Lead
- Sulfur dioxide.

F.2.4.2.2.3 Conditions and Key Parameters.

- For alternate DOE sites and the Barnwell Plant, the diesel fuel was stored in bulk storage tanks.
- For shipyards, the diesel fuel was stored in a portable diesel power unit.
- For the ship accident, the diesel fuel was stored in large tanks adjacent to the hold.
- For alternate DOE sites and the Barnwell Plant, 1950 gallons of diesel fuel could be spilled.
- For shipyards, 315 gallons of diesel fuel could be spilled.
- For the ship accident, 121,000 gallons of diesel fuel could be spilled.
- For all facilities, the entire quantity of diesel fuel was spilled and ignited in open air.
- For alternate DOE sites and the Barnwell Plant, the spill area was 261 square feet.
- For shipyards, the spill area was 66 square feet.
- For the ship accident, the spill area used was 4812 square feet.
- For alternate DOE sites and the Barnwell Plant, the entire amount of diesel fuel was consumed by the fire over a 2-hour period.
- For shipyards, the entire amount of diesel fuel was consumed by the fire over a 1-hour period.
- For the ship accident, the entire amount of diesel fuel was consumed by the fire over a 6-hour period.
- For all facilities, the releases per gallon of fuel burned were as follows:
  Carbon monoxide = 0.34 pound
  Oxides of nitrogen = 1.58 pounds
  Lead = 4.2 x 10-6 pound
  Sulfur dioxide = 0.105 pound.
- For alternate DOE sites, the Barnwell Plant, and shipyards, the airborne release of toxic chemicals occurred at ground level.
- For the ship accident, the airborne release of toxic chemicals occurred at 48 feet above the sea (i.e., at the middle of the flame height above the cargo hatch) for evaluation of land-based exposures. For shipboard exposures, a release height of zero was used.
- For all facilities, standard rural terrain was used and building wake effects were not considered.
- For all facilities, wind speeds and atmospheric stability classifications were based on both 50% and 95% meteorology (Section F.1.3.5).
- For all facilities, no evacuation of downwind populations occurred and the biological effects of chemical exposure act uniquely and do not affect the individual in a cumulative way.
- For all facilities, to determine the health impacts, the estimated concentrations were compared against the Emergency Response Planning Guidelines (ERPG) levels 1, 2, and 3 concentration limits or alternates.

F.2.4.2.2.4 Results. The airborne concentrations, averaged over the duration of each

exposure, were calculated using EPIcode for the combustion products resulting from the fire for the worker, MCW, NPA, and MOI (as applicable for the accident site) under both 50% and 95% meteorology. The airborne concentrations were compared to respective ERPG values where available. However, ERPG values have not been derived for some of the constituents listed. The effects of these constituents were assessed by comparison with other appropriate values for toxic effects as discussed in Section F.2.3.3.

Tables F.2.4.2-15 through -38 list the downwind concentrations at various locations and corresponding ERPG (or equivalent) values. Results for the diesel fuel fire at fuel examination sites indicate that the toxic chemical concentrations for sulfur dioxide and oxides of nitrogen may exceed ERPG-3 levels for the worker. At Savannah River and Hanford, the MCW also may be exposed to a nitric oxide concentration exceeding ERPG-3 levels under 95% meteorological conditions. The NPA and MOI exposures at all the fuel examination sites would be expected to be below ERPG-2 levels except for Oak Ridge. At this location under 95% meteorological conditions, the NPA and MOI may be exposed to concentrations of sulfur dioxide and oxides of nitrogen that exceed ERPG-3 and concentrations of carbon monoxide that exceed ERPG-2. Under 50% meteorological conditions at Oak Ridge, the NPA and MOI may be exposed to concentrations of nitric oxide that exceed ERPG-3 and concentrations of sulfur dioxide and nitrogen dioxide that exceed ERPG-2. Results for the diesel fuel fire at shipyards show that for the worker and NPA categories, the toxic chemical concentrations for sulfur dioxide and oxides of nitrogen may exceed ERPG-3 levels. For the MOI, however, these concentrations are expected to be less than the ERPG-3 levels with the exception that under 95% meteorological conditions the ERPG-3 level for nitric oxide may be exceeded at the Norfolk shipyard.
Results for the ship diesel fuel fire show that shipboard (worker) concentrations of carbon monoxide, sulfur dioxide, and oxides of nitrogen may exceed ERPG-3 levels, but the shore (MOI) concentrations are expected to be less than ERPG-3 levels. For the individuals on board the ship that might be exposed to toxic chemicals at levels above ERPG-3, it is expected that actual toxic chemical exposures would be much less due to the mitigative measures that would be implemented (Section F.2.4.3).

Additional information on the toxic properties for the chemicals that dominate the toxic effects is provided below.

Sulfur dioxide is a colorless gas with a pungent odor. It is a poison, and it is also an eye, skin, and mucous membrane irritant. It chiefly affects the upper respiratory tract and bronchi and at higher concentrations, sulfur dioxide causes respiratory paralysis (TOXnet 1993).

Nitric oxide and nitrogen dioxide occur together in dynamic equilibrium. Nitric oxide is a colorless gas, and nitrogen dioxide is a reddish brown gas. Both chemicals are eye, skin, and mucous membrane irritants and primarily affect the respiratory system. Exposure to 47 mg/m3 of nitrogen dioxide can cause respiratory irritation and chest pain, 93 mg/m3 can cause lung injuries, and 187 mg/m3 can be fatal (TOXnet 1993).

In addition to comparing the airborne concentrations to their respective ERPG or other appropriate values, each substance was evaluated to determine if it has the potential for future carcinogenic impacts. It was determined that exposure to lead could result in an increased likelihood for developing cancer. However, sufficient information to quantify this likelihood was not available in IRIS. Therefore, the concentrations of lead resulting from the accident were compared against the NAAQS value for lead. For the lead concentrations provided in Tables F.2.4.2-15 through F.2.4.2-38, no NAAQS is exceeded.

F.2.4.3 Mitigative Measures for Toxic Chemicals. Mitigative measures for potential releases of

toxic materials involve administrative controls for personnel protection and emergency response. For personnel protection, controls involve safety review committees for planned activities that establish requirements, safe work permits, and procedures for required clothing (rubber boots, gloves, face shields, eye protection) that can mitigate the effects of potential releases of toxic materials. Procedures may also require provisions for prestationing mitigative devices such as eyewash stations and emergency showers. All of the alternate facilities being evaluated employ emergency response programs to mitigate impacts of potential toxic chemical accidents to workers and the public. Emergency planning, emergency preparedness, and emergency response programs are in place and involve established resources such as warning communications, fire departments, and emergency command centers. The cargo ships used for naval spent nuclear fuel have smoke detection and fire fighting equipment on board. They also have fire suppression systems in their holds which use inert gas to smother fires. In addition, less freely available oxygen in the ship's cargo hold would tend to slow the combustion rate of the diesel fuel. Port facilities would also have available additional fire fighting equipment, public warning systems, and emergency response programs.

Table F.2.4.2-15. Summary of chemical concentrations for fire involving diesel fuel at the INEL Expended Core Facility.

CHEMICAL CONCENTRATIONS mg/m3 - 50% METEOROLOGY

F.3 AIRCRAFT CRASH PROBABILITiES

F.3.1 Introduction

The probability of an airplane crashing into a fuel storage area or a file! examination facility at the various alternate site locations is presented in this section. An airplane crash into these regions is of concern since it might result in the release of corrosion products from the stored fuel or the release of radioactive fission products from the fuel. The method outlined in ~A Methodology for Calculation of the Probability of Crash of an Aircraft into Structures in Weapon Storage Areas" (Sandia 1983) has been ~sed to predict the crash probabilities for this analysis. This calculational methodology takes into consideration the crash probabilities associated with landing and takeoff operations at nearby airports and crashes during in-flight operations.

The aircraft crash probability analysis presented herein is based on the examination of large civilian aircraft and military aircraft crossing the space within a 10-mile radius of each site. The crash probability of general aviation aircraft is not included in this assessment since aircraft of this type generally do not possess sufficient mass or attain sufficiently high velocities to produce a serious radiological threat in the event that they crash into a fuel storage area or a fuel examination facility. Further, the crash probability contribution due to air travel beyond 10 miles was determined to be very small based on the models and conditions used in this analysis, and therefore has been omitted.

F.3.2 Methodology

The Sandia report provides the methodology which has been used for this assessment (Sandia 1983). In this report, the following expressions are given for calculating the crash probability associated with takeoff and landing operations at a given airport runway, and in-flight operations along a given airway:

Pto= ENi * Pnto * A * c(a)* e- lxijl/0(x,a) * e- lyijl/0(y,a)
Pl= ENil * Pnl * A * c(a) * e- lxijl/0(x,a) * e- lyijl/0(j,a)
Pif= ENk * Pnif * A * c(if) * e- lxkjl/0(x,if)

where: subscript "to" refers to airport takeoff operations
subscript "l" refers to airport landing operations
subscript "if" refers to in-flight operations
Ni = the number of runway operations per year
Nk = the number of in-flight operations per year
Pn = the crash probability per operation given in Table F.3-1
= the perpendicular distance from the centerline of the runway to the target in miles
= the perpendicular distance from the airway to the target in miles
= the perpendicular distance from the end of the runway to the target in miles
c(a) = crash density constant given in Table F.3-2
c(if) = crash density constant given in Table F.3-3
0(x,a) = crash density constant given in Table F.3-2
0(y,a) = crash density constant given in Table F.3-2
e(x,if) = crash density constant given in Table F.3-3
A = effective crash area in square miles.

Table F.3-1. Crash parameter Pn. Table F.3-2. Crash density constants. Table F.3-3. Crash density constants. Figure F.3-1. Crash zones. Using these relationships, the crash probability for takeoff, landing, and in-flight operations is the product of the number of operations per year, times the crash probability per operation per year, times the effective crash area per square mile, times the crash probability density per square statute mile. To determine the crash probability associated with a given site requires the repeated application of these relationships for each airport runway and for each airway. These individual crash components are then summed to arrive at a total overall crash probability for a site.

In the Sandia report, the effective crash area is identified as the sum of the effective skid area of the plane, the effective plan view associated with the target, and the effective shadow area of the crash (Sandia 1983). The following expression relates these terms and is valid for crash attitude angles greater than zero. If the crash attitude angle is zero, an airplane would be flying along parallel to the ground at an altitude equal to or greater than the height of the target; therefore, the airplane would clear the object and there would be no crash.

A = (L + A,) * (W + 5k + H * cot)

where: L - target length dimension
W - target width dimension
H - target height
A, - aircraft wingspan
- crash attitude angle
Sk - aircraft skid distance.

F.3.3 Site Specific Information

The existence and location of airports and airways within 10 statute miles of a site have been obtained from Sectional Aeronautical Maps published by the National Oceanic and Atmospheric Administration (NOAA), and from detailed site specific maps which identify nearby airports (NOAA 1993a; NOAA 1993b; NOAA 1993e; NOAA 1993d; NOAA 1993e; NOAA 1993f; NOAA 1993g; USGS 1983a; USGS 1983b). These same sources of information were also used to obtain the distances from airport runways and airways to the sites of interest. Information regarding air traffic along airways within this region was obtained from the Federal Aviation Administration

(FAA). Airplane holding paflerns and approach and departure routes that were identified by the FAA were converted into equivalent airways for this analysis. Information regarding the number of takeoff and landing operations at each airport runway was obtained from the cogniaant airport officials (i.e., airport manager or base commander), or from the FAA. Tables F.34 and F.3-S summarize the airport and airway traffic information that was obtained.

Table F.3-4. Airport landings and takeoffs per site location per year. Table F.3-5. Airway air traffic per site location per year.

The effective crash area associated with various types of fliel storage at shipyards and prototypes was based on the storage facility footprints identified in Table D-1 of Attachment D. Length and width dimensions associated with the target area were calculated from these footprints by treating the storage area as square (i.e., equal length and width dimensions). The height of the dry storage containers was based on that of an existing M-140 shipping container, and the height of the water pool facility superstructure was based on the approximate height of the Expended Core Facility at INEL. For the water pool facility, a crash into the building might damage the fliel either by the airplane directly striking it or by the airplane causing sufficient damage to the building to cause part of the building structure to collapse and strike the fliel. The crash attitude angle used was 15 degrees, based on the recommended value identified in the Sandia report (Sandia 1983). A reduced aircraft skid distance of 300 feet was used. This skid distance is based on a review of the proposed site locations and reflects the fact that nearby buildings, dry docks, or retaining walls will generally limit the length of the aircraft skid to 300 feet or less prior to impact.

The effective crash area associated with fuel examination at the Expended Core Facility at INEL or similar facilities to be constructed at the Barnwell Plant, Hanford, Oak Ridge, the Nevada Test Site, or Savannah River was based on the vulnerable part of the facility being 667 feet long, 194 feet wide, and 60 feet high. This represents the portion of the Expended Core Facility that contains the combined dry cell, shielded cell, and water pool as identified in Attachment B. For these facilities, a crash into the building might damage the fuel either by the airplane directly striking it or by the airplane causing sufficient damage to the building to cause part of the building structure to collapse and strike the fuel. The effective crash area associated with dry storage or shipping containers waiting to be handled at these fuel examination facilities is based on the height and width of an existing M-140 shipping container and the modeling approach that two such containers could be located outside of the fuel processing facility and separated by a reasonably large distance. The crash attitude angle that was used was 15 degrees. For these facilities and containers, airplane skid distances of 2200 feet for military high performance aircraft and 1600 feet for large military and large civilian aircraft were used. These skid distances correspond to the maximum expected skid distance based on the information presented in the Sandia report (Sandia 1983).

F.3.4 Aircraft Specific Information

Aircraft wingspans which are representative of large civilian aircraft, military high performance aircraft (i.e., tactical fighter and tactical fighter trainer), and large military aircraft (i.e., cargo, transport, refueling, and bomber) have been taken into account separately in computing the overall crash probabilities for each site. Wingspans for these three class of aircraft have been based on average values computed from individual planes within each class. Data from "Aviation Week & Space Technology" served as the basis for determining these wingspans (AWST 1992). The calculated average wingspans were: 40 feet for military high-performance aircraft, 131 feet for large military aircraft, and 135 feet for large civilian aircraft. For large military and civilian aircraft, an effective wingspan that was 75% of the average wingspan was used in the probability calculations. This effective wingspan reflects the fact that only the region between the most outboard wing-mounted engines has the potential to seriously damage a fuel storage area or a fuel examination facility.

F.3.5 Results

Tables F.3-6 and F.3-7 present the crash probability results for the four methods of fuel storage at shipyards and prototypes and for fuel examination facilities. The probabilities listed within these tables represent the combined takeoff, landing, and in-flight crash probabilities associated with each method of fuel storage at each site. Following the DOE NEPA oversight guidance, consequences for beyond design basis accidents are calculated where the probability is 10(-7) or greater per year. These consequences are discussed in Section F. 1.4 of this attachment. For cases less likely than 10(-7) per year, calculations of consequences are not included.

The probability calculated for airplane crashes at different facilities located within a particular DOE site may vary somewhat. This situation exists at INEL where low altitude testing of commercial jet airliners has been conducted near the NOAA tower. This tower is located about 1.5 miles from ICPP, and 2.3 miles from ECF. As a result of this difference in distance, the crash probabilities are expected to be about a factor of two higher at ICPP than at ECF. Further, two different methodologies have been in general use for determination of aircraft accident probabilities. In addition to the Sandia methodology used in this appendix, a technique developed by the NRC in the 1970's has been applied at some facilities. Comparison of the two methods has shown that results can differ by a factor of two to four, with the NRC method generally producing higher probabilities than the Sandia method. This difference stems from the somewhat more detailed nature of the Sandia method. Therefore, calculated aircraft crash probabilities at ICPP are expected to be about a factor of four to eight higher than those calculated for ECF.

Crash probabilities fall in the design basis range (i.e., probability of occurrence > 10(-7) per year) at Pearl Harbor for all types of fuel storage, at Norfolk for fuel storage in shipping containers on railcars, and at Oak Ridge and Savannah River for the fuel examination facility dry cell and water pool. The radiological consequences associated with an airplane crash into these areas are addressed in detail in Section F.1.4.

Crash probabilities fall in the beyond design basis range (i.e., probability of occurrence between 10(-6) and 10(-7) per year) at Norfolk for fuel storage in immobile dry storage containers, shipping containers on a concrete pad, and in the water pool facility, at Kesselring for fuel storage in shipping containers on railcars and in the water pool facility, at Portsmouth for shipping containers on railcars, at the Nevada Test Site for the fuel examination facility dry cell and water pool, and the fuel examination facility dry storage containers at Oak Ridge and Savannah River. The radiological consequences associated with an airplane crash into these areas are also addressed in detail in Section F.1.4.

Crash probabilities with a likelihood of occurrence less than 10(-7) per year are not evaluated since it is expected that they would contribute very very little to the risk. This is the case for immobile dry storage and shipping containers on a concrete pad at Kesselring and Portsmouth, the water pool facility at Portsmouth, all types of flid storage at Puget Sound, the fuel examination facilities at Barnwell, Hanford, and INEL, and the fuel examination facility dry storage containers at the Nevada Test Site.

F.4 FUGITIVE DUST

Table F.3-6. Crash probabilities for various fuel storage options per site location per year.

Table F.3-7. Crash probabilities for fuel examination facilities per site location per year.

The INEL-ECF is a large laboratory facility used to receive, examine, and ship naval nuclear fuel and irradiated test specimen assemblies. This section provides the results of an evaluation of fugitive dust emissions that could be generated during the construction of a similar laboratory facility at an alternate location (Hanford, Savannah River, the Nevada Test Site, the Barnwell Plant, or Oak Ridge).

F.4.1 Computer Modeling to Estimate Fugitive Dust Emissions

Factors such as locations of affected persons, terrain, meteorological conditions, release conditions, and grain size distributions are required as input parameters for calculations to determine particulate concentrations from fugitive dust emissions during construction activities. This section describes the computer model used to perform fugitive dust concentration estimates. Specific input parameters used in this analysis are summarized in Section F.4.2.

The Fugitive Dust Model (FDM) was the computer code chosen to evaluate fugitive dust emissions from construction activities at an alternate DOE location. FDM is a computerized air quality model specifically designed for estimating fugitive dust emissions from point, line, or area sources (EPA 1992c).

FDM is designed to work with properly prepared meteorological data such as the EPA RAMMET program or card images of meteorological data in either hourly or Stability Array (STAR) format. FDM is based on the well-known Gaussian plume formulation for computing concentrations, but the model has been specifically adapted to incorporate an improved gradient transfer deposition algorithm. Emissions for each source are apportioned by the user into a series of particle size classes. A gravitational settling velocity and a deposition velocity are subsequently calculated by FDM for each class, and dust concentrations and depositions are then calculated for locations selected by the user.

FDM is the preferred model for estimating conditions resulting from particulate matter emissions from fugitive sources such as excavation and soil handling. The ISC2 Code (Section F.2.2.2) can also be used for this purpose; however, FDM was judged to be superior to the ISC2 Code for this evaluation.

F.4.2 Conditions and Key Parameters

- Construction area was 30 acres
- Construction activities occurred over a 3- to 5-year period.
- An emission factor of 2.0 tons per acre-month was used.
- Grain sizes used were as follows:

Average Diameter (um)	% of Total
1.25	3
3.75	5
7.5	15
12.5	10
20.0	67

- Meteorological conditions used were the 5-year average STAR data sets.
- Roughness heights were 2 centimeters for Hanford and Nevada Test Site and 30 centimeters for Savannah River, the Barnwell Plant, and Oak Ridge.

F.4.3 Results

The fugitive dust concentrations were calculated using FDM for the worker, MCW, NPA, and MOl using normal meteorology. Table F.4-1 lists the fugitive dust concentrations at various locations. These airborne concentrations were compared against the TLV-TWA concentration for particulates. The TLV-TWA concentration of 10 mg/m3 was not exceeded at any of the specified locations for fugitive dust that could be generated during construction activities at the alternate locations. Since these concentrations were extremely low, it can also be concluded that similar results would be expected for the alternate shipyard locations since the facilities to be constructed would be smaller.

F.5 OCCUPATIONAL ACCIDENTS

Table F.4-1. Summay of fugutive dust concentrations for construction activities at alternate locations.

Occupational accidents can occur in the workplace during the construction or operation of any industrial facility. In order to assess the possible extent of occupational accidents during construction and non~nstruction operations at naval spent nuclear fuel facilities, projections of the number of fatalities and injuries or illnesses were made for each alternative. The projections are presented in this section. The projections are based on average occupational fatality and injury incidence rate data published by the DOE (DOE 1993a) for DOE and DOE contractor operations. The incidence rates that were used in the analyses are provided below. A more detailed discussion of the basis for these incidence rates is presented in Volume 1.

Average occupational injury/illness and fatality rates (a)

	All Labor Categories		Construction Workers	
	Total Injury/Illness	Fatalities	Total Injury/Illness	Fatalities
DOE and Contracters(b)	3.2	0.0032	6.2	0.011

(a) All incidence rates are given per 100 worker-years

(b) 1988-1992 averages (DOE 1993a)

The term "injury/illness" as used in this analysis corresponds to the DOE definition of a recordable injury illness. Specifically, an injury or illness case represents any work-related death, illness, or any work-related injury which would result in loss of consciousness, restriction of work or motion, transfer to another job, or medical treatment beyond first aid.

F.5.1 Accident Evaluation

F.5.1.1 Constiuction. The average number of construction-related fatalities and injury or illnesses

and the 4o-year total were calculated. The methods of calculating construction-related fatalities and injuries or illnesses are presented below.

The number of construction workers that would be required to construct or modify each naval spent nuclear fuel storage and examination facility was calculated for every year that construction would take place during the period 1995 through 2035. The sum of these workers represents the total number of construction workers. The 40-year total of construction fatalities was obtained by multiplying the total number of construction workers by the construction fatality rate for DOE and DOE contractors.

The annual average number of construction workers for each facility was obtained by dividing the total number of construction workers by the number of years that construction would take place. The product of the annual average number of construction workers and the construction fatality rate for DOE and DOE contractors was calculated to provide the annual average number of construction fatalities.

The annual average and 40-year total construction injuries or illnesses were calculated in the same manner as construction fatalities except that the construction injury or illness accident rate for DOE and DOE contractors.

F.5.1.2 Storage end Examination Facillty Operations. The average number of fatalities and

injuries or illnesses and the 40-year total fatalities and injuries or illnesses were calculated for operation of naval spent nuclear fuel storage and examination facilities. The methods of calculating the operational fatalities and injuries or illness are presented below.

The accident rates for DOE and DOE contractor operations other than construction were used because examination and storage facility operations would more likely be performed by DOE and DOE contractor personnel (or Navy personnel in the case of shipyards). The number of workers that would be required to operate each naval spent nuclear fuel storage and examination facility was calculated for every year during the period 1995 through 2035 and summed over the 40-year period to obtain the total number of workers. The 40-year total of fatalities was obtained by multiplying the total number of workers by the DOE fatality rate.

The annual average number of workers for each facility was obtained by dividing the total number of workers by the number of operational years (40 years). The product of the annual average number of workers and the DOE fatality rate represents the annual average number of operational fatalities.

The annual average and 40-year total estimated injuries or illnesses associated with facility operations were calculated in the same manner as fatalities associated with facility operations except that the DOE injury or illness accident rate was used.

F.5.2 Results

This section presents tabulated results of calculations of construction and operating fatalities and injuries or illnesses for each alternative. Table F.5-1 provides the projections of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations for each alternative. Tables F.5-2 through F.5-3 present the results of calculations of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations at naval sites. The results of all calculations show that the number of fatalities and injuries or illnesses for construction activities and storage and examination operations would be low for any alternative.

ATTACHMENT G

COMPARISON OF THE NAVAL SPENT NUCLEAR FUEL STORAGE ENVIRONMENTAL ASSESSMENT AND THIS ENVIRONMENTAL IMPACT STATEMENT

The Naval Nuclear Propulsion Program has prepared an environmental assessment of short-term storage of naval spent nuclear fuel until the environmental impact statement, of which this appendix is a part, can be completed and an alternative for management of naval spent nuclear fuel is selected (Federal Register, Vol. 59, No. 19, 4051, January 8, 1994). The environmental assessment considered alternatives for storing, until June 1995, naval spent nuclear fuel removed from nuclear-powered vessels and reactor prototypes at several naval sites. The environmental impact statement, which the appendix including this attachment is a part, considers alternatives for the examination and storage of naval spent nuclear fuel during a 40-year period beginning in June 1995.

Occasions may arise when comparison of the impacts for naval spent nuclear fuel described in these two documents may be desired. However, there are some differences between the environmental assessment and this appendix which should be recognized because they make such a comparison complicated. Failure to recognize these differences may lead to an erroneous conclusion that the two documents are inconsistent or contradictory.

First, and most importantly, the environmental assessment considered only a limited period, less than 2 years, needed to conduct the National Environmental Policy Act process required to reach a decision on the long-term management of Department of Energy (DOE) spent nuclear fuel. This process includes preparation of this environmental impact statement. The environmental impact statement, and therefore this appendix, provides the evaluation of the alternatives to be used for managing spent nuclear fuel for 40 years. As a result, this environmental impact statement considers a wider range of alternatives than the environmental assessment, partly because more alternatives are possible if a longer time is available to implement them and partly because some decisions which could be deferred for a short period such as 2 years should not be deferred for a period as long as 40 years.

The alternatives considered in the environmental impact statement also include more potential sites for management of naval spent nuclear fuel. This provides a wider range of choices, but, as a natural consequence, it also increases the number of potential destinations and the miles traveled by shipments of naval spent nuclear fuel under some alternatives. In the same manner, while the environmental assessment considered temporary storage of naval spent nuclear fuel at Newport News Shipbuilding, storage at Newport News is not included in the alternatives in the environmental impact statement because that shipyard is not federally owned.

The alternatives considered in the environmental impact statement also include storage of naval spent nuclear fuel in water pools and immobile dry storage casks in addition to storage in shipping containers. There is also an evaluation of alternatives for examination of naval spent nuclear fuel in the environmental impact statement. These additional storage modes and examination alternatives were not considered in detail in the environmental assessment because the period covered by that document was short and consequently, the implementation of some of the alternatives would have been impractical. For example, water pool storage facilities could not be funded and constructed at the shipyards in a period of less than 2 years.

Also, as a natural result of the longer period considered in this environmental impact statement, a larger number of naval spent nuclear fuel assemblies and additional types of naval fuel assemblies are included in the analyses. The increase in the amount of naval spent nuclear fuel occurs since a certain number of naval reactors are refueled or defueled each year, so in a greater number of years more fuel becomes available for storage. Similarly, some newer designs for naval nuclear propulsion plants will not be refueled for the first time until some time after 1995, so those types of fuel are not treated in the environmental assessment.

The environmental impact statement addresses some impacts of normal operations and some accidents not discussed in the environmental assessment because the conditions or operation which might cause these effects would not occur under the alternatives considered in the environmental assessment. The environmental impact statement also addresses several types of impacts for each alternative in greater detail than the environmental assessment. This was done because more detailed treatment was judged to be appropriate with the broader scope of alternatives in the environmental impact statement.

The methods used to perform the analyses in the environmental impact statement have been refined in the time since the environmental assessment was prepared. This occurred partly because of the larger number of naval spent nuclear fuel assemblies analyzed and the wider scope of sites and methods of storage to be evaluated, and partly because additional time was available to implement the refinements. In addition to refinements in the methods for performing the calculations, some minor changes in the calculational models were made in order to establish a high degree of consistency with the analytical methods used for the other DOE sites that are part of the environmental impact statement. This consistency is appropriate in some cases in order to establish common grounds for comparison of alternatives. The changes in the calculational methods make a direct comparison of the analytical results presented in the environmental assessment for naval sites with those in this appendix difficult.

GLOSSARY

activation	The process of making a material radioactive by exposing the material to neutrons, protons, or other nuclear particles.
activation products	The radionuclides formed as a result of a material being activated. For example, cobalt-60 is an activation product resulting from neutron activation of cobalt-59.
activity	A measure of the rate at which a material is emitting nuclear radiation. Activity is usually measured in terms of the number of nuclear disintegrations which occur in a quantity of the material over a period of time. The standard unit of activity is the curie (Ci), which is equal to 37 billion (3.7 x 1010) disintegrations per second.
aggregates	Sand, gravel, or rock which is used in concrete or mortar mixes to achieve increased strength.
airborne emissions	Radioactivity in the form of radioactive particles, gases, or both that is transported by air.
alloy	A mixture of two or more metals.
aquifer	A water-bearing stratum of permeable rock, sand, or gravel located beneath the surface of the earth, which is capable of yielding water to a well or spring.
archaeological areas	Areas of or relating to the scientific study of material remains (as fossil relics, artifacts, monuments) of past human life and activities.
average individual	An individual who could consume items or occupy areas at rates which would be typical for the population of interest.
base flood	A flood which has a 1-percent chance of occurrence in any given year. Also referred to as a 100-year flood.
benthic	Pertaining to the bottom of the ocean.
best estimate	An estimate in which the factors used in determining the estimate were chosen such that the result approximately represents what would be expected.
cladding	A metal casing that surrounds the nuclear fuel.
coastal zone	The region along the shore, adjacent to the ocean. A coastal zone is usually defined as the region within 3 nautical miles of a shoreline.
concentration factor	A factor which is defined as the concentration of an element or radionuclide in an organism or its tissues divided by the concentration directly available from the organism's environment under equilibrium or steady-state conditions.

conservative estimate	An estimate in which the factors used in determining the estimate were chosen such that the result would be unlikely to be exceeded.
containments	Devices as complex as a glove box or as simple as a plastic bag designed to limit the spread of radioactive contamination to an area as close as possible to the source, and to break the chain of transfer to prevent contaminating other material.
core	The central portion of a nuclear reactor containing the nuclear fuel.
corrosion	The process denoting the destruction of metal by chemical or electrochemical action.
corrosion products	The substances produced by corrosion of a metal. Rust is a common corrosion product resulting from the corrosion of iron.
corrosion-resistant alloy	An alloy which corrodes slowly compared to ordinary alloys. Stainless steel is an example of a corrosion-resistant alloy.
critical organ	The limiting organ for evaluating exposure to ionizing radiation. A critical organ is determined by the following criteria: (1) the organ that accumulates the greatest concentration of a radioactive material, (2) the necessity of the organ to the well being of the entire body, (3) the organ most damaged by the entry of a radionuclide into the body, and (4) the organ damaged by the lowest exposure. Usually, case (1) is the determining factor for choosing the critical organ.
critical pathways	Those pathways which result in the most significant amount of exposure to radiation.
cumulative effects	The changes in the health of an individual(s) from the sum of all yearly exposures to radiation.
curie (Ci)	The curie is the common unit used for expressing the magnitude of radioactive decay in a sample containing radioactive material. Specifically, the curie is that amount of radioactivity equal to 3.7 x 1010 (37 billion) disintegrations per second. This unit does not give any indication of the radiological hazard associated with the disintegration.
defueling	Removal of all nuclear fuel from a nuclear-powered ship.
design earthquake	The maximum intensity earthquake that might occur along the nearest fault to a structure. Structures are built to withstand a design earthquake.
diffusion	The process of spreading out or scattering from regions of higher concentration to regions of lower concentration.
dispersion	The process of scattering or distributing over a large region.
dose	A general term which denotes the quality of radiation or energy absorbed; usually expressed in rems for doses to man.
dose commitment	The total radiation dose accrued by an individual over a specified period of time due to the exposure of the individual to radiation during a given interval of time. This includes the total time the radioactive material would reside in the body, if ingested or inhaled (usually expressed in rems).
dose commitment conversion factor	A factor which converts the quantity of radioactivity taken into the body to the dose to the individual (usually expressed in rems per curie).
dose equivalent	A quantity used to express all radiations on a common scale for calculating the effective absorbed dose. It is defined as the product of the absorbed dose and certain modifying factors and is expressed in rems.
dose rate	The amount of radiation dose delivered in a unit amount of time; for example, in rems per hour.
dose rate conversion factor	A factor which converts the exposure to a given radiation level to the dose that an individual could receive. It is usually expressed in rems per hour per curie per cubic meter (or square meter).
dredge spoil	Bottom sediments or materials that have been excavated from a waterway.
ecosystem	A community of plant and animal populations together with their physical environment. An organizational unit which can maintain its biological activities independent of other units.
element	A chemical substance that cannot be divided into simpler substances by chemical means. A substance whose atoms all have the same atomic number.
endangered species	A species or subspecies which is in danger of extinction throughout all or a significant portion of its range.
environmental consequences	Changes to the environment as a result of the effects of radiation or radioactive materials.
epidemiological study	A scientific study that deals with the incidence, distribution, and control of disease in a specified population.
exclusion area	An area where access would result in personnel exceeding radiation exposure limits in a very short time.
Expended Core Facility (ECF)	A large laboratory facility, located at the Naval Reactors Facility in Idaho, consisting of water pools and shielded cells used to receive, examine, and ship naval spent nuclear fuel and irradiated test specimen assemblies. Naval spent nuclear fuel is prepared at ECF for storage and shipment to the Idaho Chemical Processing Plant.
exposure, external	The subjecting of the outside of the body of an organism to ionizing radiation.
exposure, internal	The subjecting of the inside of the body of an organism to ionizing radiation.

exposure, occupational	The subjecting of an individual to ionizing radiation in the course of employment.
exposure, radiation	The subjecting of a material or organism to ionizing radiation.
fauna	Animals.
fissile	A material whose nucleus is capable of being split (fissioned) by neutrons of all energies.
fission	The splitting of a heavy nucleus into two approximately equal parts which is accompanied by the release of a relatively large amount of energy and generally one or more neutrons.
fission products	During operation of a nuclear reactor, heat is produced by the fission (splitting) of "heavy" atoms, such as uranium, plutonium, or thorium. The residue left after the splitting of these "heavy" atoms is a series of intermediate weight atoms generally termed "fission products." Because of the nature of the fission process, many fission products are unstable and, hence, radioactive.
floodplain	The lowlands which adjoin inland and coastal waters and relatively flat areas and floodprone areas of offshore islands which are covered with water from a 1-percent or greater chance flood in any given year.
floodplain/wetlands assessment	An evaluation which consists of a description of a proposed action, a discussion of its effects on the floodplain/wetlands, and a consideration of alternatives.
flora	Plants.
fuel	Fissionable material used or useable to produce energy in a nuclear reactor. It may also refer to a mixture, such as natural uranium, in which only part of the atoms are readily fissionable.
gamma ray	[Symbol - (gamma)] High-energy, short wavelength electromagnetic radiation. Gamma radiation frequently accompanies beta particle emissions. Gamma rays are very penetrating and are stopped most effectively by dense materials such as lead or uranium. They are essentially similar to x-rays but are usually more energetic and originate from the nucleus. Cobalt-60 is an example of a radionuclide that emits gamma rays.
geology	The study of the origin, history, materials, and structure of the earth.
geophysical survey	An examination of the condition, situation, or value of the earth using the physics of the earth including the fields of meteorology, hydrology, oceanography, seismology, volcanology, magnetism, radioactivity, and geology.
glaciation	The act of having been subjected to glaciers, extreme cold, and ice.
groundwater	Water that exists or flows beneath the earth's surface in the zone of saturation between saturated soil and rock.
half-life, biological	The time required for a biological system, such as an organ or tissue in an organism, to clear by natural (non-radioactive) processes, half the amount of a substance that has entered it.
half-life, radioactive	The time required for half of the atoms of a radioactive material to decay to another nuclear form.
hazardous wastes	Excess chemical material that is dangerous to human health.
health detriment	The sum of all fatal cancers, a fraction of the non-fatal cancers proportional to the severity of the cancer types, and all genetic defects.
health effect	The occurrence of a fatal cancer, a non-fatal cancer, or a genetic defect.
high-efficiency particulate filter	A ventilation system device that can separate a particle size of 0.3 micron from the air into a filter medium at an efficiency of at least 99.97 percent.
hydrology	The study of the properties, distribution, and effects of water on the earth's surface, in the soil and underlying rocks, and in the atmosphere.
incident-free operations	Routine, day-to-day operations without accidents or other unexpected or unusual occurrences. Synonymous and interchangeable with normal operations.
ion	An atom or molecule which has acquired an electrical charge by gaining or losing electrons.
ionizing radiation	Any radiation which displaces electrons from atoms or molecules, thereby producing ions. Examples include alpha, beta, and gamma radiation. Exposure to ionizing radiation may produce skin or tissue damage.
irradiate	To expose to radiation.
isotope	One of two or more nuclides which have the same number of protons but have different numbers of neutrons in their nuclei. Therefore, the isotopes of an element have the same atomic number but different atomic weights. Isotopes usually have very nearly the same chemical properties but somewhat different physical properties.
long-lived radioactivity	Radioactive nuclides which decay slowly, therefore having relatively long half-lives.
man-rem	A unit used to measure the radiation exposure to an entire group and to compare the effects of different amounts of radiation on groups of people. It is obtained by multiplying the average dose equivalent

	(measured in rems) to a given organ or tissue by the number of persons in the population of interest.
maximally exposed individual (MEI)	A theoretical individual who receives the highest radiation exposure from the facility or activity in question.
maximally exposed off-site individual (MOI)	A theoretical individual located at the point on the DOE site or shipyard boundary nearest to the facility or activity in question.
maximum individual	An individual who could consume items or occupy areas at rates which would be at a maximum for the population of interest.
maximum organ	The organ which receives or could receive the largest amount of exposure to radiation.
metric ton	[Abbreviation MT] A unit of mass which is equal to 1000 kilograms or approximately 2205 pounds.
microcurie	[Abbreviation -Ci] A unit of activity which is equal to one-millionth (1 x 10-6) of a curie.
mil	A unit of length which is equal to one-thousandth (1 x 10-3) of an inch.
millicurie	[Abbreviation mCi] A unit of activity which is equal to one-thousandth (1 x 10-3) of a curie.
millirem	[Abbreviation mrem] A special unit for measuring dose equivalents which is equal to one-thousandth (1 x 10-3) of a rem.
monitoring, environmental	The periodic or continuous determination of the amount of radioactivity or radioactive contamination present in a region.
natural background radiation exposure	The total amount of radiation from cosmic radiation emitted by the sun and the radiation emitted by natural minerals in the earth's crust. Typically, an average annual exposure of 100 mrem to the total body occurs from background radiation.
Naval Nuclear Propulsion Program	A joint program of the Department of Energy and the Department of the Navy which has as its objective the design and development of improved naval nuclear propulsion plants having high reliability, maximum simplicity, and optimum fuel life for installation in ships ranging in size from small submarines to large combatant surface ships. The program is frequently referred to as the Naval Reactors Program.
neutron	An uncharged particle with a mass slightly greater than that of a proton, found in the nucleus of every atom heavier than hydrogen. Neutrons sustain the fission chain reaction in a nuclear reactor.
nuclear disintegration	A spontaneous nuclear transformation which is characterized by the emission of particles and/or energy from the nucleus of an atom.
nuclear fuel	See fuel.
nuclear reactor	A device in which nuclear fission is initiated and controlled to produce heat which is then used to generate power.
nuclear reactor accident	An accident which results in release of fission products from the nuclear fuel.
nuclide	An atomic form of an element which is distinguished by its atomic number, atomic weight, and the energy state of its nucleus. These factors determine the other properties of the element, including its radioactivity.
organ	A group of tissues which together perform one or more definitive functions in a living body.
organism	Any living plant or animal.
overburden	Material overlying a deposit of useful geological materials.
particulate	Pertaining to a very small piece or part of a material.
pathway	The route or course along which radionuclides from defueled nuclear-powered ships could reach man.
percolate	To drain or seep through a material.
permeability	The quality or state of being able to diffuse or pass through a material.
pH	A measure of the relative acidity or alkalinity of a solution. A neutral solution has a pH of 7, acids have pH's less than 7, and bases have pH's greater than 7.
picocurie	[Abbreviation pCi] A unit of activity which is equal to one-trillionth (1 x 10-12) of a curie.
prototype plants	Land-based naval nuclear reactor plants that are typical of a first design for a naval warship and are used to test equipment and the nuclear fuel prior to use on a shipboard nuclear plant. The prototype plants are also used to train naval officers and enlisted personnel as propulsion plant operators with extensive watchstanding experience and a thorough knowledge of all propulsion plant systems and their operating requirements.
radiation	The emission and propagation of energy through matter or space by means of electromagnetic disturbances which display both wave-like and particle-like behavior. In this context, the "particles" are known as photons. The term has been extended to include streams of fast-moving particles such as alpha and beta particles, free neutrons, and cosmic radiations. Nuclear radiation is that which is emitted from atomic nuclei in various nuclear reactions and includes alpha, beta, and gamma radiation and neutrons.

radiation field	A region where radiation is present.
radiation level	The measured amount of radiation in a region.
radiation survey	The evaluation of an area or object with instruments to detect, identify, and quantify radioactive materials and radiation fields which may be present.
radiation worker	A person specially trained and tested in basic information regarding radiation, its effects, and radiological control techniques and practices.
radioactive contamination	The deposition of radioactive material in any place where it may harm persons, invalidate experiments, or make products or equipment unsuitable or unsafe for some specific use. The presence of unwanted radioactive matter.
radioactive decay	The process of spontaneous transformation of a radioactive nuclide to a different nuclide or different energy state of the same nuclide. Radioactive decay involves the emission of alpha particles, beta particles, or gamma rays from the nuclei of the atoms. If a radioactive nuclide is transformed to a stable nuclide, the process results in a decrease of the number of original radioactive atoms. Radioactive decay is also referred to as radioactive disintegration.
radioactive waste	Equipment and materials which are radioactive and for which there is no further use. Radioactive wastes are generally classified as high-level waste (those resulting from reprocessing reactor fuel or the used reactor fuel itself), as low-level waste, or as low-level waste containing transuranic elements or uranium-233.
radioactivity	The process of spontaneous decay or disintegration of an unstable nucleus of an atom; usually accompanied by the emission of ionizing radiation.
radioisotope	An unstable isotope of an element that decays or disintegrates spontaneously and emits radiation.
radiological consequences	The changes to the environment or the health of a person(s) as a result of the effects of radiation exposure or radioactive materials.
radionuclides	Atoms that exhibit radioactive properties. Standard practice for naming radionuclides is to use the name or atomic symbol of an element followed by its atomic weight (e.g., cobalt-60 or Co-60, a radionuclide of cobalt).
reactor vessel (or reactor pressure vessel)	A very strong, thick-walled steel structure which contains the nuclear fuel and cooling water under high pressure during reactor operations.
rem	A unit of measure used to indicate the amount of radiation exposure a person receives (an acronym for roentgen equivalent man).
risk	The product of the consequences of an event multiplied by the probability of that event.
river stage	The level of the surface of a river in relation to some reference elevation.
sediment	Particles of organic or inorganic origin that accumulate in loose form.
seismicity	The quality or state of shaking or vibrating caused by an earthquake.
shipping container	A specially designed large, stainless steel or lead-lined, steel-shelled cask that is transported in the vertical position on a well-type or depressed center railcar. The container is certified by the Department of Energy and the Department of Transportation for the shipment of naval spent nuclear fuel.
short-lived radioactivity	Radioactive nuclides which decay rapidly, therefore having relatively short half-lives.
socioeconomics	The welfare of human beings as related to the production, distribution, and consumption of goods and services.
special nuclear material	Materials containing nuclides such as plutonium-239, uranium-233, or uranium enriched to a higher percentage than normal in the uranium-235 isotope.
specific activity	The ratio between the amount of radioactive isotope present and the total amount of all other isotopes of that same element, both radioactive and stable. It is usually expressed in microcuries of radioisotope per gram of total element.
specimen	A small sample of material (fuel or non-fuel) inserted into a reactor for testing to characterize the material's performance. Test specimens may be constructed of plant materials, reactor structural materials, or fuel materials.
steam generator	The portion of the nuclear power plant where the heat from the primary system is transferred to the secondary system without physical contact between the water in the two systems.
survey meter	Any portable instrument which is used to detect radiation and is especially adapted for surveying or inspecting an area to establish the existence and amount of radioactive material present.
tectonic	Pertaining to or designating the rock structures which result from the deformation of the earth's crust.
threatened species	Any species or subspecies which is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range.

topography	The detailed physical description of the surface of a region, including the relative elevations of features. The graphical representation of the physical configuration of a region on a map.
toxic	Relating to or caused by a toxin which is a poisonous substance that is a specific product of the metabolic activities of a living organism and is usually very unstable when introduced into human tissues.
tritium	A radioactive isotope of hydrogen with atoms that are three times the mass of ordinary light hydrogen atoms. Tritium is present in the reactor coolant as the result of neutron interaction with naturally occurring deuterium present in the water.
uranium	[Symbol U] A natural radioactive element with the atomic number 92 and, as found in natural ores, an average weight of approximately 238. The two principal natural isotopes are uranium-235 (0.7 percent of natural uranium) and uranium-238 (99.3 percent of natural uranium). Natural uranium also includes a minute amount of uranium-234.
vadose zone	The unsaturated region of soil located between the ground surface and water table.
water pools	Deep pools of water that are used to inspect and hold spent nuclear fuel modules. Storage racks are located below the water surface to support and position the fuel modules in place for handling and to prevent the formation of a critical mass.
water table	The upper surface boundary of an uncontrolled aquifer, below which groundwater occurs. It is usually defined by the levels at which water stands in wells that barely penetrate the aquifer.
watershed	The region which drains into a river, river system, or body of water.
wetlands	Those areas which are covered by water with a frequency sufficient to support a prevalence of vegetative or aquatic life that requires saturated or seasonally saturated soil conditions for growth and reproduction. Wetlands generally include swamps, marshes, bogs, and similar areas such as sloughs, potholes, wet meadows, river overflow, mudflats, and natural ponds.
x-rays	Penetrating electromagnetic radiations with wavelengths shorter than those of visible light. They are usually produced (as in medical diagnostic x-ray machines) by irradiating a metallic target with large numbers of high-energy electrons. In nuclear reactions, it is customary to refer to photons originating outside the nucleus as x-rays and those originating in the nucleus as gamma rays, even though they are the same.

ABBREVIATIONS AND ACRONYMS

AEA	Atomic Energy Act
AEC	Atomic Energy Commission

TABLE OF CONTENTS

TABLES

1. INTRODUCTION

The U.S. Department of Energy (DOE) is performing a DOE-wide programmatic evaluation of spent nuclear fuel (SNF) management alternatives in order to determine the appropriate means of managing existing and projected quantities of SNF from now until the year 2035. At the same time, the DOE is performing a site-specific assessment of the Idaho National Engineering Laboratory (INEL) in order to determine how to manage environmental restoration, waste management, and SNF at the INEL. Sites currently involved with the management of major fractions of DOE SNF (i.e., the Hanford Site, Savannah River Site, and INEL), alternative sites being analyzed for management of SNF (Oak Ridge Reservation and Nevada Test Site), and sites involved with management of SNF from Naval Reactors are addressed in separate appendixes to this volume of the environmental impact statement (EIS).

This appendix addresses other DOE sites and locations which currently generate and manage small quantities of SNF. These facilities are presently storing and/or generating, in most cases, relatively small quantities of SNF which the DOE has taken title to, has possession of, or will take possession of at sometime in the future. These facilities, referred to in this document as "originating sites," include the following:

- DOE, University, and Other Research and Test Reactors

  The following DOE facilities are addressed in this appendix:

  Brookhaven National Laboratories
  - High Flux Beam Reactor
  - Brookhaven Medical Research Reactor

  Los Alamos National Laboratory
  - Omega West Reactor
  - Chemistry-Metallurgy Research Facility

  Sandia National Laboratories
  - Manzano Storage Structures
  - Annular Core Research Reactor
  - Sandia Pulse Reactor II and III and Critical Assembly
  - Hot Cell Facility
  - Special Nuclear Materials Storage Facility

  Argonne National Laboratory - East
  - Alpha-Gamma Hot Cell
  - Chicago Pile 5

  In addition, the DOE has title to SNF from university and other domestic research reactors. These facilities are identified and data provided on both the quantity of spent fuel in storage and estimates of the future generation rate of SNF at these facilities. However, rather than address each of these university and other research reactor facilities individually, representative facilities will be used when addressing specific topics related to facilities, the SNF, or projected environmental impacts associated with the various fuel management alternatives.

- Commercial Power Reactor Fuels

  The DOE has possession of 125 spent nuclear fuel assemblies and 20 complete or sectioned spent nuclear fuel rods from various nuclear power plants that were to be used to support DOE-sponsored research and development programs. This SNF is currently in storage at either the West Valley Demonstration Project in West Valley, New York, or the B&W Lynchburg Technology Center in Campbell County, Virginia.

  In addition, according to the terms of a three-party agreement between the Public Services Company of Colorado, General Atomics, and the Atomic Energy Commission, the DOE has a commitment to provide dry storage at the INEL for eight segments of Fort St. Vrain spent fuel (approximately 1,920 spent fuel elements). Three segments of this SNF have been shipped to the INEL; the other five are currently being stored at the Fort St. Vrain site.

  The DOE also has possession of other commercial SNF, including that from the Arkansas, Calvert Cliffs, Connecticut Yankee, Consolidated Edison, Cooper, Dresden, H. B. Robinson, Monticello, Oconee, Peach Bottom, Point Beach, Quad Cities, Saxton, Shippingport, Surry, and Three Mile Island reactors. These represent very small quantities of SNF and are currently stored at the Hanford Site, INEL, SRS, Naval

Reactor Facility at the INEL, or the ORR. This commercial SNF is addressed in the corresponding appendix for each of these sites and is not discussed in detail in this appendix.

Spent nuclear fuel from commercial power reactors which is currently at commercial reactor sites will fall under the purview of the DOE's Office of Civilian Radioactive Waste Management and is outside the scope of this EIS.

Although these facilities represent small sources of SNF, an evaluation has been conducted in order to consider the impacts at these originating sites along with the cumulative impacts of management of all DOE SNF.

Of the five SNF management alternatives being evaluated (Volume 1, Chapter 3), only the two alternatives that preclude the shipment of SNF (Alternative 1 - No Action and Alternative 2 - Decentralization) have a definable impact on the sites and facilities discussed in this appendix.

Several facilities generating SNF have limited storage capacities, and/or the facility license from the U.S. Nuclear Regulatory Commission (NRC) may limit the quantity of fuel permitted to be stored onsite. Implementation of the No Action Alternative could mean that some of the facilities with limited SNF storage capacity would have to shut down. The impact on some facilities would be the need to construct additional onsite SNF storage capacity in order to continue safe operation. Expansion of SNF storage capacity is only viable provided adequate space and adequate funding are available and expansion is approved through the NRC licensing process.

In the case of the West Valley Demonstration Project, the SNF is currently being stored in accordance with the applicable DOE Orders. Extended storage of SNF at this site would require construction of a concrete pad for a dry storage facility. However, the DOE has entered into an agreement with an agency of the State of New York to remove all SNF from the West Valley Demonstration Project. An extension to the schedule for removal of SNF has been requested by DOE and the agreement with the state is being renegotiated.

The other alternatives, which involve the shipment of the SNF from the site at which it is generated to one or more DOE SNF interim storage facilities, reflect the current mode of SNF management at the generating facilities. Even though the selection of a site where SNF may be transported and stored may be different than the current planning basis, shipment to a different location does not impact the facility or site at which the SNF is generated.

Section 2 of this appendix presents a description of SNF management at the originating sites, including an overview of the types and inventories for SNF in three major categories: DOE test and experimental reactors; domestic research reactors; and nuclear power reactor spent fuel. Section 3 presents summary descriptions of the potentially affected environments for the three categories, and Section 4 describes the environmental consequences of SNF management alternatives at these sites. Cumulative impacts are presented in Section 5, adverse impacts that cannot be avoided in Section 6, and irreversible and irretrievable commitments in Section 7.

2. SNF MANAGEMENT AT ORIGINATING SITES

2.1 Overview of SNF Types, Inventories, and Generation Rates

This appendix addresses the management of SNF at originating sites, defined as DOE test and experimental reactors, domestic research reactors, and certain nuclear power plant spent fuels now in storage. Specific discussions of the various sites are provided in following sections.

DOE experimental reactors and small-quantity storage: These reactors and SNF storage facilities are located on DOE-owned sites, such as Brookhaven National Laboratory, Los Alamos National Laboratory, and Sandia National Laboratories. These sites host a variety of research and development or production activities, which may include test or experimental reactors and storage of small quantities of SNF, in different areas of the site.

- Domestic research reactors: The greatest variations in site characteristics are those associated with research reactors. Most sites are at colleges or universities. However, a few of them are sited at government and industrial facilities.
- Nuclear power plant spent fuel: The SNF in this category is not located at currently operating nuclear reactor facilities. The facilities housing the subject SNF are located at the following sites: 1) the former West Valley fuel reprocessing site, 2) the shutdown Fort St. Vrain nuclear power plant site (currently undergoing decommissioning), and 3) a commercial research laboratory (B&W Lynchburg Technology Center) located on a large rural site. The DOE also has possession of other commercial SNF, including that from the Arkansas, Calvert Cliffs, Connecticut Yankee, Consolidated Edison, Cooper, Dresden H. B. Robinson, Monticello, Oconee, Peach Bottom, Point Beach, Quad Cities, Saxton, Shippingport, Surry, and Three Mile Island reactors. These represent very small quantities of SNF and are currently stored at the Hanford Site, INE~ SRS, Naval Reactors Facility at the INEl, or the ORR. This commercial SNF is addressed in the corresponding appendix for each of these sites and is not discussed further in this appendix.

The SNFs addressed in this appendix are of varying sizes and design configurations. In general, nuclear fuel consists of an assembly of structural components, such as plates or hollow rods, containing fissionable material. The fuel may be in the form of metal or a compound (e.g., oxide, carbide, nitride) and may vary in the degree of enrichment of the uranium -235 isotope. The structural materials may be aluminum, stainless steel, zirconium alloy, or other material such as ceramics. They form a barrier isolating the fuel (and fission products) from the reactor coolant or storage facility environment as well as providing structural support for maintaining the geometry of the fuel. The components are arranged into a specific geometric configuration determined by the type of reactor and desired performance. This assembly of fuel-bearing components is referred to as a "fuel element" (also referred to in the nuclear industry as a fuel assembly).

For each of the major facility categories, the following subsections provide details on the quantities of SNF currently in storage and the quantities of additional SNF expected to be produced by the end of the year 2035.

2.1.1 DOE Experimental Reactors and Small-Quantity Storage

The Brookhaven National Laboratory, Los Alamos National Laboratory, and Sandia National Laboratories use test and experimental reactors for research and for small-scale production of medical and other specific isotopes. In addition, small quantities of SNF are currently in storage at these sites as well as at Argonne National Laboratory - East. The amount of SNF generated by these facilities, the amount expected to be generated through the year 2035, and accommodations being undertaken at the present time to store the SNF located at these facilities are discussed in the following sections.

2.1.1.1 Brookhaven National Laboratory.

2.1.1.2.1 High Flux Seam Reactor-By mid-1995 there are projected to be 937

High Flux Beam Reactor elements (0.
241 MmlIM) in the reactor or in onsite wet storage. A total of 5,600 additional SNF elements (1.498 MThM) are predicted to be produced if the reactor continues operation through the year 2035 (Wichmann 1995a).

2.1.1.2.2 Brookhaven Medical Research Reactor-The Brookhaven Medical

Research Reactor is operating at the present time and has 36 elements (0.
0034 MTHM) in the rcactor or in onsite wet storage. Thirty-two additional SNF elements (0.0028 MTHM) are expected to be produced by the year 2035 (Wichmann 1995a).

2.1.1.2 Los Alamos National Laboratory.

2.1.1.2.1 Omega West Reactor-The Omega West Reactor has been permanently

shut down.
This reactor is being decommissioned. There are no elements in the reactor, and all of the 86 elements (0.014 MTHM) are in temporary dry storage at the Chemistry and Metallurgy Research Complex (Wichmann 1 995a).

Additional reactor sites and critical facilities that are part of the los Alamos National Laboratory are listed below. Each contains some radioactive and fissionable materials but does not routinely produce SNF (ANS 1988):

Big Ten Critical Assembly
- Fast Burst Reactor - GODWA
- Fast Burst Reactor - SKUA
- Flattop Critical Assembly
- General Purpose Critical Assembly - COMET
- General Purpose Critical Assembly - HONEYCOMB
- General Purpose Critical Assembly - PLANET
- General Purpose Critical Assembly - VENUS
- General Purpose Critical Assembly Machine
- Solution High Energy Burst Assembly

2.1.1.3 Sandla National Laboratories. The Sandia National Laboratory reactors operate

as needed on a low duty cycle, so the fission product inventories remain low and the fuel loading lasts for the life of the reactor, eliminating routine generation of spent fuel. Hence, except for a few broken plates that are in storage, the SNF at Sandia National Laboratories is still in use in the reactors (DOE 1993d).

The Sandia National Laboratories contain five SNF storage facilities: the Manzano Storage Structures, the Annular Core Research Reactor Facility, the Sandia Pulse Reactor Facility, the Hot Cell Facility, and the Special Nuclear Materials storage facility (DOE 1993b).

2.1.1.3.1 Manrano Storage Structures-The Manzano Storage Structures are

reinforced concrete bunkers located in the southeast portion of Kirtland Air Force Base. Until recently, when Sandia National Laboratories took responsibility for the site, the Manzano facilities were operated and maintained by the Department of Defense. The Sandia National Laboratories currently use four structures for dry storage of reactor-irradiated nuclear material (DOE 1993b). There is a total of 0.025 metric tons of heavy metal (MTHM) of SNF in storage at this facility (Wichmann 1995a).

2.1.1.3.2 Annular Core Research Reactor-The Annular Core Research Reactor is

a pool-type research reactor capable of steady-state, pulse, and tailored transient operation. The Annular Core Research Reactor facility includes the reactor pool, one safe, and eight dry floor storage vaults, all located in the high-bay of Building 6588. The eight storage vaults on the high-bay floor are used to securely store irradiated experiments containing a variety of nuclear materials, but principally U-235. Materials from only three experiments containing reactor irradiated nuclear materials are stored at the Annular Core Research Reactor (DOE 1993b). There are a total of 438 elements plus uranium from three experiments (for a total of 0.04MTHM) in use or storage at these facilities (Wichmann 1995a).

In addition, DOE is considering using the Annular Core Research Reactor for production of molybdenum-99. If the molybdenum -99 production mission is assigned to the Annular Core Research Reactor, the current reactor fuel would likely be removed and would need to be stored at the start of, or within a few years of starting, operation (SNL 1994).

2.1.1.3.3 Sandia Pulse Reactor Hand HI, and Critical Assembly- Three reactors

are in operation at the Sandia Pulse Reactor facility: Sandia Pulse Reactor II and Sandia Pulse Reactor III are unmoderated, fast-burst reactors capable of pulsed and steady-state operation. The Critical Assembly is a small, water-moderated reactor used to perform measurements of key reactor parameters to benchmark the computer calculations and thereby refine the designs for a planned space propulsion reactor. The yard storage holes are 19 stainless-steel types located in a corner of the Sandia Pulse Reactor compound. These tubes are surrounded by a high-density concrete monolith. The yard holes are used to securely store irradiated experiments containing a variety of nuclear materials, but principally U-235. All of the materials remain in their own containers, some of which consist of double containment. At the Special Nuclear Material dry storage facility, Sandia National Laboratories stores previously failed fuel elements from Sandia Pulse Reactor II and elements from experiments that have been exposed to short irradiation periods (DOE 1993b). There are a total of 43 elements (with a total of 0.37 MTHM) of SNF in use or storage at these facilities (Wichmann 1995a).

Future plans include bringing on-line an additional pulse reactor named Sandia Pulse Reactor IlIM. With this new reactor, a total of three pulse reactors would be located at Sandia National Laboratories' Technical Area V.

2.1.1.3.4 Hot Cell Facilty-The Hot Cell Facility at Sandia National Laboratories is

a nonreactor nuclear facility housed in Building 6580 in Technical Area V. Research programs at Sandia National Laboratories--material studies, fuel studies, and safety studies.-require that experiments containing radioactive materials be assembled and/or disassembled, samples prepared, and microscopic and chemical analyses performed. The principal storage facility for the Hot Cell Facility is Room 108, which is a heavily shielded room used previously as a preparation room next to the irradiation room of the Sandia Engineering Reactor, which has been defueled. There are a series of 13 storage holes under the Hot Cell Facility Monorail that are available to store irradiated material coming into or out of the Hot Cell Facility. Only one of the holes is currently in use. The other areas of the Hot Cell Facility are used for storing minor amounts of material (DOE 1993b) There is a total of 0.009 MTHM of SNF in storage at this facility (Wichmann 1995a).

2.1.1.4 Argonne National Laboratory - East. The Alpha-Gamma Hot Cell Facility,

operated by the Materials Science Division, consists of a concrete-shielded, low-flow inert-atmosphere complex that was designed for the examination of irradiated plutonium fuel assemblies and related hardware (DOE 1993d). There are a total of four units of Experimental Breeder Reactor fuel, one canister containing remnants of commercial SNF, and 16 SNF elements from Oak Ridge (For a total of 0.081 MTHM) in storage (Wichmann 1995a).

The Chicago Pile 5 Building houses a heavy-water, moderated reactor whose fuel has been removed and shipped offsite. Currently, the Chicago Pile S is in the process of being decontaminated and decommissioned and contains only two highly enriched uranium target (i.e., converter) elements (DOE 1993d).

2.1.2 Domestic Licensed Research Reactors

Table 2.1-1 identifies 57 non-DOE facilities representing domestic, licensed, small generators of SNF (NRC 1993a; ANS 1988). They include training, research, and test reactors at universities, commercial establishments, and several government installations; all but one (McClellan Air Force Base) have been licensed by the NRC. Although they are not DOE Facilities, DOE has title to the SNF and has the responsibility for interim storage and ultimate disposition.

In order to assess their SNF management capabilities, these 57 facilities have been identified as belonging to one of three categories. These categories identify the key characteristics of a facility relevant to the assessment of DOE-postulated SNF alternatives. The three categories are:

Category 1 - Facilities that have limited onsite storage capacity compared to the amount of SNF projected to be generated at their facility by the year 2035
Category 2 - Facilities that do not routinely generate additional SNF
Category 3 - Facilities that no longer possess SNF onsite.

The category for each facility is identified in Table 2.1-1.

2.1.2.1 Reactors with Limited Storage Capacity. The sites in Category I have limited

storage capacity when compared to the amount of SNF that is projected to be generated by 2035. Table 2.1-2 lists the projected inventory as of June 1, 1995 with the corresponding MTHM at **each of the Category 1 sites.** Assuming continuing operation of each reactor, the projected amount of additional SNF that would be generated through 2035 is also provided in Table 2.1-2.

To reduce the risk of theft or diversion of highly enriched uranium fuel and the consequences to public health, safety, and the environment from such theft or diversion, the NRC has imposed limitations on the use of highly enriched uranium fuel in domestic nonpower reactors. Unless the NRC has determined that the nonpower reactor has a unique purpose requiring the use of high enriched uranium fuel, each licensee will replace all highly enriched uranium fuel in its possession with available low enriched uranium fuel acceptable to the Commission. If federal government funding for conversion is not available, the conversion from high enriched uranium fuel to low enriched uranium fuel may be deferred on an annual basis. A number of domestic research reactors are in the process of converting from highly enriched uranium fuel to low enriched uranium fuel.

2.1.2.2 Reactors with Sufficient Storage Capacity. Licensed domestic research reactor

sites with sufficient SNF storage capacity are listed in Table 2.1-3. These Category 2 sites include operating facilities with low fuel burnup rates, where the amount of SNF generated is not expected to exceed the current onsite storage capacity. Some Category 2 sites are also converting from highly enriched uranium fuel to low enriched uranium fuel but have sufficient capacity to store this additional SNF onsite.

The projected inventory at each reactor site as of June 1, 1995 and the corresponding MTHM are presented in Table 2.1-3. The amount of SNF that is projected to be generated through the year 2035 is also listed in Table 2.1-3.

2.1.2.3 Reactors without SNF Onsite. The licensed domestic research reactors that are

no longer operating and have shipped all SNF offsite are identified as Category 3 in Table 2.1-1. These sites either have been decommissioned or are in the process of decommissioning. Some of the facilities have been decontaminated, although they may not have been completely dismantled.

a. Source: Wichmann 1995a and Wichmann 1995b.

b. Fuel pins, not reactor assemblies.

c. Reactor scheduled to shut down in 1998.

d. Contact-handled fuel/targets (i.e., with radiation levels low enough to permit handling without shielding or remote operations), even though slightly irradiated, are not included as SNF.

Note: The projected inventory as of June 1, 1995 is expected to be 1.323 MTHM and the approximate total for the additional SNF projected to be generated through 2035 is 1.054 MTHM. Numbers may not sum due to rounding.

The SNF that originated at these sites has either been reprocessed or is stored and accounted for at DOE storage facilities.

2.1.3 Nuclear Power Plant Spent Nuclear Fuel

This subsection addresses spent nuclear power plant fuel that DOE has possession of or will take possession of sometime in the future. Currently this fuel is in storage at one of three sites: the West Valley Demonstration Project, the Fort St. Vrain nuclear power plant site, and the

B&W Lynchburg Technology Center in Lynchburg, Virginia. In all cases, no new additional SNF is being or will be added to existing SNF inventories.

2.1.3.1 West Valley Demonstration Project. The West Valley Demonstration~ Project is

located on the site of the first U.S. commercial nuclear fuel reprocessing plant, which was operated by Nuclear Fuel Services, Inc., until 1972 (WVNS 1994).

Nuclear Fuel Services, Inc., shut down the reprocessing facility in 1972 in order to implement modifications for the purpose of increasing the facility's capacity. From 1973 to 1975 Nuclear Fuel Services, Inc., continued to accept a total of 750 SNF elements. However, in 1976, it withdrew from the reprocessing business (WVNS 1994).

In 1980 Congress enacted Public Law 96-368, the West Valley Demonstration Project Act. The act directed the DOE to develop and demonstrate the technology for solidifying high-level waste in storage at the West Valley Demonstration Project so that this waste would be suitable for transportation to and long-term disposal in a federal repository (wvNS 1994).

The owners of the 750 SNF elements still in storage at the West Valley facility fuel storage pool were informed in 1981 that they would have to take back their SNF. By 1986, 625 of the elements had been returned to their respective owners; then, however, DOE took possession of the remaining 125 SNF elements (26.65 MTHM) under an agreement with Nuclear Fuel Services, Inc. The DOE was to use these 125 elements to demonstrate the safe transportation and long-term storage of SNF in a dual-purpose cask. These 125 SNF elements are included in this EIS (Wichmann 1995a).

2.1.3.2 Fon St. Vrain. Fort St. Vrain, a 330 MWe (Megawatt electric) high-temperature

gas-cooled reactor power plant, went into operation in January 1979 and teriminated commercial operation in August 1989. It is currently undergoing decommissioning (FSV 1990a; NRC 1991a)

Prior to August 1989 a three-party agreement was reached between the Public Services Company of Colorado (the owner of Fort St. Vrain), General Atomics (the reactor developer), and the DOE that called for the DOE to take possession of eight segments of approximately 240 SNF elements each of SNF from the Fort St. Vrain for dry storage at the INEL. SNF from the Fort St. Vrain had been shipped to the INEL when a court action was initiated by the state of Idaho to stop any additional shipment of SNF to INEL.

In an effort to facilitate the continued decommissioning of the Fort St. Vrain station, the Public Services Company of Colorado has decided to store the Fort St. Vrain's SNF in a modular vault dry storage system, which is a reinforced concrete and sheathed steel frame building located on the Fort St. Vrain site immediately adjacent to but outside the fence around the Fort St. Vrain site. The modular vault dry storage system, designed to house 1,482 high-temperature, gas-cooled reactor SNF elements, 6 neutron source elements, and 37 keyed top reflector elements, became operational in late 1991 (FSV 1990a). There are 1,464 elements (16 MTHM) currently in storage in the modular vault dry storage system (Wichmann 1995a).

2.1.3.3 B&W Lynchburg. The B&W facility in Lynchburg, Virginia, is engaged in

research and development on uranium fuels and the overall fuel cycle, and in the examination and testing of irradiated fuels (NRC 1987).

B&W Lynchburg currently has in storage at its facility 0.044 MTHM of SNF stored in 15 cannisters (Wichmann 1995a) consisting of 3 full.length fuel rods, 17 sectioned fuel rods, and a small quantity of fuel debris from Three Mile Island 2. All of this SNF material is in the possession of the DOE and was provided to B&W under a DOE contract for Fuel Performance Improvements Programs. None of the activities ongoing at B&W Lynchburg could result in the generation of additional SNF for which the DOE has responsibility, since the facility's three reactors have been decommissioned (Wright 1993; ANS 1988).

2.2 Spent Nuclear Fuel Management Program Plans and Alternatives

The plans for management of SNF at originating sites, including generating and storage sites, or facilities generating small annual quantities of SNF, were determined by conducting a survey of the NRC licensees and others operating these sites. These plans, as they are projected to be affected by the alternatives being assessed in this EIS, are presented in this section.

Availability of onsite SNF storage capacity is the primary consequence of DOE SNF management decisions for all originating sites. Of the five DOE SNF management alternatives, only Alternative 1 (No Action - no SNF transportation) may not have been addressed under the NRC licensing process for an individual SNF originating site. DOE management plans for the alternatives which involve SNF transportation- would not affect the originating sites. The. management plans at the DOE facilities to which the SNF may be shipped are addressed in the sections of this EIS dealing with those DOE facilities. The alternate plans with regard to transportation are analyzed in Appendix I to Volume 1. Accordingly, the next few subsections will focus primarily on the No Action Alternative and describe general information on SNF produced at the originating sites, including non-DOE facilities storing SNF.

2.2.1 No Action

The No Action Alternative is intended to evaluate the impact of storage of SNF at the current storage and originating sites. This means that all facilities which are generating or storing SNF and intend to ship SNF to a DOE facility would maintain their SNF onsite. If the SNF-originating site has adequate storage capacity, operations at the site would continue without change of plans. If SNF storage capacity is inadequate, new plans, including expansion of storage capacity or decreasing the rate of fuel burn-up, would have to be considered. Possible SNF management plans are discussed more specifically in the following subsections.

Of the total of approximately 2,700 MThM of SNF estimated as the total DOE inventory by 2035, approximately 51 MTHM of SNF is associated with the facilities addressed in this appendix (Wichmann 1995a).

2.2.1.1 DOE Experimental Reactors and Small Quantity Storage. There is insufficient

onsite storage capacity at the High Flux Beam Reactor at Brookhaven National Laboratory to store all of the SNF projected to be generated through the year 2035. If SNF shipments are no made to another DOE storage facility, at the current rate of generation the remaining onsite storage space would be depleted in January 1996. There is a plan to install a storage rack in the existing wet storage facility that would add space for 162 elements. Even with this rack, storage space would be depleted in 1998. If SNF could not be shipped by that time, the arrangement of existing racks could be modified to provide additional space. There are no plans to shut down the reactor in the near future (Carelli 1993).

2.2.1.2 Domestic Research Reactors. Based on current projections, the onsite storage

capacity of 11 of the 45 domestic research reactors would be exhausted before the year 2035 if the No Action Alternative were to be implemented. All 11 of these facilities have been identified as Category 1.

Several of the facilities in Category 1 have indicated that they would consider various options of increasing storage capacity if the No Action Alternative were to be implemented. Five would consider reracking, one would consider expanding dry storage within the reactor building, three would consider expanding wet storage within the reactor building, and one would consider adding 200 square feet (18.6 square meters) of wet storage area outside the reactor building.

Any previously planned expansion of onsite SNF storage capacity at individual odginating facilities is addressed in site-specific NRC environmental assessments and thus is not considered to be a consequence of the proposed actions under this ElS. The facilities that are already planning to expand their SNF storage capacity include the Massachusetts Institute of Technology and the National Institute of Standards and Technology.

At one of these facilities the expanded storage capacity is projected to be adequate through the year 2005. However, without SNF transportation through the year 2035, none of the facilities would have adequate storage capacity. One of the facilities in Category 1 has offloaded its highly enriched uranium fuel and would consider reracking but might elect to shut down in 2001 because of a lack of wet storage capacity (Jentz 1993).

All 34 facilities identified as Category 2 have sufficient SNF storage capacity onsite to accommodate any of the DOE SNF alternatives. Two facilities may elect to shut down before the year 2005: one because it may not renew its license; the other because, without transferring SNF offsite, it might not meet licensing limits on possession of uranium-235 after conversion from highly enriched uranium fuel to low enriched uranium fuel. One facility, which expects to convert from highly enriched uranium fuel to low enriched uranium fuel, might elect to shut down in the year 2005 if no offsite transportation were available, unless it can expand its SNF wet storage capacity. A few facilities have indicated that they will appeal the NRC-required conversion of highly enriched uranium fuel to low enriched uranium fuel if no oflsite transportation is allowed.

Although several Category 2 facilities can operate practically indefinitely without refueling, it is questionable how many of them would operate as planned if there were no SNF transportation through the year 2035. Many research reactors operate with variable core loadings, storing, and reusing partially depleted fuel elements as well as adding new fuel to the reactor (Jentz 1993).

2.2.1.3 Nuclear Power Plant Spent Nuclear Fuel. The No Action Alternative

necessitating extended interim onsite storage of SNF would require a revision of the SNF management program at the West Valley Demonstration Project. The need to revise this program is a result of the following (DOE 1993b):

The West Valley fuel pool is almost 30 years old and does not meet current DOE design criteria.

The pool is single-walled, unlined, and lacks the capability for leak detection, thus presenting the potential for an undetected release to the environment.

Continued storage of fuel onsite would interfere with and for some areas prevent the ongoing decontamination and decommissioning activities at the West Valley Demonstration Project facility from proceeding as planned.

The management of SNF at the West Valley Demonstration Project is to continue the use of the existing spent fuel pool with no modifications.

Loss of access to the INEL for storage of its SNF has already resulted in the construction o new onsite SNF storage at Fort St. Vrain. However, under this alternative Public Service Company of Colorado would not achieve its goal of becoming free of radioactive materials by 1998 under this option.

Adequate storage capacity exists and the storage facilities are in adequate condition at the B&W Lynchburg Technology Center (DOE 1993b).

2.2.2 Decentralization

Alternative 2, Decentralization, is similar to the No Action Alternative except that limited offsite shipments are permitted as required to allow continued operation of the given facility. Decentralization is not expected to impose additional requirements for storing SNF at the facilities included in this appendix above those already identified under the No Action Alternative. Planning at the sites receiving SNF shipments that would be allowed under this alternative is addressed in Appendixes A, B, and C. Intersite transportation impacts are analyzed in Appendix I to Volume 1.

2.2.2.1 DOE Experimental Reactors and Smell Ouantity &orage. Compared to the

restrictions imposed under the No Action Alternative, Decentralization does not change the management plans at these DOE experimental reactors and small.quantity storage facilities.

2.2.2.2 Domestic Research Reactors. The Decentralization Alternative is similar to the

No Action Alternative, except that limited offsite shipments are permitted as required to allow continued operation of the given facility. Under this alternative, the domestic research reactors are allowed to return to DOE any SNF in excess of their current onsite storage capacity. Additional storage capacity would be not be required at these originating facilities. Therefore, decentralization does not affect existing SNF management plans at university research reactors or other facilities in the domestic research reactor group, except for possible rerouting of SNF shipments to INEL or Savannah River Site.

2.2.2.3 Nuclear Power Plant Spent Nuclear Fuel. The Decentralization Alternative is

similar to the No Action Alternative, except that limited offsite shipments are permitted as required to allow continued operation of the given facility. The three facilities being addressed in this subsection are only storing SNF and do not generate additional SNF. Because SNF would not be shipped offsite, SNF remaining at the site could interfere with the planned decontamination and decommissioning operations at West Valley Demonstration Project. Under this option, Public Service Company of Colorado would not achieve its goal of becoming free of radioactive material by 1998.

2.2.3 1992/1993 Planning Basis

Alternative 3, 1992/1993 Planning Basis, would not be expected to change any existing SNF management plans at the sites included in this appendix. Alternative 3 would permit the timely shipment of SNF from the originating sites to DOE interim storage facilities at INEL or Savannah River Site. Planning at these SNF-receiving sites is addressed in Appendixes A, B, and C. Interstate transportation impacts are analyzed in Appendix I to Volume 1.

2.2.3.1 DOE Experimental Reactors and Small Quantity Storage. Implementation of

this alternative could require a transition period of several years. Therefore, limited onsite construction of temporary SNF storage facilities or acquisition of SNF transportation containers, suitable for use as temporary dry storage containers, may be necessary until shipment to a D9E interim storage site(s) is accomplished.

2.2.3.2 Domestic Research Reactors, Alternative 3 does not affect the existing SNF

management plans at domestic research reactor facilities. Management of SNF at these reactors would continue to follow the same plans as in the past.

2.2.3.3 Nuclear Power Plant Spent Nuclear FueL Under Alternative 3, DOE plans to

ship the SNF currently in storage at the West Valley Demonstration Project to INEL Test Area North for storage. Implementation of this alternative would therefore preclude the need for any additional action at the West Valley Demonstration Project related to providing a new onsite SNF storage facility.

If Public Service Company of Colorado shipped the remaining fuel segments, the Fort St. Vrain Site would be free of radioactive materials by 1998.

This alternative would have no impact on the management of the SNF material in storage at the B&W Lynchburg Technology Center.

2.2.4 Regionalization

Alternative 4, Regionalization, would not be expected to change any existing SNF management plans at the sites included in this appendix, Alternative 4 would permit the shipment of SNF from the originating sites to regional DOE interim storage facilities. Planning at the SNF-recieving sites is addressed in Appendixes A, B, C, and F. Intersite transportation impacts are analyzed in Appendix I to Volume 1.

2.2.4.1 DOE Experimental Reactors and Small Quantity Storage. Implementation of

this alternative could require a transition period of several years. Therefore, limited onsite construction of temporary SNF storage facilities or acquisition of SNF transportation containers, suitable for use as temporary dry storage containers, may be necessary until shipment to a DOE interim storage site(s) is accomplished.

2.2.4.2 Domestic Research Reactors. Regionalization does not affect the existing SNF

management plans at domestic research reactor facilities, except for possible rerouting of SNF shipments.

2.2.4.3 Nuclear Power Plant Spent Nuclear Fuel. The Regionalization Alternative for

SNF addressed in this appendix is the same as the 1992/1993 Planning Basis Alternative except that the SNF would be sent to other locations. With the exception of INEL, facilities are not presently available for SNF storage at receiving sites considered under regionalization for SNF from West Valley Demonstration Project and Fort St. Vrain. The SNF would remain in storage at West Valley Demonstration Project and Fort St. Vrain until facilities are available for receipt at the selected regional SNF management sites.

2.2.5 Centralization

Alternative 5, Centralization, would not be expected to change any existing SNF management plans at the sites included in this appendix. Alternative 5 would permit the shipment of SNF from the originating sites to centralized DOE interim storage facilities.

planning at the SNF-receiving sites is addressed in Appendixes A, B, C, and F. Intersite transportation plans are analyzed in Appendix I to Volume 1.

2.2.5.1 DOE Expedmental Reactors and Small Ouantity Storage. Implementation of

this alternative could require a transition period of several years. Therefore, limited onsite construction of temporary SNF storage facilities or acquisition of SNF transportation containers, suitable for use as temporary dry storage containers, may be necessary until shipment to a DOE interim storage site(s) is accomplished.

2.2.5.2 Domestic Research Reactors. Centralization does not affect the existing SNF

management plans of domestic research reactor facilities except for rerouting of SNF shipments.

2.2.5.3 Nuclear Power Plant Spent Nuclear Fuel. The Centralization Alternative for

SNF being addressed in this appendix is described as being the same as the 1992/1993 Planning Basis Alternative except that the SNF would be sent to other locations. With the exception of INEL, facilities are not presently available for SNF storage at receiving sites considered under centralization for SNF from West Valley Demonstration Project and Fort St. Vrain. The SNF would remain in storage at West Valley Demonstration Project and Fort St. Vrain until facilities are available for receipt of the SNF at the selected central SNF management site.

3. AFFECTED ENVIRONMENTS

Descriptions of those facilities generating and/or storing small quantities of spent nuclear fuel for which DOE has accepted responsibility are presented in this section. The following subsections present environmental information for each of the three categories of originating sites: DOE Test and Experimental Reactors, Domestic Research Reactors, and Nuclear Power Plant Spent Nuclear Fuel Storage Sites.

The wide variety of facilities and installations included in this category precludes the definition of their affected environments in a consistent and uniform manner. The information available in existing facility documents used as the bases for this analysis varies widely with the nature of the installation and the requirements of the overseeing or regulatory agencies.

3.1 DOE Experimental Reactors and Small-Quantity Storage

The DOE experimental reactors and small-quantity SNF storage facilities included in this category are located at the Brookhaven National Laboratory, Los Alamos National Laboratory, Sandia National Laboratory, and Argonne National Laboratory - East. The facilities, sites, and their environments are described in this section. Only those DOE sites at which spent nuclear fuel is currently generated and/or stored are discussed. Information on environmental factors that are not uniformly available in existing National Environmental Policy Act documentation for all four sites (including aesthetic and scenic resources, noise, traffic and transportation, and utilities and energy) is not provided in this document.

3.1.1 Brookhaven National Laboratory

There are two reactors at the Brookhaven National Laboratory which generate SNF potentially affected by actions analyzed in this EIS: the 60 MW High Flux Beam Reactor and the 5 MW Brookhaven Medical Research Reactor (ANS 1988).

3.1.1.1 High Flux Beam Reactor. The 60 MW High Flux Beam Reactor is a heavy water

moderated and cooled research reactor which replaces an earlier 40 MW reactor. The High Flux Beam Reactor began operation in 1965. The High Flux Beam Reactor facility is composed of five buildings located on the 5,265-acre (2,131-hectare) site of the Brookhaven National Laboratory. The distance from the reactor to the nearest site boundary is to the south at 3700 feet (1288 meters). The spent nuclear fuel is stored in an 8-foot-wide, 43-foot-long, 20-foot-deep canal (2.4 meters wide, 13.2 meters long, 6.1 meters deep). Within the canal, the fuel is located in storage racks, either in a 30-cell rack or in a long-term storage rack (Carelli 1993).

3.1.1.2 Brookhaven Medical Research Reactor. The Brookhaven Medical Research

Reactor is a 5 MW heterogeneous, thermal, tank type reactor which is light water moderated and cooled. The reactor, used for research, became fully operational in 1959. The Brookhaven Medical Research Reactor is located in one building at the Brookhaven National Laboratory approximately 0.25 mile (0.4 kilometer) south of the High Flux Beam Reactor site. Fuel storage at the Brookhaven Medical Research Reactor consists of a shelf, lined with boral sheets, in the upper part of the reactor vessel above the active core region. The shelf is located under 8 feet (2.5 meters) of water and is considered critically safe when fully loaded. Like the High Flux Beam Reactor, there is no facility for dry storage at the Brookhaven Medical Research Reactor (Carelli 1993).

3.1.1.3 Affected Environment at Brookhaven National Laboratory.

3.1.1.3.1 Land Use-The Brookhaven National Laboratory is located approximately

60.
1 miles (97 kilometers) east of New York City on Long Island, New York. The site is located in a primarily suburban area. Land on the 5,265-acre (2,131-hectare) site is divided between undeveloped natural areas and the developed areas that support the laboratory's scientific research (BNL 1992c).

Regional land use includes a variety of residential, commercial, industrial, agricultural, institutional, recreational, and public uses. Although agricultural and undeveloped forest land have been the dominant land uses in the region, development pressures for residential and commercial land uses have increased steadily in recent years (BNL 1992c).

3.1.1.3.2 Socioeconomics-The Brookhaven National Laboratory is located in

central Suffolk County just at the fringe of developed areas, in an area of rapidly growing population.
About 1.32 million persons reside in Suffolk County and about 410,000 persons reside in Brookhaven Township, within which the Laboratory is situated. Between 1995 and 2040, population in Suffolk County is expected to increase 14.6 percent (DOC 1991a). Approximately 8,000 persons reside within a half mile (0.8 kilometer) of the laboratory boundary (BNL 1992b).

The population of Suffolk County is approximately 96 percent urban and has a substantially higher median family income than the rest of the state (DOC 1991c). Between 1970 and 1990, total employment in Suffolk County increased 103.8 percent (DOC 1992).

Dominant industries in the area include government, manufacturing, retail and services, with approximately 20 percent of earnings in Suffolk County coming from government spending (DOC 1992).

The Brookhaven National Laboratory is composed of a total staff of 3449 regular employees (BNL 1993a).

As reported in 1988, there were a total of 69 personnel working at the reactors (ANS 1988). This number included operators, experimenting scientists, and support personnel. While not their main occupation, part of the duties of the operators and some support personnel include tasks associated with refueling, storing, inventorying, packaging, and shipping SNF.

3.1.1.3.3 Cultural Resources-The Brookhaven National Laboratory has no

properties designated as National Historic Landmarks.

The Old Reactor Building (Building 701) and the Old Cyclotron Enclosure (Building 902) are eligible for inclusion on the National Register of Historic Places (NRHP). Camp Upton training trenches from World War I are also eligible for inclusion on the NRHP.

3.1.1.3.4 Geology-The Brookhaven National Laboratory site is in the upper part

of the Peconic River Valley, which is bordered by two lines of low hills. These extend east and west beyond the limits of the valley nearly the full length of Long Island and form its most prominent topographic features (ERDA 1977).

A maximum horizontal ground surface acceleration of 0.19 g at Brookhaven National Laboratory is estimated to result from an earthquake that could occur once every 2000 years (DOE 1994a). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility specific basis consistent with DOE orders and standards and site specific procedures.

No earthquake has yet been recorded in the Brookhaven National Laboratory area with a Modified Mercalli intensity in excess of III. Long Island lies in the Uniform Building Code Zone 2A (moderate) seismic hazard area. No active earthquake producing faults are known in the Long Island area (ERDA 1977).

3.1.1.3.5 Air Resources-In terms of meteorology, the laboratory can be

characterized, like most Eastern Seaboard areas, as a well-ventilated site. The prevailing ground-level winds are from the southwest during the summer, from the northwest during the winter, and about equally from these two directions during the spring and fall (BNL 1992b).

The mean annual temperature for the site during 1991 was 52.8yF (11.6yC), with temperatures ranging from 21.2yF (-6yC) to 83.8yF (28.8yC). The annual precipitation during 1991 was 45.3 inches (115 centimeters), which is about 3.6 inches (9.0 centimeters) below the 40-year annual precipitation average of 48.4 inches (123 centimeters) (BNL 1992b).

The State of New York has adopted ambient air quality standards that specify maximum permissible short- and long-term concentrations for various contaminants. These standards are generally the same as the national standards for criteria pollutants (NYSDEC 1977). Suffolk County, in which the site is located, is classified as being in nonattainment of the standards for the criteria pollutant ozone. The county is in attainment of standards for carbon monoxide, particluates, sulfur dioxide, nitrogen dioxide, and lead (NYSDEC 1993).

3.1.1.3.6 Water Resources-The Brookhaven National Laboratory site lies on the

western rim of the shallow Peconic River watershed. The marshy areas in the north and eastern sections of the site are a portion of the Peconic River headwaters. The Peconic River both recharges and receives water from the groundwater aquifer, depending on the hydrogeological potential. In times of drought the river water typically recharges to groundwater, while in times of normal to above normal precipitation, the river receives water from the aquifer (BNL 1992b).

Groundwater flow in the vicinity of Brookhaven National Laboratory is controlled by many factors. The main groundwater divide lies 1.25 to 5 miles (2 to 8 kilometers) south of Long Island Sound parallel to the Sound. This divide is known to shift 0.6 to 1.25 miles (1 to 2 kilometers), north to south. East of Brookhaven National Laboratory is a secondary groundwater divide that defines the southern boundary of the area contributing groundwater to the Peconic River. The exact location of the triple-point intersection of these two divides is not known and may be under Brookhaven National Laboratory. South of these divides, the groundwater moves southward to Great South Bay and to Moriches streams. In general, the groundwater from the area between the two branches of the divide moves out eastward to the Peconic River. North of the divide, groundwater moves northward to Long Island Sound. Pressure of a higher water table to the west of the Brookhaven National Laboratory area generally inhibits movement toward the west. Variability in the direction of flow in the Brookhaven National Laboratory site is a function of the hydraulic potential and is further complicated by the presence of clay deposits that accumulate perched water at several places plus the pumping/recharge of groundwater that are part of Brookhaven National Laboratory daily operations. In general, groundwater in the northeast and northwest sections of the site flows toward the Peconic River. On the western portion of the site, groundwater flow tends to be toward the south, while along the southern and southeastern sections of the site it tends to be toward the south to southeast (BNL 1992b).

In all areas of the site, horizontal groundwater velocity is estimated to range from 12 to 18 inches (30 to 45 centimeters) a day. The site occupied by Brookhaven National Laboratory has been identified by the Long Island Regional Planning Board and Suffolk County as being over a deep recharge zone for Long Island. This implies the precipitation and surface water which recharges within this zone has the potential to replenish the lower aquifer systems (Magothy and/or Lloyd) which exist below the Upper Glacial Aquifer. The extent to which the Brookhaven National laboratory site contributes to deep flow recharge is currently under evaluation. However, it is estimated that up to two-fifths of the recharge from rainfall moves into the deeper aquifers. These lower aquifers discharge to the Atlantic Ocean (BNL 1992b).

The three aquifers (Upper Glacial, Magothy and Lloyd) underlying the Brookhaven

National Laboratory comprise the Nassau/Suffolk Aquifer System, which has been designated as a sole source aquifer by the U.S. Environmental Protection Agency. More detailed aquifer characterization information can be found in the Brookhaven National Laboratory Site Baseline Report (SAIC 1992).

3.1.1.3.7 Ecological Resources-Approximately 75 percent of Brookhaven National

Laboratory is primarily woodland.
Terrestrial habitats include pine plantations, moderately mature pitch pine/oak forest, predominantly deciduous forest, early successional shrub/sapling community, pine barrens shrub/sapling wetlands, and lawn areas (BNL 1993a).

The isolation of the Brookhaven National Laboratory site and its variety of wildlife habitats have made it a refuge for a surprisingly diverse animal population. Thirty species of mammals have been recorded on site or within a 10-mile (16-kilometer) radius. All of these are year-round residents except for five summer-resident and two migrant species of bats. (BNL 1992c)

About 400 non-extinct species of birds have been recorded on all of Long Island since records have been kept, and at least 180 of these have been recorded on site. Thirty-three species are found throughout the year and all except six of these breed on site. Forty-nine other species are summer residents. All except nine nest on site, four others probably do, and the rest nest elsewhere on Long Island, most nearby (BNL 1993).

In September 1990, the U.S. Fish and Wildlife Service confirmed that no Federal or State endangered species occur in the vicinity of Brookhaven National Laboratory. However, the State endangered tiger salamander breeds in a pond in the southeast corner of the site (BNL 1992c).

3.1.1.3.8 Public Health and Safety-The calculated effective dose equivalent

associated with effluent releases from the most recent reports for a 5-year period are presented below (BNL 1993b, 1992a, 1992b, 1990, 1989).
The annual doses for each year are only a fraction of the DOE Public Dose Limit of 100 millirem per year. The data are from all laboratory operations, including storage of SNF.

Year	Airborne effluents (maximum site boundary)	Liquid effluents (maximum individual)
1988	0.113 millirem	0.15 millirem
1989	0.120 millirem	0.96 millirem
1990	0.067 millirem	0.85 millirem
1991	0.170 millirem	0.74 millirem
1992	0.097 millirem	0.91 millirem

The collective (population) dose equivalent (total population dose) beyond the site boundary, within a radius of 50 miles (80 kilometers), attributed to laboratory operations from reports for a 5-year period is presented below (BNL 1993b, 1992a, 1992b, 1990, 1989). The data are from all laboratory operations, including storage of SNF.

1988	2.5 person-rem
1989	3.2 person-rem
1990	1.8 person-rem
1991	3.6 person-rem
1992	3.2 person-rem

3.1.1.3.9 Waste Management-Brookhaven National Laboratory generates low-

level, low-level mixed and hazardous wastes, in conjunction with its activities as a scientific research center.
In 1992, the site generated approximately 508 tons (461 metric tons) of solid waste and 19.6 cubic yards (15 cubic meters) of liquid waste (DOE 1994b).

Brookhaven National Laboratory currently stores about 110 cubic yards (84 cubic meters) of low-level mixed waste and has no current or planned onsite treatment facilities. All waste streams are currently shipped to Hanford. These waste streams include organic liquids, acid and alkaline solutions, uranium hydride, cleaning/degreasing solvents, chromic acid cleaning solutions, and lead- and mercury-contaminated equipment (DOE 1993g).

In 1989, EPA listed BNL on the National Priorities Lists and in 1992 an Interagency Agreement was signed among DOE, EPA Region II, and the New York State Department of Environmental Conservation. Seven operable units have been identified for remedial investigation/feasibility studies and evaluated for suitable remedial action. The operable units consist of various groupings (generally by area) of buildings and sumps, underground pipes and tanks, the sewage runoff and discharge areas, trichloroethylene and reactor spill areas and groundwater. Some contamination at the site was the result of U.S. Army practices from 1917 to

1947 (DOE 1993g).

3.1.2 Los Alamos National Laboratory

The Omega West Reactor, operated by the Los Alamos National Laboratory, is a thermal, heterogeneous, closed-tank research reactor normally functioning at a power level of 8 MW. The Omega West Reactor was operational from 1956 until December 1992, when it was shut down. This reactor is permanently shut down and is being decommissioned. All spent nuclear fuel, consisting of 86 fuel elements, is in temporary storage at the Chemistry and Metallurgy Research Complex in Wing 9. They are being stored in old "Rover Project" casks which were once certified for transport of spent nuclear fuel. LANL has no permit for long-term storage of spent fuel.

3.1.2.1 Land Use. Los Alamos National Laboratory is located approximately 60 miles (96 kilometers) north-northeast of Albuquerque, New Mexico. Los Alamos occupies an area of about 28,000 acres (11,000 hectares) located primarily in Los Alamos County in northern New Mexico, about 24 miles (39 kilometers) northwest of Santa Fe. The County of Los Alamos has zoned the entire area of the lab Federal Land. Los Alamos National Laboratory has developed nine land use classifications for its operations. There are no prime farmlands on the Los Alamos National Laboratory, although portions are designated as a National Environmental Research Park (DOE 1993a).

3.1.2.2 Socioeconomics. The civilian labor force in the region of interest grew 144 percent, increasing from 34,467 in 1970 to 84,107 in 1990. Total employment increased from 31,155 to 79,846 between 1970 and 1990, an annual growth rate of 5 percent. The unemployment rates for 1970 and 1990 were 9.6 percent and 5.1 percent, respectively. For the same years, personal income increased from approximately $324.7 million to $2.3 billion (an annual average of 10 percent), and per capita income increased from $3,396 to $15,348 (DOE 1993a).

Between 1975 and 1990, employment at Los Alamos National Laboratory increased from 5,094 to 7,622, representing 10 percent of the region of interest employment in 1990. As of September 1992, employment at Los Alamos National Laboratory had increased to 7,450. The prepared Fiscal Year 1994 budget projects a reduction in expenditures at the site resulting in reduced employment (DOE 1993a).

In 1991, more than half of the Los Alamos National Laboratory workforce resided in the unincorporated communities of Los Alamos and White Rock in Los Alamos County. Between 1970 and 1990, the population in the region of interest increased 61 percent to 151,408. During the same period, the New Mexico population increased 49 percent. The population in the three-county region of interest is projected to increase from an estimated 169,000 in 2000 to 191,000 by 2020, an annual rate of less than 1 percent (DOE 1993a).

Employment associated with SNF management such as routine operations of the facility including care and periodic inventories of the SNF amounts to about 1.3 person-years per year (Cruz 1995).

3.1.2.3 Cultural Resources. The prehistoric chronology for the Los Alamos National Laboratory area consists of six broad time periods: Paleoindian (10,000-4000 B.C.), Archaic (5500 B.C.-A.D. 600), Early Developmental (A.D. 600-900), Late Developmental (A.D. 900-1100) Coalition (A.D. 1110-1325), and Classic (A.D. 1325-1600). Prehistoric site types identified in the vicinity of Los Alamos National Laboratory include large multiroom pueblos, pithouse villages, field houses, talus houses, cave kivas, shrines, towers, rockshelters, animal traps, hunting blinds, water control features, agricultural fields and terraces, quarries, rock art, trails, campsites, windbreaks, rock rings, and limited activity sites. Approximately 75 percent of Los Alamos National Laboratory has been inventoried for cultural resources. Coverage for some inventories has been less than 100 percent; however, about 60 percent of Los Alamos National Laboratory has received 100 percent coverage. Over 975 prehistoric sites have been recorded; about 95 percent of these sites are considered eligible or potentially eligible for the National Register of Historic Places (DOE 1993a).

Native Americans in this area include those living in the San Ildefonso, San Juan, Santa Clara, Nambe, Tesuque, Pojoaque pueblos east of Los Alamos, and the Jemez and Cochiti pueblos. Native American resources on Los Alamos National Laboratory may consist of prehistoric sites with ceremonial features such as kivas, village shrines, petroglyphs, or burials; all of these site types or features would be of concern to local groups (DOE 1993a).

3.1.2.4 Geology. Los Alamos National Laboratory is located on the Pajarito Plateau.

The surface of the plateau is dissected by deep, southeast-trending canyons separated by long, narrow mesas (DOE 1993a).

Los Alamos National Laboratory lies in the Uniform Building Code Zone 2B seismic hazard area. The strongest earthquake in the last 100 years within a 50-mile (80-kilometer) radius was estimated to have a magnitude of 5.5 to 6 and a Modified Mercalli Intensity of VII. Studies suggest that several faults have produced seismic events with a magnitude of 6.5 to 7.8 in the last 500,000 years. Los Alamos National Laboratory operates a seismic hazards program which monitors seismicity through a seismic network and conducts studies in paleoseismology. These studies have determined the presence of three faults in the area that are considered active as defined by 10 CFR 100, Appendix A. These form the Pajarito fault system, which includes the Pajarito, Water Canyon, and Guaje Mountain faults. The Guaje Mountain fault had movement on it between 4,000 and 6,000 years ago. There is no evidence of movement along the Pajarito fault system during historical times. The 100-year earthquake at Los Alamos is regarded as having a magnitude of 5, with an event of magnitude 7 being the maximum reasonably foreseeable earthquake. These values are currently used in design considerations at Los Alamos (DOE 1993a).

Maximum horizontal ground surface accelerations ranging from 0.17 to 0.25g at Los Alamos National Laboratory are estimated to result from an earthquake that could occur once every 2000 years (DOE 1994a). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility specific basis consistent with DOE orders and standards and site specific procedures.

Geological concerns associated with the Los Alamos National Laboratory area include potential downslope movements in association with regional seismic activity. Although isolated rockfalls commonly occur from the canyon rims, landslides are an unlikely hazard (DOE 1993a).

3.1.2.5 Air Resources. The climate at Los Alamos National Laboratory and in the

surrounding region is characterized as a semiarid tropical and subtropical steppe. Mountain barriers deplete a large portion of the moisture from the maritime air masses from the Pacific Ocean, a condition that contributes to the semiaridness. The annual average temperature in the area is 56.2oF (13.4oC); average daily temperatures range from 22.3oF (-5.4oC) in January to 92.8oF (33.8oC) in July. The average annual precipitation in the area is 8.1 inches (20.6 centimeters). The average monthly precipitation ranges from 0.38 inch (0.97 centimeter) in November to 1.51 inches (3.84 centimeters) in August (DOE 1993a).

3.1.2.6 Water Resources. The major surface water body in the immediate vicinity of Los

Alamos National Laboratory is the Rio Grande east of the site. The primary surface water features near Los Alamos National Laboratory are intermittent streams. Sixteen drainage areas pass through or start in the Los Alamos National Laboratory site. Most Los Alamos National Laboratory facilities are located well above the streambeds. Only those Technical Areas located within canyons would be within the 500-year floodplain (DOE 1993a).

No surface water is withdrawn at Los Alamos National Laboratory for either drinking water or facility operations. The water supply system for Los Alamos is based on a series of groundwater supply wells and springs (DOE 1993a).

Los Alamos, Sandia, and Mortandad canyons currently receive treated industrial or sanitary effluent. Acid-Pueblo Canyon does not receive Los Alamos National Laboratory effluents. Surface waters in these canyons are not a source of municipal, industrial, or agricultural water supply. Only during periods of heavy precipitation or snow melt would waters from Acid-Pueblo, Los Alamos, or Sandia Canyons extend beyond Los Alamos National Laboratory boundaries and reach the Rio Grande. In Mortandad Canyon, there has been no surface runoff to the laboratory's boundary since studies were initiated in 1960 (DOE 1993a).

The main aquifer consists mainly of sediments of the Santa Fe Group. Nearly all groundwater at Los Alamos National Laboratory is obtained from deep wells that produce water from this aquifer. The Bandelier Tuff, a volcanic unit that lies above the Santa Fe Group, contains fractures that yield small amounts of water to springs. A minor amount of groundwater at Los Alamos National Laboratory is obtained from springs. The aquifers that lie beneath Los Alamos National Laboratory are considered Class II aquifers, having current sources of drinking water and water with other beneficial uses (DOE 1993a).

The water in the main aquifer moves slowly from the major recharge area in the west to discharge springs in White Rock Canyon along the Rio Grande. The depth to the aquifer ranges from about 1,200 feet (365 meters) on the west to about 600 feet (183 meters) on the east. The total saturated thickness penetrated by production wells ranges up to at least 1,700 feet

(518 meters) (DOE 1993a).

3.1.2.7 Ecological Resources. Terrestrial habitats within undeveloped areas of Los

Alamos National Laboratory support six major vegetative communities: juniper-grassland, pinyon pine-juniper, ponderosa pine, mixed conifer, spruce-fir, and subalpine grassland. Undeveloped areas within Los Alamos National Laboratory provide habitat for a diversity of terrestrial wildlife.

Los Alamos National Laboratory was designated a National Environmental Research Park in 1976 (DOE 1993a).

National Wetland Inventory maps indicate that wetlands within Los Alamos National Laboratory are restricted to several canyons containing the Rio Grande or its tributaries. Most of the wetlands shown on the National Wetland Inventory maps have been designated as temporary or seasonal (DOE 1993a).

Aquatic habitats on Los Alamos National Laboratory are limited to the Rio Grande and several springs and intermittent streams in the canyons. These habitats currently receive National Pollutant Discharge Elimination System-permitted wastewater discharges. Fourteen species of fish are known to inhabit the roughly 6-mile (10-kilometer) reach of the Rio Grande between Los Alamos National Laboratory and Chochiti Lake. The springs and streams on the site support limited, if any, aquatic life (DOE 1993a).

Seventeen federally listed or New Mexico-listed threatened, endangered, or candidate species potentially occur in the vicinity of Los Alamos National Laboratory. Four of these species have been observed on Los Alamos National Laboratory, including the bald eagle (Haliaeetus leucocephalus)(a federally listed endangered species that roosts along the Rio Grande); the peregrine falcon (Falco peregrinus)(a federally listed endangered species that historically nests in the northeast corner of Los Alamos National Laboratory); the northern goshawk (Accipiter gentilis) (A Federal candidate Category 2 species that forages in the northwest corner of Los Alamos National Laboratory); and the giant helleborine orchid (Epipactic gigantea) (a state-listed endangered species that occurs near springs in White Rock Canyon). Five other species occur in close proximity to Los Alamos National Laboratory and are likely to exist on the site (DOE 1993a).

3.1.2.8 Public Health and Safety. The total maximum individual dose to a member of

the public associated with both gaseous and liquid effluents from the most recent reports for a 5-year period is presented below (LANL 1993, 1992, 1990, 1989, 1988). The annual doses for each year are only a fraction of the DOE Public Dose Limit of 100 millirem per year. The data are from all laboratory operations, including storage of SNF.

1987	6.1 millirem
1988	6.2 millirem
1989	3.9 millirem
1990	3.1 millirem
1991	4.4 millirem

The population collective effective dose equivalent attributable to laboratory operations to persons living within 50 miles (80 kilometers) of the laboratory for a 5-year period is presented below (LANL 1993, 1992, 1990, 1989, 1988). The data are from all laboratory operations, including storage of SNF.

1987	3.5 person-rem
1988	2.2 person-rem
1989	3.1 person-rem
1990	3.1 person-rem
1991	1.1 person-rem

3.1.2.9 Waste Management. Current low-level radioactive waste management activities

at Los Alamos National Laboratory may require expansion of the existing landfill at Los Alamos National Laboratory. A portion of the proposed expansion area for the existing landfill has been contaminated by a chemical plume from the hazardous chemical disposal site, which restricts further development. DOE is considering the expansion to ensure continued operation of laboratory activities that generate low level radioactive waste and to provide safe isolation of the wastes (DOE 1993a).

Waste minimization has been implemented by Los Alamos National Laboratory's Environmental Management Division using programmatic controls such as source reduction, inventory control, product substitution, and waste exchange programs. A Waste Minimization and Pollution Prevention Awareness Plan was completed in 1991. Major waste generating operations have been prioritized by severity of hazard and volume in order to determine which generating systems to address. Also, halogenated solvent substitution has been evaluated for a number of research processes (DOE 1993a).

3.1.3 Sandia National Laboratories

Sandia National Laboratories, headquartered in Albuquerque, New Mexico, maintain facilities in three locations: Albuquerque, New Mexico; Livermore, California; and Tonopah, Nevada. The facilities discussed in this document refer only to the Albuquerque location, located adjacent to the city of Albuquerque, New Mexico. The site is approximately 6.5 miles (10 kilometers) southeast of downtown Albuquerque. Sandia National Laboratories consist of 8,300 acres (3,360 hectares) on Kirtland Air Force Base allocated to DOE.

Sandia National Laboratories use facilities at five Technical Areas and a Test Field (DOE 1993a).

- Technical Area I--Administration, site support, technical support, component development, research, energy programs, microelectronics, defense programs, and exploratory systems.
- Technical Area II--Testing of explosive components.
- Technical Area III--Testing and simulation of a variety of natural and induced environments, including two rocket sled tracks, two centrifuges, and a radiant heat facility.
- Technical Area IV--A remote site for pulsed power sciences such as X-ray, gamma-ray, and particle beam fusion accelerators.
- Technical Area V--A remote area for experimental and engineering reactors and particle accelerators.
- Coyote Test Field--Land parcels scattered throughout the Coyote Test Field used for testing.

The Sandia National Laboratories contain five SNF storage facilities: the Manzano Storage Structures, the Annular Core Research Reactor Facility, the Sandia Pulse Reactor Facility, the Hot Cell Facility, and the Special Nuclear Materials storage facility (DOE 1993b).

3.1.3.1 Manzano Storage Structures. The Manzano Storage Structures are reinforced

concrete bunkers located in the southeast portion of Kirtland Air Force Base. Until recently, when the Sandia National Laboratories took responsibility for the site, the Manzano facilities were operated and maintained by the Department of Defense. The Sandia National Laboratories currently use four structures for dry storage of reactor irradiated nuclear material.

The two types of bunkers which Sandia National Laboratories utilize are reinforced concrete bunkers with an earth covering, and reinforced concrete bunkers bored into the mountain. The average storage space available is 1800 square feet (167 square meters). A ring road encircles the mountain and provides access to all of the bunkers. The ventilation is natural air circulation (DOE 1993b).

3.1.3.2 Annular Core Research Reactor. The Annular Core Research Reactor is a pool-

type research reactor capable of steady-state, pulse, and tailored transient operation. The reactor has a large central irradiation cavity (primary experiment location) that extends through the core, two interchangeable, fuel-ringed external cavities, an unfueled external cavity and two neutron radiography facilities. The Annular Core Research Reactor facility includes the reactor pool, one safe, and eight dry floor storage vaults, all located in the high-bay of Building 6588. The Annular Core Research Reactor is used primarily for testing electronics and for reactor safety research. The eight storage vaults on the high-bay floor are used to securely store irradiated experiments containing a variety of nuclear materials, but principally uranium-235. Materials from only three experiments containing reactor irradiated nuclear materials are stored at the Annular Core Research Reactor (DOE 1993b).

3.1.3.3 Sandia Pulse Reactor II and III, and Critical Assembly. Three reactors are

operated at the Sandia Pulse Reactor facility; Sandia Pulse Reactor II and Sandia Pulse Reactor III are unmoderated, fast-burst reactors capable of pulsed and steady-state operation. They are designed to produce a neutron energy spectrum similar to that produced from fission. The primary experiment location for each reactor is a central cavity that extends through the core. The principal use of the reactors is to irradiate electronic devices requiring high neutron fluence and/or high dose rates. The Critical Assembly is a small, water-moderated reactor used to perform measurements of key reactor parameters to benchmark the computer calculations and thereby refine the designs for a planned space propulsion reactor. The yard storage holes are 19 stainless-steel types located in a corner of the Sandia Pulse Reactor compound. These tubes are surrounded by a high-density concrete monolith. The yard holes are used to securely store irradiated experiments containing a variety of nuclear materials, but principally uranium-235. All of the materials reside in their own containers, some of which have double containment (DOE 1993b).

3.1.3.4 Hot Cell Facility. The Hot Cell Facility at Sandia National Laboratories is a

nonreactor nuclear facility that is housed in Building 6580 in Technical Area V. The Hot Cell Facility includes the Hot Cell, the Glove Box Laboratory, Radiochemistry Laboratory, and support facilities in rooms 101, 104, 105, 106, 107, 108, 110, 111, 112, 113, 113A, 203, and 212A. This facility is designed to permit safe handling and experimentation with Special Nuclear Materials, both irradiated and unirradiated. Research programs at Sandia National Laboratories (material studies, fuel studies, and safety studies) require that experiments containing radioactive materials be assembled and/or disassembled, samples prepared, and microscopic and chemical analyses performed. The principal storage facility for the Hot Cell Facility is Room 108, which is a heavily shielded room used previously as a preparation room next to the irradiation room of the Sandia Engineering Reactor which has been defueled. There are a series of 13 storage holes under the Hot Cell Facility Monorail that are available to store irradiated material coming into or out of the Hot Cell Facility. Only one of the holes is currently in use. The other areas of the Hot Cell Facility are used for storing minor amounts of material (DOE 1993b).

3.1.3.5 Special Nuclear Material Storage Facility. At this dry storage facility, Sandia

National Laboratories stores previously failed fuel elements from Sandia Pulse Reactor II and elements from experiments that have been exposed to short irradiation periods. The complex also provides for a loading area, a maintenance area, and an administrative office area. The ventilation consists of a forced air filtered system (DOE 1993b).

3.1.3.6 Affected Environment at Sandia National Laboratories.

3.1.3.6.1 Land Use-Sandia National Laboratories are located approximately

6.
5 miles (10.5 kilometers) southeast of downtown Albuquerque, New Mexico. There are no prime farmlands on Sandia National Laboratories (DOE 1993a).

3.1.3.6.2 Socioeconomics-The civilian labor force in the region of interest grew

132 percent, increasing from 133,798 in 1970 to 310,252 in 1990. Total employment increased from 124,605 to 293,905 between 1970 and 1990, an annual growth rate of 4 percent. The unemployment rates for 1970 and 1990 were 6.9 percent and 5.3 percent, respectively. For the same years, personal income increased from approximately $1.3 billion to $9.4 billion (an annual average of 10 percent), and per capita income increased from $3,438 to $15,992 (DOE 1993a).

Between 1970 and 1990, employment levels at Sandia National Laboratories increased from 6.440 to 7,536, representing 3 percent of the region of interest employment in 1990. Changes in mission requirements have historically led to fluctuations in employment levels over the period. For example, employment decreased to 5,542 in 1975 and increased to 7,051 by 1985. As of September 30, 1992, employment levels at Sandia National Laboratories had increased to 8,473. The prepared Fiscal Year 1994 budget projects a reduction in expenditures at the site, resulting in reduced employment. The reduction in work force associated with the budget reductions is only estimated at this time (DOE 1993a).

Between 1970 and 1990, the population in the region of interest increased 58 percent to 589,131. During the same period, the population of New Mexico increased 49 percent. The population in the three-county region of interest is projected to increase from an estimated 682,000 in 2000 to 771,000 by 2020, an annual rate of less than 1 percent (DOE 1993a).

As reported in 1988, there were a total of 21 personnel working at the reactors (ANS 1988). This number included operators, experimenting scientists, and support personnel. While not their main occupation, part of the duties of the operators and some support personnel include tasks associated with refueling, storing, inventorying, packaging, and shipping SNF.

3.1.3.6.3 Cultural Resources-The prehistoric chronology for the Sandia National

Laboratories area consists of three broad time periods: Paleoindian (10,000-5500 B. C.), Archaic (5500 B.C.-A.D. 1), and Anasazi (A.D. 1600). Prehistoric site types include pueblos, pithouse villages, rockshelters, hunting blinds, agricultural terraces, quarries, lithic and ceramic scatters, lithic scatters, and hearths. About 22 percent of Sandia National Laboratories/DOE-controlled land has been intensively inventoried for cultural resources; another 28 percent has received less intensive surveys. Because techniques and procedures varied greatly between projects in these areas, most surveys are not considered adequate. All five DOE Technical Areas have been intensively surveyed; no prehistoric sites were recorded. Sixty-four prehistoric sites have been recorded in DOE-owned or controlled lands beyond the five Technical Areas. About 88 percent of these sites are considered eligible for the National Register of Historic Places (DOE 1993a).

Native Americans in this area include those living on the Sandia Pueblo, north of Albuquerque, and the Isleta Pueblo, south of Kirtland Air Force Base. Native American resources on Sandia National Laboratories/DOE-controlled lands may consist of prehistoric sites with ceremonial features such as kivas, village shrines, petroglyphs, or burials; all of these types or features would be of concern to local groups (DOE 1993a).

3.1.3.6.4 Geology-Sandia National Laboratories lie on a sequence of sedimentary,

igneous, and Precambrian basement rocks. The northern and western sections of Sandia National Laboratories rest on Miocene to Quaternary gravels, sands, silts, and clays deposited in the basin formed by uplift of the mountains to the east. The eastern portion of Sandia National Laboratories is underlain primarily by Precambrian rocks (DOE 1993a).

The eastern portion of Sandia National Laboratories is cut by the Tijeras, Hubble Springs, Sandia, and Manzano faults. Both the Tijeras and Sandia faults, which intersect on the site, are considered capable faults (DOE 1993a).

Sandia National Laboratories lies in the Uniform Building Code 2B seismic hazard area. The facility is situated in a region of high seismic activity but low magnitude and intensity. Available records indicate that more than 1,100 earthquakes have occurred during the past 127 years. However, during the past century, only three have caused damage at Albuquerque. Intensities have been as high as a Modified Mercalli Intensity of VII, which can cause damage (DOE 1993a).

Possible geological concerns include potential ground shaking and rupturing associated with regional seismic activity and the two capable faults intersecting on the site. Statistical studies indicate that a nondamaging earthquake (Modified Mercalli Intensity less than III) may be expected every 2 years, with a damaging event every 100 years (DOE 1993a).

A maximum horizontal ground surface acceleration of 0.28g at Sandia National Laboratory is estimated to result from an earthquake that could occur once every 2000 years (DOE 1994a). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility specific basis consistent with DOE orders and standards and site specific procedures.

3.1.3.6.5 Air Resources-The climate at Sandia National Laboratories and in the

surrounding region is characteristic of a semiarid steppe. The annual average temperature in the area is 56.2oF (13.4oC); temperatures vary from an average daily minimum of 22.3oF (-5.4oC) in January to an average daily maximum of 92.8oF (33.8oC) in July. The average annual precipitation is 8.1 inches (20.6 centimeters) (DOE 1993a).

3.1.3.6.6 Water Resources-Sandia National Laboratories are located within the

Kirtland Air Force Base on the Albuquerque East Mesa. The mesa slopes gently southwest to the Rio Grande, the primary drainage channel for the area. The average flow of the Rio Grande is 1,008 cubic feet (28.5 cubic meters) per second. No perennial streams flow through the Sandia National Laboratories area. The two primary surface channels at Sandia National Laboratories are Tijeras Arroyo and the smaller Arroyo del Coyote. The Arroyo del Coyote joins the Tijeras Arroyo to discharge into the Rio Grande approximately 5 miles (8 kilometers) from the western edge of Kirtland Air Force Base. Both arroyos flow intermittently during spring snow melt or following thunderstorms. Springs in the eastern mountains provide a perennial flow in the upper reaches of Tijeras Arroyo. Most of this flow evaporates or percolates into the soil before reaching Kirtland Air Force Base (DOE 1993a).

High peak flows of short duration characterize floods in the area. High-intensity summer thunderstorms produce the greatest flows, but the probability of flooding is not considered high at Kirtland Air Force Base. The southeast corner of Technical Area IV and the east side of Technical Area II lie within the 500-year floodplain of Tijeras Arroyo (DOE 1993a).

Sandia National Laboratories lie within the north-south trending Albuquerque basin. The principal aquifer of the Albuquerque basin is the Valley Fill aquifer. The Valley Fill consists of unconsolidated and semiconsolidated sands, gravels, silts, and clays that vary in thickness from a few feet (meters) adjacent to the mountain ranges to over 21,000 feet (6,400 meters) at a point 5 miles (8 kilometers) southwest of Kirtland Air Force Base airfield. The Valley Fill aquifer is considered a Class IIa aquifer, having a current source of drinking water and waters with other beneficial uses. (DOE 1993a)

The regional water table is separated by a fault complex that divides the area into a deep region on the west side of the complex and a shallower region on the east side. The depth to groundwater ranges from 50 to 100 feet (15 to 30 meters) on the east side of the fault complex and from 380 to 500 feet (115 to 1150 meters) on the west side. Based on available data, the apparent direction of groundwater flow west of the fault complex is generally to the north and northwest. The direction of groundwater flow east of the fault complex typically is west toward the fault system (DOE 1993a).

3.1.3.6.7 Ecological Resources-Most undeveloped lands within Technical Areas I

and III of Sandia National Laboratories support grassland vegetation. Terrestrial wildlife using grassland habitats on Sandia National Laboratories are typical of similar habitats in central New Mexico. The size and diversity of wildlife populations are thought to be limited by the poor availability of water. An inventory of wildlife species on Kirtland Air Force Base (including Sandia National Laboratories) has been recently updated (DOE 1993a).

No wetland inventories have been performed for Sandia National Laboratories, and no National Wetland Inventory maps have been published. Several springs exist on Kirtland Air Force base, including Sol se Mete Spring, Coyote Springs, and G Spring. These are associated with canyons and arroyos. No springs exist in Technical Areas I through V, and none are located within permitted land to which Sandia National Laboratories has access (DOE 1993a).

Potential aquatic habitat within Kirtland Air Force Base is limited to arroyos and canyons and the few springs associated with them. The nearest major perennial aquatic habitat is the Rio Grande, approximately 5 miles (8 kilometers) to the west (DOE 1993a).

No federally listed threatened or endangered species are known to occur on Sandia National Laboratories. The peregrine falcon (Falco peregrinus), a federally and state-listed endangered species, could potentially occur in the mountainous areas of Kirtland Air Force Base surrounding Sandia National Laboratories, but the likelihood is low because of the poor quality habitat for this species. The grama grass cactus (Pediocactus papyracanthus), a Federal Candidate Category 2 and state-listed endangered species, is known to occur in grasslands on Kirtland Air Force Base similar to those occurring on Sandia National Laboratories. The spotted bat (Euderma maculatum), also a Federal Category 2 and state-endangered species, has a low probability of occurrence on Sandia National Laboratories. Sandia National Laboratories lie within the breeding range of several Federal Candidate bird species (DOE 1993a).

3.1.3.6.8 Public Health and Safety-The annual dose to a maximally exposed

individual due to release of gaseous radionuclides from laboratory operations from reports for a 5-year period is presented below (SNL 1993, 1992, 1991, 1990, 1989). The data are from all laboratory operations, including storage of SNF.

1988	0.00034 millirem
1989	0.00088 millirem
1990	0.0020 millirem
1991	0.0014 millirem
1992	0.0034 millirem

The estimated population dose to persons living within a 50-miles (80-kilometer) radius surrounding the laboratory due to release of gaseous radionuclides from laboratory operations from reports for a 5-year period is presented below (SNL 1993, 1992, 1991, 1990, 1989). The data are from all laboratory operations, including storage of SNF.

1988	0.039 person-rem
1989	0.097 person-rem
1990	0.82 person-rem
1991	0.052 person-rem
1992	0.020 person-rem

3.1.3.6.9 Waste Management-Low-level radioactive waste at Sandia National

Laboratories is generated in both technical and remote test areas as a result of research and development activities.

Most of the low-level radioactive waste consists of contaminated equipment and combustible decontamination materials and cleanup debris. All generated low-level radioactive waste is temporarily stored at generator sites or above ground in transportation containers at the Technical Area III disposal site. All low-level radioactive waste packages are currently onsite pending approval of transport by commercial carriers offsite for burial (DOE 1993a).

Mixed wastes include radioactively contaminated oils and solvents and radioactively contaminated or activated lead or other heavy metals. Other mixed wastes may be generated as a result of weapons tests (DOE 1993a).

3.1.4 Argonne National Laboratory - East

The Argonne National Laboratory - East stores reactor irradiated nuclear materials in the Alpha-Gamma Hot Cell (Building 212, Wing F), the Chicago Pile 5 Building, and analytical laboratories within Building 205. The principal mission (past and present) of the Alpha-Gamma Hot Cell is research on the behavior of materials, fuel, and structures used in nuclear reactors. Chicago Pile 5 houses a shut-down, heavy-water, moderated reactor whose fuel has been removed and shipped offsite. Currently Chicago Pile 5 is in the process of being decontaminated and decommissioned and contains only two highly enriched uranium target (i.e., converter) elements. Building 205 contains analytical laboratories that perform analyses on gram quantities of SNF samples coming from the Alpha-Gamma Hot Cell (DOE 1993b).

3.1.4.1 Land Use. The laboratory and support facilities occupy about a 200-acre

(81-hectare) tract; 1,700 acres (688 hectares) within the site perimeter are devoted to forest and landscaped areas. The Dupage County Forest Preserve District operates 2,040-acre (826-hectare) green belt forest preserve, known as the Waterfall Glen Forest Preserve, which surrounds the site. Much of this forest preserve was formerly Argonne National Laboratory property but was deeded to the Forest Preserve District in 1973 for use as a public recreation area, nature preserve, and demonstration forest. In the past few years, a number of industrial parks have been constructed to the north and northwest of the laboratory. Also, many commercial establishments and a large number of dwelling units have been constructed within a few miles (kilometers) of Argonne National Laboratory. Before being occupied by Argonne National Laboratory, most of the site was wooded and the remaining land was used for farming (ANL-E 1993a).

3.1.4.2 Socioeconomics. Argonne National Laboratory is located within the Chicago

Standard Metropolitan Statistical Area, which comprises six Illinois and two Indiana counties around the southwest corner of Lake Michigan. The population between 1970 and 1990 in the region increased 1.2 percent from 6,491,300 to 6,568,800 people. During this time total Illinois population increased 2.9 percent. Data sources for this information include U.S. Bureau of the Census, Bureau of Economic Analysis, and Department of Energy documents (DOC 1992).

The nearby areas of Will and Cook Counties have generally developed at a considerably lower rate than has the DuPage County area, except along the Illinois Waterway where industrial development has taken place. Included within a 50-mile (80-kilometer) radius are portions of Lake and Porter Counties in Indiana, and all of DuPage, Will, Cook, Kendall, and Kane Counties in Illinois (DOC 1992).

Beyond the forest preserve at Argonne National Laboratory's perimeter, the population density is low, except for a high-density residential area--over 15 units per acre (37 units per hectare) and about 4,500 residents--beginning some 650 yards (600 meters) east of the perimeter. DuPage County's growth rate has been the highest of any metropolitan Illinois county. In 1990, the total number of housing units within region equaled 2,548,736. Cook County contained the largest percentage of the region's housing units (DOC 1991b).

With its workforce of about 4,700 persons, Argonne National Laboratory is one of the three largest employers in DuPage County. Employees commute to Argonne National Laboratory from distances as far as 30 miles (50 kilometers); thus the payroll is spread over a wide area. However, nearby villages, notably Lemont and Downers Grove, do house high numbers of Argonne National Laboratory employees. About 50 percent of Argonne National Laboratory employees reside within 10 miles (16 kilometers) of the site. The laboratory also purchases much of its utilities, outside services, equipment, and supplies locally (DOC 1992).

Employment associated with SNF management such as routine operations of the facility including care and periodic inventories of the SNF amounts to about 0.5 person-years per year (Neimark 1995).

3.1.4.3 Cultural Resources. The ANL-E site has no properties designated as National

Historic Landmarks or listed on the National Register of Historic Places.

In 1992, 26 archaeological properties had been recorded at ANL-E. One site has been evaluated as being potentially eligible for the National Register, 19 sites are not considered eligible, and 6 sites have not been evaluated (ANL-E 1993a).

The Illinois State Historic Preservation Agency has not evaluated the ANL-E site's potential to contain additional unidentified archaeological or architectural resources. The potential of the ANL-E site to contain traditional cultural resources of interest to Native American groups has not been evaluated (ANL-E 1993a).

3.1.4.4 Geology. The topography at ANL-E is generally gently rolling; the average

elevation is 725 feet (221 meters) above sea level. Slopes of consequence are found only adjacent to streams and near the southern edge of the site, where the fall into the Des Plaines River Valley begins (ANL-E 1993b). The geology of the Argonne National Laboratory area consists of about a 100-foot-thick (30-meter-thick) deposit of glacial till on top of dolomite bedrock. The bedrock at Argonne National Laboratory is the Niagaran and Alexandrian dolomite of Silurian age (about 400 million years old). These formations are underlain by Maquoketa shale of Ordovician age, and older dolomites and sandstones of Ordovician and Cambrian age. The beds are nearly horizontal (ANL-E 1993b).

The Niagaran and Alexandrian dolomite are about 200 feet (60 meters) thick in the Argonne National Laboratory area, and are widely used in DuPage County as a source of groundwater. The Maquoketa shale separates the upper dolomite aquifer from the underlying sandstone and dolomite aquifers. This shale retards hydraulic connection between the upper and lower aquifers; the lower aquifer has a much lower piezometric level and does not appear to be affected by pumpage from the overlying Silurian bedrock (ANL-E 1993a).

A capable fault is one that has had movement at, or near, the ground surface at least once within the past 35,000 years or recurring movement within the past 500,000 years (10 CFR 100, Appendix A). A few minor earthquakes have occurred in northern Illinois, believed to have been caused by isostatic adjustments of the Earth's crust in response to glacial unloading. Several areas of seismic activity are present at moderate distances from ANL-E, including the New Madrid Fault zone in the St. Louis area of southwestern Missouri, the Wabash Valley Fault zone along the southern Illinois-Indiana border, and the Anna region of western Ohio. Ground motions induced by near and distance seismic sources are expected to be minimal at the Laboratory (ANL-E 1993a).

A maximum horizontal ground surface acceleration of 0.15g at Argonne National Laboratory - East is estimated to result from an earthquake that could occur once every 2000 years (DOE 1994a). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility specific basis consistent with DOE orders and standards and site specific procedures.

No active volcanoes are considered to be in the ANL-E region (Keller 1979). Therefore, the potential for damage from volcanic activity is minimal.

The major soil type present at ANL-E is Morley silt loam. This soil covers approximately 70 percent of the site. Stream valley soils, including the Askum, Peotone, and Sawmill silty clay loams, cover approximately 15 percent of the site, urban land soils approximately 10 percent, and other minor soils the remaining 5 percent (Mapes 1979).

3.1.4.5 Air Resources. The regional climate around Argonne National Laboratory is

characterized as being continental, with relatively cold winters and hot summers. The area is subject to frequently changing weather as storm systems move from the Great Plains toward the east. The weather is slightly modified by Lake Michigan, which is about 22 miles (35 kilometers) east-northeast of the Laboratory (ANL-E 1993a).

Meteorological data presented here were compiled from the National Weather Service Station at the O'Hare International Airport in Chicago and from the meteorological tower operated at ANL-E. The prevailing winds for the airport are from the south and southwest with a northeast component. The frequency of calm winds, defined as those less than 2 miles per hour (1 meter per second), was approximately 4 percent. The 1992 average wind rose for the ANL-E site is very similar to this pattern, with prevailing winds from the west to south, but with a more significant northeast component. In 1992, the percentage of calm winds at ANL-E was approximately 3 percent (ANL-E 1993a).

The amount of rainfall recorded in 1992, 31.5 inches (80.01 centimeters), was nearly identical to the site's historical average of 31.48 inches (79.95 centimeter). The temperatures recorded during 1992 were also similar to the site's long-term averages. The coldest months during 1992 were January and December, with monthly averages of 27.9yF (-2.3yC) and 28.0yF (-2.2yC), respectively. The warmest months were July and August, with monthly averages of 68.5yF (20.3yC) and 66.9yF (19.4yC), respectively (ANL-E 1993a).

The area experiences about 40 thunderstorms annually. Occasionally, these storms are accompanied by hail, damaging winds, or tornadoes. From 1957 to 1969 there were 371 tornadoes in the state, with more than 65 percent occurring in the spring months. The theoretical probability of a tornado strike at Argonne is 8.54 x 10-4 each year, or a recurrence interval of 1 tornado every 1,200 years. The Argonne National Laboratory site was struck by tornadoes in 1976 and 1978, with minor damage to power lines, roofs, and trees.

The State of Illinois has adopted ambient air quality standards that specify maximum permissible short- and long-term concentrations of various contaminants (State of Illinois Rules and Regulations 1992). These standards are the same as the National Ambient Air Quality Standards for criteria pollutants (NAAQS; 40 CFR 50). In addition to standards for criteria pollutants, the Illinois Environmental Protection Agency has made applicable all regulations promulgated by the EPA relating to National Emission Standards for Hazardous Air Pollutants (NESHAP), under Section 112 of the Clean Air Act (40 USC 7412, 7601a).

The ANL-E site and the surrounding counties are classified by the EPA as severe nonattainment areas for the criteria pollutant ozone (O3). All other surrounding counties and areas are in attainment of the remaining National Ambient Air Quality Standards criteria pollutants: nitrogen dioxide (NO2), sodium dioxide (SO2), lead (Pb), particulate matter less than 10 microns in diameter (PM10) and carbon monoxide (CO) (with the exception of the Lyons Township in southeast Chicago, which is listed as a moderate nonattainment area for PM10) (ANL-E 1993b).

3.1.4.6 Water Resources.

Surface Water - The ANL-E is in the Des Plaines River drainage basin 24 miles (39 kilometers) west of Lake Michigan and is on the northern margin of the Des Plaines River valley. The largest onsite stream is Sawmill Creek, which originates north of the site and enters the Des Plaines River about 1.25 miles (2.01 kilometers) southeast from the center of the site. Two small streams originate onsite and combine to form Freund Brook, which discharges into a Sawmill Creek. Most of ANL-E is drained by Freund Brook. The Des Plaines River flows southwest about 30 miles (48 kilometers) until it joins with the Kankakee River to form the Illinois River (ANL-E 1993a). As noted in National Wild and Scenic Rivers System, December 1992 (USGS, 1992) the ANL-E region has no federally designated wild and scenic rivers.

Flow in Sawmill Creek, upstream from the ANL-E wastewater outfall, averaged 6.3 cubic feet (0.18 cubic meters) per second in 1992. Flow in the Des Plaines River near the site is approximately 900 feet3 (25.5 meters) per second (ANL-E, 1991). In addition, ANL-E facilities are not in the 500-year floodplain. The floodplain areas are largely confined to areas within 200 feet (61 meters) of the surface streams (ANL-E 1993a).

The potable and site water supplies are obtained from groundwater (ANL-E 1993b). The first downstream location where surface water is used for drinking is at Alton, on the Mississippi River, about 370 miles (595 kilometers) from ANL-E. The first downstream location where surface water is used for drinking is at Alton, on the Mississippi River, about 370 miles (595 kilometers) from ANL-E (ANL-E 1993b).

The ANL-E has nine National Pollutant Discharge Elimination System permitted outfalls, most of which discharge directly or indirectly to Sawmill Creek (ANL-E 1991).

In addition to this outfall monitoring, surface water bodies in the region are routinely monitored for radioactive and nonradioactive parameters. In 1990, measurable levels of americium-241, californium-249, californium-252, cesium-137, curium-242, curium-244, neptunium-237, plutonium-238, plutonium-239, strontium-90, and tritium were detected in Sawmill Creek downstream from the only small fraction of the DOE-derived concentration guides for water (DOE Order 5400.5). Dilution in the Des Plaines River reduced the concentration of the measured radionuclides to levels below their respective detection limits. Streams sediments in the ANL-E region are routinely sampled for radionuclides at 3 onsite and 10 offsite locations. These samples are not routinely analyzed for chemical constituents (ANL-E 1991).

Groundwater - The ANL-E vicinity uses two principal aquifers for its water supply. The upper aquifer is the Niagara and Alexandria dolomite, which is about 200 feet (61 meters) thick in the region and has a potentiometric surface between 500 and 100 feet (152 and 30 meters) below ground (ANL-E 1993b). Water flows through this unit in a southern direction (ANL-E 1991). No aquifers in the region are considered sole source aquifers under the Safe Drinking Water Act regulations (EPA 1994).

The ANL-E receives its potable water supply from four wells in the Niagara dolomite aquifer. These wells are approximately 300 feet (91 meters) deep and provide hard water that requires treatment before use (ANL-E 1993b). Treated sanitary and laboratory wastewater from ANL-E are combined and discharged into Sawmill Creek. This effluent averaged 0.83 million gallons (3.1 million liters) per day (ANL-E 1993a).

Groundwater is monitored for radioactive and nonradioactive parameters at 32 ANL-E locations. Groundwater in the four onsite drinking water wells is also monitored for radioactive and nonradioactive parameters, as required by the Safe Drinking Water Act. In 1990, all results were less than the limits established by the Safe Drinking Water Act except for elevated levels of total dissolved solids and turbidity. The average concentration of tritium was approximately 1 percent of the EPA Primary Drinking Water Standard of 20,000 picocuries per liter. One well was removed from service in 1990 (ANL-E 1991).

3.1.4.7 Ecological Resources. The Argonne National Laboratory site lies within the

Prairie Peninsula Section of the Oak-Hickory Forest Region. The Prairie Peninsula is a mosaic of oak forest, oak openings, and tall-grass prairie occurring on glaciated parts of Illinois, northwest Indiana, southern Wisconsin, and parts of other states. Forests in the Argone National Laboratory-East region are predominantly oak hickory. Other forested areas consist of sugar maple, red oak, and basswood (ANL-E 1993a).

The mixture of vegetational communities (open fields, deciduous forests, pine plantations, wetlands, and mowed rights-of-way), coupled with a large degree of protection from human intrusion, makes the Argonne National Laboratory site an effective refuge for many species of animals. These animals are characteristically found in open fields, forests, and forest-edge communities in the Midwest. Also other bird species use the Argonne National Laboratory site as a stopover during spring and fall migrations. By far, the most numerous animals on the site are the small invertebrates (ANL-E 1993b).

The site is inhabited by fallow deer, (Dama dama), eastern cottontail rabbit, opossum, raccoon and squirrels. Although fallow deer have several color varieties, only the white variety occurs at Argonne. Invertebrate fauna consist primarily of dipteran larvae, crayfish, caddisfly larvae, and midge larvae. Few fish are present due to the low summer flows and high temperatures. Wetlands include a cattail marsh and wooded swamp habitat (ANL-E 1993b).

An opinion rendered by the U.S. Fish and Wildlife Service indicated that the only federally listed endangered or threatened vertebrate species likely to be present in the vicinity of the Argonne National Laboratory site is the Indiana bat (Miotis sodalis). An unconfirmed capture of an Indiana bat in nearby waterfall Glen Forest Preserves indicates that the bat may occur on the ANL-E site. In addition, a September 1980 updated of the "Red Book" for the North-Central Region lists the federally endangered bald eagle (Haliaeetus leucocephalus) as wintering in nearby Will County. Both American and Arctic subspecies of the peregrine falcon (Falco peregrinus anatum and F. p. tundrius) and Kirtland's warbler (Dendroica kirtlandii) migrate through northeastern Illinois and thus might occasionally be found on or near the Argonne National Laboratory site. All three of these bird taxa are on the Federal endangered species list (ANL-E 1993b).

At least two plant species proposed for Federal endangered/threatened designation are known to occur in counties near the Argonne National Laboratory site and therefore might be present here. These are Thismia americana, found on wet prairies in Cook County; and Plantago cordata, a plant of wet woodlands recorded in Will County (ANL-E 1993b).

3.1.4.8 Public Health and Safety. The highest annual dose received by an offsite

resident from a combination of the separate airborne and direct exposure pathways from the most recent reports for a 5-year period is presented below (ANL-E 1993a, 1992, 1991, 1990, 1989). The annual doses are only a fraction of the DOE Public Dose Limit of 100 millirem per year. The data are from all laboratory operations, including storage of SNF.

1988	0.66 millirem
1989	0.49 millirem
1990	0.41 millirem
1991	0.29 millirem
1992	0.34 millirem

The total annual population dose to the entire area within a 50-mile (80-kilometer) radius of the laboratory for a 5-year period is presented below (ANL-E 1993a, 1992, 1991, 1990, 1989). The data are from all laboratory operations, including storage of SNF.

1988	25 person-rem
1989	17 person-rem
1990	15 person-rem
1991	15 person-rem
1992	17 person-rem

3.1.4.9 Waste Management. Activities conducted at ANL-E generate a variety of

radioactive and hazardous waste streams (DOE 1994b).

The ANL-E reports 10 mixed waste streams in the inventory of operations waste. Of these, eight are low-level mixed waste streams and two are mixed transuranic waste streams. The ANL-E currently stores about 2.5 cubic yards (1.9 cubic meters) of mixed transuranic waste and projects that 2.1 yards3 (1.6 meters3) of additional transuranic wastes will be generated through the end of 1997. This waste will be processed as necessary (characterized, repackaged, immobilized) to meet the waste acceptance criteria of the Waste Isolation Pilot Plant (DOE 1993e).

The ANL-E has no facilities for treating low-level mixed waste and transuranic waste. ANL-E currently stores about 125 cubic yards (96 meters3) of low-level transuranic waste, which includes low-level waste and transuranic waste reclassified as low-level transuranic waste. Roughly 30 meters3 (39 cubic yards) of low-level transuranic waste are projected to be generated through the end of 1997 (DOE 1993e).

Two major, unused facilities at ANL-E are undergoing environmental restoration. The Laboratory expects to complete removal of the Experimental Boiling Water Reactor vessel by the end of Fiscal Year 1995 and to complete the conversion of the CP-5 reactor building to an interim safe storage condition during Fiscal Year 1994 (DOE 1993f).

3.2 Domestic Research Reactors

The environments of domestic research reactors that may be affected by SNF activities are described in this section. Representative environments of sites generating and storing SNF are described as a basis for assessing the 57 reactor sites identified in Subsection 2.1.2. This approach was selected to permit enveloping the characteristics of the large number of sites covered. Additionally, it is recognized that the programmatic SNF analyses in this EIS are not intended to be site specific. Site-specific environmental information has already been presented to the NRC and analyzed as part of the facility licensing process.

Domestic research reactors are located in a wide variety of environmental settings, ranging from relatively densely populated urban areas to rural/semirural university campuses and industrial parks. To provide reasonably representative descriptions of potentially affected environments for these diverse installations, environmental information has been provided for 5 of the 11 Category 1 reactor sites. These five reactor sites encompass the diverse range of reactor types and power level as well as diverse environmental setting.

As reported in 1988, there were a total of 268 personnel working at the 11 Category 1 reactors (ANS 1988). This number included operators, experimenting scientists, and support personnel. While not their main occupation, part of the duties of the operators and some support personnel include tasks associated with refueling, storing, inventorying, packaging, and shipping SNF.

Environmental information is provided for those facilities whose ability to store SNF is limited when compared to their fuel burnup rate. For those operating facilities possessing adequate storage for their SNF, projected to be generated through 2035, there would be no incremental impacts on the surrounding environment. Accordingly, no environmental analyses have been performed and no information is provided in this section.

The environmental information for each of these reactors has been presented as part of their license applications to the NRC and has been assessed by that agency as part of the licensing process for each facility. The environmental impacts of expanded storage of SNF at these facilities are expected to be minimal (although other effects on the institutions themselves may be extensive). Information on environmental factors that are not affected by the activities of storing SNF at these sites (including cultural resources, aesthetic and scenic resources, ecological resources, noise, traffic and transportation, utilities and energy, materials and waste management) is not provided in this document.

Data on the calculated doses to the general public resulting from effluents from NRC licensed research reactors is not available, since their license and reporting requirements were not the same as those for DOE facilities. At the time of the reports (1987-1993), the effluent release limits in 10 CFR 20 (specified as maximum permissible concentrations) were based on a dose limit of 500 millirem per year to a hypothetical member of the public. The conservative assumptions made in calculating the 10 CFR 20 concentration limits were that the person only drank the water and breathed the air released from the licensed facility. The licensed research reactors proved to the NRC that the dose limit of 500 millirem per year for the general public was being met by maintaining the release concentrations at the site boundary below the maximum permissible concentration limits specified in 10 CFR 20. In reality, the actual dose received by any member of the public was well below the prescribed limit of 500 millirem per year because 1) no individual drinks the water discharged in the sewer systems from these facilities, 2) no individual stands at the closest downwind location for 24 hours a day, 365 days a year, and 3) the radioactivity concentrations at the site boundary are well below the concentration limits.

As of 1993, licensed research reactors are required to meet the dose limits specified by the EPA in 40 CFR 61 of 10 millirem per year to the maximum exposed individual from airborne effluents. In addition, as of 1994, the licensed research reactors are required to comply with the new 10 CFR 20, in which exposure to any member of the public from all pathways is limited to 100 millirem per year.

3.2.1 National Institute of Standards and Technology Research Reactor

The National Institute of Standards and Technology research reactor, formerly known as the National Bureau of Standards Reactor, is a highly enriched, heavy-water-cooled and moderated vessel-type reactor. The National Institute of Standards and Technology reactor received an Atomic Energy Commission provisional license in 1967 to operate at 10 MW. On May 16, 1984, the NRC upgraded the National Institute of Standards and Technology research reactor license to operate for 20 years at up to 20 MW (NRC 1983).

The spent fuel storage pool, located in the basement of the confinement building, is used to store spent fuel under filtered, demineralized water until the fuel is shipped offsite. A spent-fuel storage pool cooling system is installed to dissipate the decay heat from elements stored in the pool. Storage racks are provided to store both full fuel elements and cut fuel pieces in a defined geometry. Boral or stainless steel spacers are placed between elements as required to control criticality. The storage rack arrangement ensures that the fuel in the pool remains subcritical (NRC 1983).

The National Institute of Standards and Technology site is a 576-acre tract of land in upper Montgomery County, Maryland, approximately 1 mile (1.6 kilometers) southwest of the City of Gaithersburg, Maryland. According to the 1990 census, the population of Gaithersburg was 39,542 (Rand 1992). The general area is a combination of residential and rural. The nearest population centers are Gaithersburg, adjacent to the site, and Rockville, 5 miles (8 kilometers) southeast of the site. The National Institute of Standards and Technology site is located approximately 20 miles (32 kilometers) northwest of the center of the District of Columbia. The National Institute of Standards and Technology campus is bounded on the east by a major interstate highway (I-270), on the north and west by Maryland Route 124, and on the southeast by Muddy Branch Road. The area adjacent to the reactor building is occupied by a parking lot, the reactor cooling tower, and roads. Thus, the area within a 500-foot (152-meter) radius of the reactor building stack is not readily available for the construction of new buildings, and planning for future development of the National Institute of Standards and Technology site does not include any new buildings within 500 feet (152 meters) of the reactor stack. The site boundary nearest to the National Institute of Standards and Technology reactor is approximately 0.25 mile (0.4 kilometer) southwest of the reactor. The nearest offsite residential or commercial housing is about 1,500 feet (457 meters) to the southeast of the reactor (NRC 1983).

During the period 1955-1967, 28 tornadoes were reported in a 2 degree latitude-longitude square containing the site. The computed recurrence interval for a tornado at the National Institute of Standards and Technology site is about 2000 years. Numerous tropical storms, tornadoes and hurricanes have affected the area. In the period from 1871 to 1978, about 20 tornadoes or hurricanes have passed within 100 miles (160 kilometers) of the site (NRC 1983).

There is no known major fault in the site vicinity (Seismic Zone 1). There is no known relationship between mapped faults and the moderate seismicity in the region. The maximum potential earthquake for the area was estimated to result in a maximum ground acceleration of 0.07 g at the reactor site. The effects of stresses developed by 0.1 g earthquake loadings have been evaluated, and it was demonstrated that the confinement building and reactor equipment would remain intact and maintain their capability (NRC 1983).

A summary of the radioactive material released in airborne and liquid effluents from the National Institute of Standards and Technology from the most recent reports for a 5-year period is presented below (NIST 1993, 1992, 1991, 1990, 1989).

Year	Airborne effluents		Liquid effluents into sanitary sewer	
	Argon-41	Tritium	Tritium	Other beta-gamma emitters
1988	900 Ci	393 Ci	5.1 Ci	0.0026 Ci
1989	328 Ci	461 Ci	2.9 Ci	0.0039 Ci
1990	687 Ci	309 Ci	2.2 Ci	0.0011 Ci
1991	971 Ci	251 Ci	1.8 Ci	0.0016 Ci
1992	665 Ci	351 Ci	1.5 Ci	0.0004 Ci

3.2.2 Massachusetts Institute of Technology Research Reactor

The Massachusetts Institute of Technology Reactor is a tank-type, light-water cooled and moderated, heavy-water reflected, plate fuel, research and training reactor. The Massachusetts Institute of Technology Reactor received its 5 MW operating license June 9, 1958 and originally was designed to have a heavy-water moderated and cooled core utilizing curved plate-type fuel elements, highly enriched in uranium-235. The major revision of the core design occurred in 1970 (MIT 1981, 1970).

The reactor building is a steel, gas-tight, 70-foot (21.3-meter) internal diameter, 50-foot (15.2-meter) high, domed right cylinder with 2-foot (0.6-meter) thick concrete shielding walls on the inside. The reactor building basement contains an 8-foot (2.4-meter) diameter, 20-foot-deep (6-meter-deep) spent fuel storage tank of demineralized water. The containment building has an air conditioning and multiple filter ventilation system which exhausts to a 150-foot (46-meter) stack.

Irradiated fuel elements can be stored in any of the following locations:

a) In the reactor core
b) In the cadmium-lined fuel storage ring (holds 27 SNF elements) attached to the flow shroud, or briefly in a three-element rack in the core tank used during transfers of spent fuel out of the core tank
c) In 22 steel-lined dry storage holes, 5 inches (13 centimeters) in diameter, on the reactor top biological shield
d) In the spent fuel storage tank in the basement of the reactor building
e) In the fuel element transfer flask or other proper shield within the controlled area.

The Massachusetts Institute of Technology Reactor is located a few blocks northwest of the main Massachusetts Institute of Technology campus in Cambridge, Massachusetts and less than 2,000 feet (610 meters) from the Charles River, which separates Cambridge from Boston. According to the 1990 census, Cambridge had a population of 95,802 (Rand 1992). The MIT Reactor is located in the midst of a heavily industrialized section of Cambridge. The site measures approximately 280 feet in length by 150 feet in width (85 meters by 46 meters). Boston and Albany Railroad tracks, used exclusively for freight traffic, run parallel to the back of the reactor exclusion area. Although the site boundary comes nearest to the reactor on the side facing the railroad tracks, the closest point of normal public occupancy near the site boundary is on the Albany Street side at approximately 120 feet (37 meters). (MIT 1970)

The Massachusetts Institute of Technology Meteorology Department has stated that conditions for the reactor site should vary only slightly from those at Logan Airport in east Boston. The area atmospheric conditions vary from highly stable situations with light winds to unstable periods with strong winds in excess of 47 miles (75.6 kilometers) per hour. Water drainage from the reactor site is into the Charles River and on into Boston Harbor and Massachusetts Bay. The drainage in this section of Cambridge is such that after a record-breaking 20 inches (0.5 meter) of rain fell in 48 hours, the Charles River did not overflow its banks, nor was the area inundated (MIT 1970).

The Cambridge area lies in the Boston Basin which has been relatively free of earthquakes in the past 150 years but had several earthquakes in the preceding centuries. The region is located in Seismic Zone 2. The most severe shock with a probable epicenter near Cambridge occurred in 1755 with a Rossi-Forel intensity of 9 (equivalent to Modified Mercalli Intensity IX or X). Partial or total destruction of some buildings occurred. Since 1817, no earthquake with a Rossi-Forel intensity of more than 5 (equivalent to Modified Mercalli Intensity VI) has been reported near Boston (MIT 1970).

A summary of the radioactive material released in airborne and liquid effluents from the Massachusetts Institute of Technology Research Reactor from the most recent reports for a 5-year period is presented below (MIT 1992, 1991, 1990, 1989, 1988). Liquid radioactive wastes generated at the Massachusetts Institute of Technology Research Reactor facility are discharged only to the sanitary sewer serving the facility. All releases were in accordance with Technical Specifications 3.8-1 and 10 CFR 20. All activities were substantially below the limits specified in 10 CFR 20.303. Gaseous radioactivity is discharged to the atmosphere from the containment building exhaust stack. All gaseous releases were in accordance with the Technical Specifications and all nuclides were below the limits of 10 CFR 20. The information is reported by fiscal year, from July 1 of the previous year to June 30 of the current year.

Year	Airborne effluents	Liquid effluents into sanitary sewer	
	Argon-41	Tritium	Other beta-gamma emitters
1988	2627 Ci	0.071 Ci	0.0011 Ci
1989	1529 Ci	0.107 Ci	0.0034 Ci
1990	543 Ci	0.059 Ci	0.0220 Ci
1991	684 Ci	0.115 Ci	0.0071 Ci
1992	728 Ci	0.023 Ci	0.0137 Ci

3.2.3 University of Missouri/Columbia Research Reactor

The University of Missouri/Columbia Research Reactor is a 10 MW tank in pool light water moderated and cooled research reactor. The reactor uses plate-type fuel containing 93 percent enriched uranium-235. The core forms an annular fuel region which is pressurized and cooled by forced convection. The University of Missouri/Columbia Research Reactor received its operating license October 11, 1966 and initially operated at 5 MW. The reactor power was increased to 10 MW in 1974 (UMC 1965; NRC 1991b).

The reactor is housed in a five-level, poured-concrete, gas-tight containment building which is in the center of the Research Reactor Facility, a one-level building of poured-concrete, block and brick construction. The reactor vessel is located eccentrically within an open pool 10 feet (3 meters) in diameter and 30 feet (9 meters) deep. Permanent SNF storage is provided within the biological shield, in a pool separated from the reactor by a massive submerged concrete weir (UMC 1965).

The University of Missouri/Columbia Research Reactor currently has 44 fuel elements in the core, 20 SNF elements in wet storage and none in dry storage. Without offsite shipment of SNF, the University of Missouri/Columbia Research Reactor's storage capacity of 120 elements would be filled by June 1996. Before this could occur, NRC approval would be required to raise the reactor's uranium-235 possession limit above 165 pounds (75 kilograms). Increased SNF storage capacity could be achieved by reracking and building a new wet-storage area within the reactor building. However, there are no plans to expand the current SNF storage capacity (Jentz 1993).

The University of Missouri/Columbia Research Reactor Facility is located within the 85-acre (0.344-square-kilometer) Research Park about 1 mile (1.6 kilometers) southwest of the main campus of the University of Missouri, south of the main business district of the city of Columbia, Boone County, Missouri. According to the 1990 census, the population of Columbia was 69,101 (Rand 1992). The nearest permanent residence is approximately 1,000 feet (305 meters) from the reactor. There are a number of small industrial activities in the area, but for the county, agriculture is the leading activity.

Wind speeds up to 50 miles (80 kilometers) per hour are not uncommon at Columbia. Ninety-four-mile-per-hour (151-kilometer-per-hour) winds have an average recurrence interval of 100 years; winds of 105 miles (169 kilometers) per hour have an average recurrence interval of

200 years. The frequency of tornadoes is so low that it is difficult to estimate the probability of the event. In most of the Midwest, there are an average 2.5 tornadoes per year in a 10,000 square-mile (25,900-square-kilometer) area. Surface drainage from the site moves south to enter Hinkson Creek, which drains to Perche Creek and then to the Missouri River (UMC 1961).

Columbia's position within the stable area of Missouri (Seismic Zone 1) and the seismic history of the area indicate that the probability of seismic damage to the area is extremely low.

A summary of the radioactive material released in airborne and liquid effluents from the University of Missouri/Columbia Research Reactor from the most recent reports for a 5-year period is presented below (UMC 1992, 1991, 1990, 1989, 1988). The information is reported by fiscal year, from July 1 of the previous year to June 30 of the current year.

Year	Airborne effluents		Liquid effluents into sanitary sewer	
	Argon-41	Tritium	Tritium	Other beta-gamma emitters
1988	813 Ci	14.5 Ci	0.077 Ci	0.0080 Ci
1989	920 Ci	2.8 Ci	0.0352 Ci	0.0085 Ci
1990	590 Ci	2.3 Ci	0.555 Ci	0.0385 Ci
1991	520 Ci	15.0 Ci	0.1600 Ci	0.0250 Ci
1992	440 Ci	0.73 Ci	0.2094 Ci	0.0488 Ci

3.2.4 University of Michigan Ford Nuclear Reactor

The University of Michigan's Ford Nuclear Reactor is a pool-type heterogeneous 2-megawatt-thermal reactor that is light-water cooled and moderated. The Ford Nuclear Reactor has been operated since 1957 and received a 20-year license renewal from the NRC on July 29, 1985 (NRC 1985c). Its principal function is for teaching, research, activation, and experiments (NRC 1985d).

The reactor is located in a windowless, four-story reinforced concrete building that is approximately a 70-foot (21.3-meter) cube. The reactor room, designed to restrict leakage, is equipped with its own ventilation system and exhaust stack (NRC 1985d).

The Ford Nuclear Reactor site situated on the North Campus, which is about 1.75 miles (2.8 kilometers) northeast of the old University of Michigan campus. The North Campus is a tract of nearly 900 acres (3.64 square kilometers), approximately 1.5 miles (2.4 kilometers) northeast of the center of Ann Arbor. According to the 1990 census, the population of the city of Ann Arbor was 109,592 (Rand 1992). The University of Michigan controls all the land within 1500 feet (457 meters) of the reactor site, with the exception of a small portion of the highway right-of-way along Glacier Way to the southeast and the Arborcrest Cemetery, located 800 feet (244 meters) to the east of the site. The reactor exclusion area consists of all the land 500 feet (152 meters) to the east, 1000 feet (305 meters) to the west and north, and 1200 feet (366 meters) to the south (NRC 1985d).

The reactor building and the contiguous Phoenix Memorial Laboratory are located near the center of the North Campus area. The following guidelines were used by the university in developing the North Campus area: (1) only laboratory and research buildings will be constructed within 50 feet (15 meters) of the reactor and (2) no housing or other buildings containing housing facilities will be erected within 1500 feet (457 meters) of the reactor. Therefore, all buildings, except the reactor and laboratory buildings, are generally occupied during normal school hours only. The closest permanent residences are about 1500 feet (457 meters) from the Ford Nuclear Reactor facility (NRC 1985d).

The heaviest rainfall intensity occurs in connection with thundershower activity, and the heaviest recorded 24-hour period of rainfall was approximately 5 inches (13 centimeters). Hourly intensities as high as 1.2 inches (3 centimeters). occur with a frequency of once every 2 years. Average annual snowfall is 30.2 inches (76.7 centimeters.). Annual totals have ranged from 13 to 54 inches (33 to 137 centimeters). The heaviest recorded snowfall for a single day was 6.2 inches (15.7 centimeters). The highest wind velocity recorded in the Ann Arbor area was 60 miles per hour (27 meters per second). Michigan lies at the northeastern edge of the nation's maximum frequency belt for tornadoes. For the past decade, Michigan has averaged nine tornadoes per year, 90 percent of which have been in the southern half of the lower peninsula (NRC 1985d).

The University of Michigan Ann Arbor site, within the Central Stable Region, is characterized by a relatively low level of seismic activity (Seismic Zone 1). Recent interpretations of geophysical investigations suggest that different areas of the Central Stable Region exhibit different levels of seismic activity. For instance, Barstow et al. developed an earthquake frequency map for the eastern United States that places Ann Arbor in a zone where 8-15 earthquakes per 4500 square miles (11,660 square kilometers), with Modified Mercalli Intensities of III or greater, have occurred during the time period 1800-1977. The Anna, Ohio, location experienced a frequency of 32-63 earthquakes per 4500 square miles (11,660 square kilometers) with Modified Mercalli Intensity III or greater for the same time period. The Michigan Basin area, in general, is considered to have had no more than 0-3 earthquakes per 4,500 square miles (11,660 square kilometers) of Modified Mercalli Intensity III or greater. A seismicity map developed by the Geological Survey of the State of Michigan shows that for the time period from 1872-1967, only 34 earthquakes were felt (reported) in the entire State of Michigan. A U.S. Geological Survey seismicity map of the State of Michigan shows a total of 83 earthquakes in the state since 1872. The nearest of these to Ann Arbor (March 13, 1978; Modified Mercalli Intensity IV) was about 30 miles (48 kilometers) away. Only six earthquakes have been reported within 60 miles (96 kilometers) of Ann Arbor. The risk of damage from earthquakes to well-designed structures is relatively low for the Ann Arbor area. In addition, the earthquake intensity/magnitude potential is relatively low for the Michigan region, and there are no known structures in the Ann Arbor area capable of causing earthquakes (NRC 1985d).

A summary of the radioactive material released in airborne and liquid effluents from the Ford Nuclear Reactor from the most recent reports for a 5-year period is presented below (UMI 1994, 1993, 1992, 1991, 1990).

Year	Airborne effluents	Liquid effluents into sanitary sewer	
	Argon-41	Tritium	Other beta-gamma emitters
1989	31 Ci	0.051 Ci	0.18 Ci
1990	35 Ci	0.069 Ci	0.48 Ci
1991	41 Ci	0.079 Ci	0.11 Ci
1992	39 Ci	No discharges	
1993	39 Ci	No discharges	

3.2.5 University of Texas TRIGA

The University of Texas General Atomic TRIGA Mk-II Reactor replaces an earlier TRIGA Mk-I reactor which had been in operation on the main campus in Austin, Texas since 1963. The TRIGA Mk-II is a 1.1 MW heterogeneous, pool-type reactor incorporating solid uranium-zirconium hydride fuel-moderator elements with an enrichment of 19.7 percent uranium-235. The University of Texas TRIGA core is similar to most other TRIGA reactors operated throughout the world as well as the United States. It received its NRC operating license on January 17, 1992 (NRC 1985a, 1992).

The University of Texas TRIGA Mk-II Reactor facility is housed in the Nuclear Engineering Teaching Laboratory on the east tract of the Balcones Research Center about 7 miles (11.3 kilometers) north of the University of Texas main campus, in the City of Austin, Travis County. According to the 1990 census, the City of Austin had a population of 465,622 (Rand 1992). Residential areas are located from 0.8 to 1.3 miles (1.3 to 2.1 kilometers) from the reactor facility. Most areas adjacent to the research center are developed for mixed commercial and industrial activities. Major activities in the area are from the University of Texas main campus at Austin and the State of Texas government and the business district of the City of Austin (NRC 1985a).

Destructive wind and damaging hailstorms are infrequent. On rare occasions, dissipating tropical storms affect the city with strong winds and heavy rains. Tornado activity at the site is roughly one event per year per 1000 square miles (2,600 square kilometers), or 4 x 10-6 per year for an area of 333 square feet (30.8 square meters), which is roughly equal to the general site area. Water drainage at the immediate site is primarily related to the potential but temporary occurrence of extreme rainfall rates. Surface water runoff from the Balcones Research Center site is drained into the Shoal Creek Watershed except for the extreme northeast region of the site, which drains into the Walnut Creek watershed. The facility is located in the northeast site region with drainage into the Walnut Creek watershed. It is situated at an elevation well above the local area flood plain, and is located nearly equidistant 0.5 mile (0.8 kilometer) from the drainage easements of both watersheds. Thus no significant general site area flooding is anticipated (NRC 1985a).

The University of Texas TRIGA reactor site is located in a zone where no damage from earthquakes is expected (Seismic Zone 1). This does not mean, however, that the area is aseismic. The Austin region has experienced three (recorded) earthquakes within a 50-mile (92.6-kilometer) radius since the late nineteenth century:

- May 1, 1873--Manor earthquake with epicentral Modified Mercalli Intensity III-IV
- January 5, 1887--Paige earthquake with epicentral Modified Mercalli Intensity V
- October 9, 1902--Creedmore earthquake with epicentral Modified Mercalli Intensity IV-V.

Other regions in central and east Texas have experienced earthquakes of epicentral Modified Mercalli Intensity V and possibly VI. Damage from an Modified Mercalli Intensity VI earthquake is limited to cracked plaster and damage to chimneys. Structures of good design do not begin to experience damage from intensities below Modified Mercalli Intensity VII. Therefore, when state-of-the-art engineering practices for general structures of common design are adhered to, seismic excitations from earthquakes of Modified Mercalli Intensities V or VI are not expected to affect the integrity of the reactor (NRC 1985a).

The University of Texas TRIGA reactor recently became operational, with its first criticality occurring in March 1992. There is no history of releases and exposures for this reactor.

3.3 Nuclear Power Plant Spent Nuclear Fuel

In this section, the environments of three facilities housing power reactor SNF to be managed by DOE are described. These facilities are the West Valley Demonstration Project in New York State; the Fort St. Vrain SNF Storage Facility in Colorado; and the B&W Research Technology Center in Virginia. General environmental concerns related to these facilities and their operation have been addressed either during their initial licensing/permitting activities or during a subsequent amendment process. Information on environmental factors that are not uniformly available in existing NEPA documentation for all three sites (noise, traffic, utilities and energy, and waste management) are not provided in this document.

3.3.1 West Valley Demonstration Project

The West Valley Demonstration Project consists of numerous structures and facilities. The Fuel Receiving & Storage facility, located adjacent to the original fuel reprocessing plant, is where SNF management activities at the West Valley Demonstration Project are currently performed. The Fuel Receiving & Storage facility consists of the following buildings and systems (WVNS 1993).

- Fuel Receiving & Storage Building - This building contains the spent fuel pool, cask unloading pool, cask decontamination area, cask and fuel handling equipment, and the spent fuel pool water treatment system.
- The water treatment system maintains a water quality that ensures visual clarity for underwater operations and that degradation of the SNF is minimized.
- The spent fuel pool provides shielding from irradiated fuel and ensures that stored assemblies are maintained in a critically safe geometry. The pool is about 30 years old and was not designed with a liner or a leak detection system, nor were the fuel racks designed to withstand a design-basis earthquake.
- Radwaste Process Building - This building houses the equipment for the Radwaste Treatment System, including the high integrity containers used to store spent resins and filter media, as well as shields for those containers.
- Recirculation Ventilation Building - This building houses the ventilation equipment for the Fuel Receiving & Storage building including fans, filters, heaters, chiller, and controls.

The Western New York Nuclear Service Center is located in the town of Ashford, Cattaraugus County, in rural western New York State, approximately 31 miles (50 kilometers) south of Buffalo and 24.5 miles (40 kilometers) inland (east) of Lake Erie. The West Valley Demonstration Project site consists of a 220-acre (88-hectare) tract which is located in the center of the 3,345-acre (1,341-hectare) Western New York Nuclear Service Center, (WVNS 1992a).

3.3.1.1 Land Use. Regional land use is predominantly agricultural, with some scattered

residential areas. The communities of West Valley, Riceville, Ashford, Hollow, and the village of Springville are located within 5 miles (8 kilometers) of the West Valley Demonstration Project. The proximity of the city of Buffalo, Lake Erie, and Lake Ontario influence land use patterns in the region (WVNS 1992a).

3.3.1.2 Socioeconomics. The West Valley Demonstration Project comprises Cattaraugus

and Erie Counties in the State of New York. These counties collectively account for 96 percent of the site's employee residential distribution. Most West Valley Demonstration Project employees live in Erie County. Total employment in the region increased 14.4 percent between 1970 and 1990. During the same period, total population in the region decreased 12.2 percent. Personal income in 1990 for Cattaraugus and Erie County residents was $13,698 and $18,305, respectively (DOC 1992). The total number of housing units within the region is 438,970.

The number of regular employees working at West Valley Demonstration Project is 1050 personnel. Employment associated with SNF management at West Valley amounts to 9 person-years per year (Connors 1995).

3.3.1.3 Cultural Resources. The cultural resources of 360 acres (145 hectares) that may

be affected by future West Valley Demonstration Project Plans and/or West Valley Demonstration Project completion and Western New York Nuclear Service Center closure have been investigated. No recorded extant historic structures are located within or adjacent to the study area, but seven recorded prehistoric sites are within a 1.5-mile (2.4-kilometer) radius of the study area described below. There are no structures or prehistoric sites within the study area nor within the town of Ashford that are listed on the New York State Register of Historic Places or the National Register of Historic Places (WVNS 1994).

3.3.1.4 Aesthetic and Scenic Resources. The natural landscape in the area consists of

rolling wooded hillsides, a mix of actively used agricultural fields, inactive farm fields reverting to brush, and rural homesites. Large portions of the Western New York Nuclear Service Center are relatively undisturbed and consist of a mixture of abandoned agricultural areas in various stages of ecological succession, forested tracts, and wetlands joined by transitional ecotones. The terrain in the area of the Western New York Nuclear Service Center is not unique in terms of landforms, vegetation, expanses of water, or land use (WVNS 1993).

3.3.1.5 Geology. The West Valley Demonstration Project is located within the

Cattaraugus highlands, which is a transitional zone between the Appalachian Plateau Province and the Great Lakes Plain (WVNS 1993).

No fold or fault of any consequence is recognized within the site. The Clarendon-Linden Structure is the closest active "capable" earthquake (fault)-producing feature known to exist in the region. It is approximately 23 miles (37 kilometers) from the site (WVNS 1993). The site has experienced a moderate amount of relatively minor seismic activity. During historical times, ground motion at the site probably has not exceeded a Modified Mercalli Intensity of IV or a horizontal acceleration of 0.05g. It is estimated that the maximum earthquake on the Claredon-Linden Structure would produce an earthquake of Modified Mercalli Intensity of VI to VII and a maximum horizontal acceleration of approximately 0.12g at the site. The Claredon-Linden Fault Zone is located approximately 18 miles (29 kilometers) east of the West Valley Demonstration Project (WVNS 1993).

The West Valley Demonstration Project region has no active volcanoes (Keller 1979). The major soil types at the West Valley Demonstration Project include the well-drained Chenango gravelly loam, the poorly drained Erie silt loam, and the poorly drained Mahoning silt loam.

3.3.1.6 Air Resources. A 200 feet (60-meter) onsite meteorological tower is operated by

DOE at the West Valley Demonstration Project. A review of the West Valley Demonstration Project tower's 1992 data indicates that the prevailing wind was from the south-southeast with a mean wind speed of 5.4 miles per hour (2.4 meters per second). The precipitation for 1992 was 7.1 inches (18 centimeters) above the annual average of 40.9 inches (104 centimeters). The onsite 1992 wind data and National Weather Service wind data collected at Buffalo airport did not compare well, thereby indicating that Buffalo airport is not representative for predicting conditions at the West Valley Demonstration Project.

The state of New York has adopted national ambient air quality standards. The West Valley Demonstration Project is in a Class II Prevention of Significant Deterioration area. The nearest Class I Prevention of Significant Deterioration area is the Edwin B. Forsyth National Wildlife Refuge, approximately 300 miles (483 kilometers) southeast of the site.

3.3.1.7 Water Resources. The West Valley Demonstration Project is located in the

Cattaraugus Creek drainage basin, which is part of the Great Lakes - St. Lawrence watershed. All surface drainage from the West Valley Demonstration Project is to Buttermilk Creek, which flows into Cattaraugus Creek and ultimately into Lake Erie (WVNS 1992a). Cattaraugus Creek is used for swimming, canoeing, and fishing. Although limited irrigation water for nearby golf course greens and tree farms is taken from Cattaraugus Creek, no public water supply is drawn from the creek downstream of the site. The West Valley Demonstration Project has three National Pollutant Discharge Elimination System permitted outfalls that discharge to Erdman Brook (WVNS 1992a).

The West Valley Demonstration Project site has two aquifers, but neither is considered highly permeable. The Cattaraugus Creek Basin aquifer system is a sole source aquifer under Safe Drinking Water Act regulations (EPA 1994). Groundwater beneath the West Valley Demonstration Project is not used for process or drinking water. The site receives all of its water supply from surface water. Offsite water supplies north of the site and south of Cattaraugus Creek derive mainly from springs and shallow dug wells (WVNS 1992a).

More detailed aquifer characterization information can be found in the West Valley Demonstration Project Safety Analysis Report for Project Overview and General Information, WVNS-SAR-001 (WVNS 1993).

3.3.1.8 Ecological Resources. The West Valley Demonstration Project lies within the

Humid Temperature Domain, Warm Continental Division (Bailey 1994). The West Valley Demonstration Project is in a transitional zone between the Appalachian Plateau to the south and east and the Great Lakes Plain to the north and west (WVNS 1992b). The West Valley Demonstration Project is equally divided between forest land and abandoned farm fields (WVNS 1993).

Native vegetation, removed by previous agricultural activity, is becoming reestablished and, if left undisturbed, will slowly revert by successional stages to a climax hardwood community (WVNS 1992b).

Terrestrial wildlife is abundant within the Western New York Nuclear Services Center and surrounding areas because of the mixture of open areas and forested lands as well as the Center's protected nature (WVNS 1992b). Fifty-four species of mammals potentially occur on the site (22 have been recorded onsite). The most common mammal is the white-tailed deer (Odocoileus virginianus), which is also the most abundant game species in the region. However, hunting is prohibited. Other common game and furbearer species include raccoon (Procyon lotor), muskrat (Ondatra zibethica), red fox (Vulpes fulva), gray fox (Urocyon cinereoargenteus), woodchuck (Marmota monax), mink (Mustela vison), beaver (Castor canadensis), eastern cottontail (Sylvilagus floridanus), red squirrel (Tamiasciurus hudsonicus), and gray squirrel (Sciurus carolinensis) WVNS 1992b).

The various old-field, deciduous, and coniferous woodlands, marshes, reservoirs, and streams within the Western New York Nuclear Services Center provide a diversity of habitats used by a wide variety of birds. Bird species at the West Valley Demonstration Project include permanent and summer residents, migrants, and visitants. The abundance of upland meadow ecosystem within the Western New York Nuclear Services Center provides a unique habitat for several New York protected birds (WVNS 1992b).

Aquatic communities at the Western New York Nuclear Services Center include common shiners, eastern blacknose dace, common white sucker, and bluegill sunfish (WVNS 1992b).

Total wetland area is approximately 35 acres (14 hectares). The general types of wetlands on the West Valley Demonstration Project can be described as palustrine, emergent, shrub/scrub, and forested (WVNS 1993a).

A riparian area on Cattaraugus Creek is recognized by New York State as Habitat Significant for Wildlife (WVNS 1992b; WVNS 1993). Canada geese and other waterfowl have been observed periodically using the onsite reservoirs during migration (WVNS 1992b).

3.3.1.9 Transportation. Transportation in the Western New York Nuclear Service

Center vicinity is primarily by highway system. Roads in Cattaraugus County are considered rural roads, except for those in Olean and Salamanca, located 38 miles (61 kilometers) and 26 miles (42 kilometers), respectively, south of the Western New York Nuclear Service Center. New York State classifies rural roads as interstate, principal arterial, minor arterial, major collector, minor collector, and local. Rock Springs Road, next to the Western New York Nuclear Service Center on the west, is a local road that services as the site-access road and connects with U.S. Route 219 about 2.5 miles (4 kilometers) west of the Western New York Nuclear Service Center. Route 219 connects with Interstate 90 (the New York State Thruway) approximately 25 miles (40 kilometers) north and with Interstate 17 (the Southern Tier Expressway) approximately 29 miles (46 kilometers) south of the Western New York Nuclear Service Center (WVNS 1993a).

Rail service to the Western New York Nuclear Service Center is provided by the Buffalo & Pittsburgh Division of the CSX Railroad, located 0.6 mile (1 kilometer) east of the Western New York Nuclear Service Center. A rail spur connects the West Valley Demonstration Project to the CSX (WVNS 1993a).

The Buffalo International Airport is located approximately 31 miles (50 kilometers) north. A general aviation airport, Olean Municipal Airport, is approximately 20 miles (32 kilometers) southeast of the Western New York Nuclear Service Center (WVNS 1993a).

3.3.1.10 Public Health and Safety. Nuclear Fuel Services, Inc. developed an

environmental surveillance program in March 1963 before beginning fuel reprocessing. The program was intended to establish onsite background levels of gross radiological activity in surface water and air. The West Valley Demonstration Project began groundwater monitoring in 1982 (WVNS 1994).

Fallout data show the environmental levels of deposition at West Valley to have been within the nationwide normal range of the Radiation Alert Network measurements. Gross beta measurements in air taken at West Valley also were within the normal range of such readings taken throughout the United States. Levels of airborne particulates and deposition beyond the Western New York Nuclear Service Center perimeter have consistently been indistinguishable from the natural background.

The calculated total dose associated with airborne and liquid effluents released from West Valley Demonstration Project for a 6-year period are presented below (WVNS, 1994). The annual doses for each year are only a fraction of the DOE public dose limit of 100 millirem per year.

Year	Maximum Individual at Site Boundary EDE	Collective Dose Within 50-Miles (80-km)

1988	0.11 millirem	0.031 person-rem
1989	0.08 millirem	0.065 person-rem
1990	0.25 millirem	0.058 person-rem
1991	0.06 millirem	0.015 person-rem
1992	0.05 millirem	0.011 person-rem
1993	0.03 millirem	0.072 person-rem

3.3.2 Fort St. Vrain

Between 1979 and 1989 a high temperature gas-cooled reactor was in operation at the Fort St. Vrain site. In 1989, the Fort St. Vrain reactor was permanently shut down. At that time the Public Services Company of Colorado, the owner of Fort St. Vrain, proceeded with plans to decommission the Fort St. Vrain powerplant. To facilitate the decommissioning, the SNF had to be removed from the reactor. However, implementation of an agreement between the DOE and the Public Services Company of Colorado which would have provided for the storage of Fort St. Vrain SNF at the INEL was blocked, requiring the Public Services Company of Colorado to provide storage for the SNF from the Fort St. Vrain reactor. The SNF from the Fort St. Vrain is being stored in an independent spent fuel storage installation located on the Fort St. Vrain site (FSV 1990b).

The Fort St. Vrain site is located in Weld County in northeastern Colorado, approximately 3.5 miles (5.6 kilometers) northwest of the town of Platteville, 0.5 mile (0.8 kilometer) west of the South Platte River, and 35 miles (56 kilometers) north of Denver. The Fort St. Vrain site consists of 2,798 acres (1,132 hectares). About 1 mile (1.6 kilometers) north of the northern portion of the site is the confluence of the South Platte River and St. Vrain Creek. St. Vrain Creek flows in a northerly direction and passes within approximately 0.75 mile (1.2 kilometers) west of the site at its nearest approach (NRC 1991c; PSC 1994).

3.3.2.1 Land Use. Most of the land in the immediate area of the Fort St. Vrain site is

disturbed, agricultural land. Its agricultural value is enhanced by a number of irrigation ditches fed by surface water diversions from the South Platte River and St. Vrain Creek. The predominant use of the land, surface water, and groundwater is agricultural (NRC 1991c).

3.3.2.2 Socioeconomics. The immediate area surrounding the Fort St. Vrain Nuclear

Generating Station site is rural, with many communities within commuting distance. The nearest community is Platteville. Larger cities in the vicinity include Boulder, Denver, Estes Park, Fort Collins, Greeley, Longmont, Loveland, and Lyons (NRC 1991a).

The population density in the vicinity of the Fort St. Vrain Nuclear Generating Station is low. The nearest residence is more than 2,600 feet (0.8 kilometer) north-northwest of the site. The number of residents living within 1 mile (1.6 kilometer) of the Independent Spent Fuel Storage Installation site (based on projections from 1980 census data) is 39; the projected figure for the year 2012 is 40. However, 1990 figures indicate populations are changing at a similarly low rate, less than 1 percent per year, and consequently the projections will not change significantly (NRC 1991a).

Based on the 1980 census, the population within a 5-mile (8-kilometer) radius of the site at that time was 3,148, with 1,662 residing in the town of Platteville. The projected population for the year 2012 (through the 20-year license) for this same area is 4,526, with 3,040 residing in Platteville (FSV 1990a).

At the present time there are approximately 230 personnel working at the Fort St. Vrain site. Of these approximately 16 full time equivalent personnel work on the Fort St. Vrain SNF storage facility (Holmes 1995).

3.3.2.3 Cultural Resources. There are no known archaeological, cultural, or historical

resources within, adjacent to, or in the immediate vicinity of the Independent Spent Fuel Storage Installation site. The nearest landmarks fitting any of these designations are more than 2 miles (3.2 kilometers) from the site. They include (NRC 1991a):

- The Dent site, an archaeological excavation with mammoth remains left by prehistoric Indians, situated about 4.5 miles (7.2 kilometers) northeast of Fort St. Vrain
- The original Fort St. Vrain, located 2.5 miles (4 kilometers) northeast of the Independent Spent Fuel Storage Installation site
- Fort Vasquez, located 4 miles (6.4 kilometers) southeast of the Independent Spent

Fuel Storage Installation, and listed on the National Register of Historic Places
- Fort Jackson, situated 8 miles (12.8 kilometers) southeast of the Independent Spent Fuel Storage Installation site.

3.3.2.4 Aesthetic and Scenic Resources. The topography at the Independent Spent

Fuel Storage Installation site is flat. It is situated on the high plains, overlooked by the foothills of the Front Range, which rise about 20 miles (32 kilometers) to the west, and by the Front Range crest, which rises to 14,255 feet (4,345 meters) (Longs Peak) about 45 miles (72 kilometers) to the west. The Front Range crest due west of the Independent Spent Fuel Storage Installation site is the most easterly section of the continental divide in the Rocky Mountains. The divide runs along ridges at an altitude of approximately 12,000 feet (3,650 meters) to a high point of 13,327 feet (4,062 meters) (McHenry's Peak) (NRC 1991a).

3.3.2.5 Geology. The Fort St. Vrain site is located on the east flank of the Colorado

Front Range, a complexly faulted anticlinal arch. Numerous faults and smaller folds are superimposed on the arch and are related to the uplift of the Front Range which began in the Late Cretaceous and continued into the Tertiary. In addition to the axes of the superimposed folds, two groups of high angle faults have been recognized: a series of faults along the mountain front that extend in a generally northwest-southeast direction from the Precambrian into the Paleozoic-Mesozoic sediments, and northeast-southwest-oriented faults observed primarily in coal mines located east of Boulder (NRC 1991a).

The Fort St. Vrain site has not experienced any observed earthquake activity (Seismic Zone 1). A field examination and photo interpretation of the area provided no evidence of recent movement along any of the known faults. The closest area of recent activity is about 25 miles (40 kilometers) south of the site. Between April 1962 and May 1967, there were approximately 1,130 earthquake events in this area with magnitudes ranging from 1.0 to 5.0 on the Richter Scale. The 5.0 earthquake produced ground accelerations in the Vrain Valley of 0.002 y 0.001 g. An earthquake with a Modified Mercalli intensity of VII (slight to moderate damage to structures) occurred on November 7, 1882, and was felt throughout Colorado and Southern Wyoming. Due to the sparse population in the epicentral region, the assigned intensity may in actuality be an underestimate. A reasonable guess for its Richter magnitude is 6.5, implying that most of the strain energy released by earthquakes of Colorado in the last century was released in this one earthquake (NRC 1991a).

3.3.2.6 Air Resources. The general climate around the Fort St. Vrain site is typical of

the Colorado eastern-slope plains region. The weather is generally mild. Most seasons are characterized by low humidity and sunny days, with occasional brief storms bringing precipitation to the area. Thermal radiation losses resulting from lack of cloud cover provide considerable variation in temperature from night to day. In this semiarid region, the precipitation averages 10 to 15 inches (25 to 38 centimeters) a year, mostly from thunderstorms in late spring and summer. Snowfall is significant; however, the snow cover is usually melted in a few days. Relative humidity averages about 40 percent during the day and 65 percent at night (NRC 1991a).

Meteorological conditions in the local area include a preponderance of stable meteorological conditions and rather low wind speeds. Wind speeds generally range from 1 to 7 miles per hour (0.45 to 3.2 meters per second) 80 percent of the time. Wind directions are rather evenly distributed, although there is a preponderance of winds from the southwest and northeast quadrants. Seasonally, winds tend to be strongest in the late winter and spring, the season with high chinook frequency, and again in the summer, when thunderstorms occur frequently. Strong winds, especially under chinook conditions, have been observed on various occasions in easter Colorado. The chinook winds are strongest immediately to the east of the mountain ridge and diminish rapidly over the plains with increasing distance from the mountains (NRC 1991a).

The region typically experiences five tornadoes per year per 10,000 square miles (25,900 square kilometers), with peak tornado activity occurring during the month of June. According to the National Weather Service, Weld County has had 117 tornadoes during the period 1950-1987. A study of tornadoes in the area concluded that 100 mile (160 kilometer) per hour winds should constitute maximum forces to be expected at Fort St. Vrain (NRC 1991a).

Northeastern Colorado has moderate thunderstorm activity. The region near Fort St. Vrain averages 50 days a year in which thunder and lightning occur. The majority of these thunderstorms are present from late spring through the summer (NRC 1991a).

3.3.2.7 Water Resources. The topography in the immediate vicinity of the site is

relatively flat and water use is primarily agricultural. Its distribution is through the use of irrigation ditches. The nearest major surface water features are the South Platte River, about 0.5 mile (0.8 kilometer) east of the site, and the St. Vrain Creek, about 0.75 mile (1.2 kilometers) west of the site. Local surface water diversions from these rivers, which feed irrigation ditches to support agriculture, are somewhat closer, about 0.33 mile (0.5 kilometer) east and west of the site, and about 0.4 mile (0.64 kilometer) to the north. The net local topography, which controls the direction of surface runoff, slopes slightly to the northeast toward the South Platte River. This trend is interrupted by the irrigation ditches. There are no liquid discharges from the dry storage facility (NRC 1991a).

3.3.2.8 Ecological Resources. Wildlife indigenous to the area include several species of

ducks and geese, the mourning dove, cottontail rabbit, fox squirrel, and to a lesser extent bobwhite quail, ring-necked pheasant, deer, and antelope. The most abundant fish species include the white sucker, carp, notropis, creek chub, and, to a lesser extent, several types of perch (NRC 1991a).

With most of the land dominated by agriculture, natural vegetation is minimal. Most of the trees found along roads, in hedgerows, and around farm houses are cottonwood. Trees found in the river area are primarily cottonwoods, willows, and Russian olives. Typical grasses and weeds found in river bottom areas include gnat heads, golden weed, snake weed, Smith grass, Indian grass, foxtail and big bluestem. The site does not have readily visible evidence of recent farming but is now overrun with plants which are typically indigenous to disturbed land; plant species include Russian thistle, cocklebur, Canada thistle, dandelion, and poor-man's pepper grass (NRC 1991a).

The only threatened or endangered animal species known to occur within the area of the project are the bald eagle and the peregrine falcon. However, this land has not been identified as a critical habitat for these or any other species. The black-footed ferret, also endangered, may be found as a transient within the region, but requires a permanent habitat which is occupied by prairie dogs. Prairie dogs are not present at the site (NRC 1991a).

3.3.2.9 Transportation. There are no airports within the immediate vicinity of the

Independent Spent Fuel Storage Installation site. Stapleton International is about 30 miles (48 kilometers) south of the site. County roads with their associated rights-of-way are adjacent the exclusion area boundary or provide access to the generating station (County Roads 21, and 19 1/2, respectively). A railroad spur connects the site to the Union Pacific Railroad main line located about 2 miles (3.2 kilometers) to the west (NRC 1991a).

3.3.2.10 Public Health and Safety. Results from an Independent Spent Fuel Storage

Installation Site Background Radiation Study, completed by Colorado State University in October 1990, including the mean integral exposure rate of 0.34 mR per day, were consistent with data acquired for the area during previous years of sampling by the Fort St. Vrain Radiological Environmental Monitoring Program. With the exception of cesium-137, whose average surface activity concentration of 0.18 pCi/g is consistent with regional levels due to global fallout, no statistically significant concentrations of activation or fission products were detected (NRC 1991a).

The design of the modular vault dry store system is such that its operation does not result in any water or other liquid discharges, generate any chemical, sanitary, or solid wastes, or release any radioactive materials in solid, gaseous, or liquid form during normal operations. The primary radiological exposure pathway associated with the Independent Spent Fuel Storage Installation operation is direct irradiation of nearby residents and site workers. The highest dose to the nearest resident for any year is about 0.1 mrem. The highest collective dose commitment for any year to the population within 5 miles (8 kilometers) of the Independent Spent Fuel Storage Installation will not exceed 0.45 person-rem (NRC 1991a).

3.3.3 B&W Lynchburg

B&W Lynchburg maintains a large nuclear fuels research facility at its Mount Athos site. This site is about 925 acres (374 hectares) in area with the research facility within a 4-acre (1.6-hectare) fenced area. Numerous support facilities are located outside and adjacent to this fenced area. The research facility is in Campbell County, Virginia near the James River, approximately 4 miles (6.4 kilometers) east of the city of Lynchburg (NRC 1987).

Building A was constructed in 1956 and housed the Lynchburg pool reactor and the Critical Experiment Facility. This facility has been decommissioned (NRC 1987).

Building B contains a hot cell facility with its associated operations area, cask handling area, transfer canal and storage pool, and various laboratories associated with the examination of radioactive materials. It also houses a demineralizer for the cleanup of the pool water (NRC 1987).

Building C was used as a plutonium fuels development laboratory and for research and development of processes for other nuclear fuels. It is undergoing decommissioning (NRC 1987).

Building J and its Annex are used for solid waste storage. High, intermediate, and low-level wastes may be stored here. Irradiated fuel wastes are being stored until they are accepted by the DOE in accordance with the provisions in the Nuclear Waste Policy Act of 1982 (NRC 1987).

3.3.3.1 Land Use. Land use in Campbell and Amherst counties is dominated by farming

and forestry. Although the site lies in an agricultural region, very few of the important agricultural characteristics attributed to the region occur within 5 miles (8 kilometers) of the site because of unfavorable terrain. The region is characterized by mixed land use consisting of small areas of farmland (crop and pasture) interspersed within large tracts of forested area (NRC 1986).

3.3.3.2 Socioeconomics. The Lynchburg Research Center and the nearby City of

Lynchburg are centrally located within the area of Amherst, Appomattox, Bedford, and Campbell counties. The combined population of these counties and Lynchburg is about 180,000 (NRC 1986).

The Lynchburg area's commercial and industrial interests provide a large percentage of the employment in the four-county area. Although farming and forestry activities dominate the land use in the region, they provide less than 1 percent of the economic activity and very little permanent employment. Other principal commercial, industrial, and population centers that may influence the four-county area or may be slightly influenced by B&W operations are Roanoke, Charlottesville, Richmond, and Danville (NRC 1986).

The Lynchburg Research Center has about 180 employees, and the other facilities on the B&W site employ about 2,200. The total employment on the B&W site is only about 3 percent of the 69,000 persons employed in the Lynchburg Standard Metropolitan Statistical Area. The B&W operation is an important, although not critical, source of employment in the Lynchburg region (NRC 1986).

3.3.3.3 Cultural Resources. A review of the Federal Register reveals that the only historic

site on the National Register of Historic Places located within 5 miles (8 kilometers) of the B&W facilities is the 19th-century Mt. Athos Plantation, which is across the road to the east of the site. There are numerous historic places between 5 and 25 miles (8 kilometers and 40 kilometers) from the B&W site, particularly in Bedford County and Lynchburg to the west. The best known historic site is the Appomattox Court House National Historic Park, about 15 miles (24 kilometers) to the east (NRC 1986).

3.3.3.4 Aesthetic and Scenic Resources. The topography of the plant site is generally

rolling with gentle slopes. The nominal river elevation is 470 feet (143 meters) above mean sea level. The dominant topographic feature of the site is a hill located approximately at the center of the property, the crest of which rises to 693 feet (211 meters) above mean sea level. The site includes a large area of relatively flat floodplain adjacent to the river. The highest point in the vicinity of the site is the top of Mt. Athos, where the elevation is 890 feet (271 meters) above mean sea level (NRC 1986).

3.3.3.5 Geology. The James River Basin of Virginia includes portions of four

physiographic provinces characterized by distinct land forms and physical features. These provinces, located west to east, are Valley and Ridge, Blue Ridge, Piedmont, and Coastal Plain. Western or inner Piedmont, where the B&W property lies, is an upland characterized by scattered hills, some of mountainous dimensions, lying eastward from the foot of the Blue Ridge (NRC 1986).

No important mineral resources have been identified at the B&W site, and U.S. Geological Survey topographic maps do not indicate any significant surface or underground mining activities within 5 miles (8 kilometers) of the site (NRC 1986).

The B&W site is located in a western part of the central Virginia cluster region which is classified as Zone 2 on the Seismic Risk Map of the United States. This zone corresponds to an intensity of VII according to the Modified Mercalli scale, which implies building damages to the extent of fallen chimneys and cracked walls. During the period 1758 through 1968, 121 earthquakes with epicenters in Virginia were reported. The largest earthquake was in 1897, with a probable epicenter in Giles County, approximately 100 miles (160 kilometers) west of the plant site. A maximum intensity of VIII was estimated in the epicentral region, but an intensity of only V-VI was estimated at the plant site. The second largest earthquake was in 1875, with a maximum epicentral intensity of VII more than 50 miles (80 kilometers) east or northeast of the site. The estimated intensity at the site was V. No other quakes have been recorded with intensities at the site greater than the 1875 or 1897 occurrences (NRC 1986).

3.3.3.6 Air Resources. The climate of the Lynchburg area is influenced by cold and dry

polar continental air masses in the winter and warm and humid gulf maritime air masses in the summer. Extremes in weather conditions in the area are rare. The mean temperature is about 56.7oF (13.7oC), with normal average temperatures ranging from 76.3oF (24.6oC) in July to 38.5oF (3.6oC) in December. Rainfall amounts at Lynchburg can be expected to reach 40.3 inches (102.4 centimeters) in any given year. The monthly rates are nearly uniform except for a slightly higher rate during the summer months. Snowfall in the Lynchburg area generally occurs between the months of December and March. The mean yearly snowfall total is 19.4 inches (49.3 centimeters). Winds at Lynchburg are predominant from the southwest with a mean speed of 8 miles per hour (3.6 meters per second). Mean relative humidity values in Lynchburg at 7:00 am, 1:00 pm, and 7:00 pm are 78, 51, and 62 percent, respectively. Heavy fog (visibility of less than 1,320 feet or 400 meters) can be expected to occur at the site on the average of 40 days per year (NRC 1986).

Severe weather at the Lynchburg Research Center is generally limited to thunderstorms, with a low probability of tornadoes. Climatological data show that the mean number of thunderstorms occurring at Lynchburg is 22 per year. According to methods for estimating tornado occurrence presented by Thom, the probability of a tornado's actually striking the site is 3.0 x 10-4 per year, with a recurrence interval of 3,333 years (NRC 1986).

The B&W Lynchburg Research Center is located in the Central Virginia Air Quality Control Region, where the air is classified by the Environmental Protection Agency as "better than national standards" for total suspended particulates and sulfur dioxide. The City of Lynchburg also meets the national standards for total suspended particulates and sulfur dioxide. For carbon monoxide, nitrogen dioxide, ozone, and hydrocarbons, the Air Quality Control Region cannot be classified because data are not available (NRC 1986).

3.3.3.7 Water Resources. A relatively large forested floodplain exists between the

normal elevation of the James River and the estimated highest flood state at the site. Since no Lynchburg Research Center structures are located in the floodplain, plant operation does not impact floodplain features (NRC 1986).

The James River is formed about 96 miles (154 kilometers) upstream of the site by the confluence of the Jackson and Cowpasture Rivers. The James River flows generally south-southeast from the Valley and Ridge Province to the Atlantic Ocean through the Hampton Roads and Chesapeake Bay. On the basis of records for two U.S. Geological Survey gaging stations, one about 20 miles (32 kilometers) upstream and the other about 21 miles (34 kilometers) downstream of the site, the annual average flow rate of the river at the plant is estimated to be about 3900 cubic feet per second (110 cubic meters per second). The estimated water surface elevation at the site at the average flow rate is approximately 470 feet (143 meters) above mean sea level (NRC 1986).

Eleven great floods of the James River occurred at the plant site in 1771, 1795, 1870, 1877, 1889, 1913, 1930, 1936, 1969, 1972, and 1985. The 1795 flood had the highest flood state, which was 535 feet or 163 meters above mean sea level at Lynchburg and 494 feet (151 meters) above mean sea level at the site (estimated). The largest recent flood occurred in November 1985 and had a flood state of 534 feet (163 meters) above mean sea level at Lynchburg (NRC 1986).

The Standard Project Flood determined by the U.S. Army Corps of Engineers for the James River would produce a discharge rate of 10,705 m3/S (378,000 cfs) and a flood state of 502 feet (153 meters) above mean sea level at the site (NRC 1986).

Because the elevation of the plant floors at the Lynchburg Research Center is 589 feet

(180 meters) above mean sea level, which is 95 feet (29 meters) above the maximum historical flood state or 37 feet (26 meters) above the Standard Project Flood elevation, James River floods would not affect the research and development facility at the Lynchburg Research Center (NRC 1986).

Measurements in potable wells located in the river floodplain near the B&W Commercial Nuclear Fuel Plant in the northeast corner of the site indicate that the groundwater elevation ranges between 440 and 460 feet (134 and 140 meters) above mean sea level, which is 10 feet (3 meters) below surface elevation at the annual average flow rate. Because of the relative impermeability of the silt and clay topsoils, neither the water in surface soils nor river flood water has a major effect on the groundwater supply or quality. B&W obtains about 100,000 gallons per day (380 cubic meters per day) from the above-mentioned wells for drinking and industrial uses. An average of 19,300 gallons per day (73 cubic meters per day) is used at the Lynchburg Research Center. Continuous pumping tests on these wells indicates a plentiful supply of groundwater. Therefore, it is not likely that the performance at nearby residential wells would be affected by B&W's operations (NRC 1986).

3.3.3.8 Ecological Resources. Natural climax vegetation in the region is classified as

oak-hickory-pine (Quercus-Caray-pinus) forest. Dominants include white (Q. alba), post oak (Q. stellata), hickory (Carya spp.), shortleaf pine (P. echinata) and loblolly pine (P. toeda). Other common species include tulip poplar (Liriodendron tulipifera), sweetgum (Liquidambar styraciflua), dogwood (Cornus florida), and several other species of oak, hickory, and pine (NRC 1986).

The great diversity of plants and vegetative communities in the site vicinity provide a wide variety of habitats for wildlife. There are approximately 24 species of mammals, 160 species of birds, 19 species of reptiles, and 17 species of amphibians expected to occur in the Lynchburg area. Species in the vicinity of the site that are economically important include game mammals, e.g., white-tailed deer (Odocoileus virginianus) and black bear (Ursus americanus), otter (Lutra canadensis), red fox (Vulpes vulpes), and beaver (Castor canadensis); and mourning dove (Zenaida macroura) and several species of water fowl (NRC 1986).

The aquatic biota of the James River in the vicinity of the Lynchburg Research Center is generally characteristic of that of a moderately polluted river. Examination of photoplankton communities downstream of the site at Cartersville shows reasonably diverse communities consisting of green, yellow-green (diatoms) and blue-green algae during the late summer. Phytoplankton communities during the fall, winter, and early summer consisted almost entirely of a few species of yellow-green algae (NRC 1986).

Most of the fish in the James River in the vicinity of the Lynchburg Research Center are primarily members of the minnow, sucker, sunfish, perch, and catfish families. Species in these families range from common to uncommon. There is no commercial fishery in the vicinity of the Lynchburg Research Center site (NRC 1986).

Federally and state-listed threatened and endangered animal species whose present or former geographic ranges include central Virginia and the B&W site are the bald eagle (Haliaeetus leucocephalus), American peregrine falcon (Falco peregrinus), gray bat (Myotis grisescens), Indiana bat (Myotis sodalis), Virginia big-eared bat (Plecotus townsendii virginianus), and eastern cougar (Felis concolor couguar). There have been no reports of these species being observed on the site or its vicinity (NRC 1986).

There are no species of rare or endangered fish or mollusks known to occur in the James River in the vicinity of the site (NRC 1986).

3.3.3.9 Transportation. The site is bounded on three sides by the James River and on

the fourth side by Virginia State Route 726. The site is serviced by a spur of the CSX Railroad, which runs through the B&W property. The site is also conveniently located for truck and automobile access, because only about 2 miles (3.2 kilometers) from the plant, State Route 726 connects with U.S. Highway 460, a major link between Roanoke and Richmond (NRC 1986).

3.3.3.10 Public Health and Safety. The total-body dose rate for the vicinity of

Lynchburg is approximately 107 millirem per year. This dose rate includes 43 millirem per year from cosmic rays, 45.6 millirem per year from terrestrial sources, and 18 millirem per year from internal emitters (NRC 1986).

4. ENVIRONMENTAL CONSEQUENCES OF SPENT NUCLEAR

FUEL MANAGEMENT ACTIVITIES

This section presents the projected impacts of implementing the programmatic alternatives for management of SNF for which DOE has accepted present or future responsibility. The SNF management activities evaluated in this section only include those actions identified by the originating sites to be implemented should the No Action Alternative be adopted, as described in Section 2. SNF management activities planned independently of this EIS are addressed only if they are directly affected or altered as a result of the programmatic SNF alternatives considered in this EIS. Only Alternative 1, No Action, has any potential for affecting some of the facilities addressed in this Appendix. Thus only the environmental consequences of SNF management activities at originating sites under Alternative 1 will be discussed here. For the other DOE alternatives, the environmental consequences of SNF transportation from originating sites are analyzed in Appendix I to Volume 1. The environmental consequences at the DOE facilities that receive the SNF originating from any facilities in this Appendix are addressed in Appendixes A, B, C and F.

4.1 No Action

4.1.1 DOE Experimental Reactors and Small-Quantity Storage

The DOE's reactors at the Brookhaven National Laboratory, Los Alamos National Laboratory, and Sandia National Laboratories would not be affected by the No Action Alternative through the year 2005. Between 2006 and 2035, however, implementation of this alternative might require modifications of SNF management activities at the reactor facilities.

4.1.1.1 Brookhaven National Laboratory. The High Flux Beam Reactor at the

Brookhaven National Laboratory is planned to continue to operate for the foreseeable future. The presently planned installation of a storage rack in the existing wet storage facility, providing 162 additional storage locations, will be depleted in 1998. It is expected that the arrangement of the existing racks will be modified to provide additional storage capacity in the existing pool if SNF cannot be shipped at that time (Carelli 1993).

Fuel storage capacities at the Brookhaven National Laboratory High Flux Beam Reactor would be severely taxed if the No Action Alternative were selected. Selection of the No Action Alternative could result in the eventual shutdown of the High Flux Beam Reactor as a result of filling the existing SNF storage capacity. Implementation of the No Action Alternative would be expected to have no operational impact on the Brookhaven Medical Research Reactor (Carelli 1993).

There is no safety analysis or technical specification limit on the number of elements stored, so the proposed addition of a new storage rack should be accompanied by a new criticality analysis (DOE 1993c).

The fuel canal is unlined and there is no continuous and accurate way of measuring leak detection. However, alarms for high and low water level are in the control room and the water level is regularly monitored. Records are maintained for canal water additions, and thus any increased amounts of canal makeup water can be detected. The canal has been sealed against evaporation about every 5 years to measure leakage, and no leakage problems have ever been detected. Also, there are groundwater monitoring wells near the High Flux Beam Reactor that are sampled twice per year, and no significant amounts of radionuclides have ever been detected. No known damaged fuel is presently stored in the fuel canal (DOE 1993c).

The fuel canal water monitoring program is adequate to control corrosion and to minimize the release of fission products. In addition, corrosion surveillance coupon samples have been photographed and evaluated yearly since stored in the canal in 1977. These photographs have shown no corrosion damage (DOE 1993c).

In view of the absence of any substantive difference in SNF management operations attributable to the No Action Alternative, effluent releases and their associated doses would be expected to be the same as those currently being experienced there.

Potential impacts on the Nassau/Suffolk Aquifer System as a result of SNF management alternatives described in this EIS are expected to be small. If the fuel canal were to leak, ground water impacts would be expected, but monitoring measures would mitigate impacts by permitting early detection of leaks.

For the Brookhaven Medical Research Reactor, which has sufficient SNF storage capacity, the No Action Alternative would cause no environmental consequences--other than those that have already been addressed and accepted under the siting and operation approval process.

4.1.1.2 Los Alamos National Laboratory. The Omega West Reactor at Los Alamos

National Laboratory is permanently shut down. It is being decommissioned. The SNF is in temporary storage at the Chemistry and Metallurgy Research complex. Although at present the stored fuel elements do not present a health or safety hazard, storage of fuel at the Chemistry and Metallurgy Research complex presents a potential radiological hazard at that facility. The Los Alamos National Laboratory does not have the capability to store, handle or monitor spent fuel for any extended length of time. The Rover casks contain no monitoring devices, and storage of spent fuel is not addressed in the current Chemistry and Metallurgy Research complex authorization. It is recommended that the fuel be relocated as soon as practical.

For the other Los Alamos National Laboratory facilities that have sufficient SNF storage capacity, the No Action Alternative would cause no environmental consequences--other than those that have already been addressed and accepted under the siting and operation approval process.

4.1.1.3 Sandia National Laboratories. Each of the reactors at Sandia National

Laboratories is designed so that the uranium fuel source essentially lasts the designed life of the reactor. Consequently, none of the reactors require periodic refueling or discharge spent fuel. Therefore, the No Action Alternative would cause no environmental consequences--other than those that have already been addressed and accepted under the siting and operational approval process for these facilities at Sandia National Laboratories (DOE 1993d).

4.1.1.4 Argonne National Laboratory - East. Essentially all of the SNF at the Argonne

National Laboratory site in Illinois is contained in the Alpha-Gamma Hot Cell Facility. The Alpha-Gamma Hot Cell Facility is an operating hot cell where fuel development programs have been conducted for 29 years. The SNF located there is a combination of material in process and the stored residues from past programs (DOE 1993d).

The condition of the stored SNF is generally good and would be an issue only if its physical and chemical state dictates that it must be treated before it will be acceptable at a long-term interim storage site or a final repository. Likewise, the physical condition of the facility is good, considering its 29-year age. The SNF is contained within the hot cell, which precludes its entry into the environment except under the most extremely low-probability events (DOE 1993d).

4.1.2 Domestic Research Reactors

In Section 2.2.1.2, it was noted that SNF storage facilities at 34 domestic research reactors would not be overloaded were the No Action Alternative (i.e., no off-site SNF transportation) to be implemented. For those sites, the adoption of the No Action Alternative would produce no incremental impacts on the environment.

This conclusion is supported by NRC determinations in a number of licensing actions related to requested increases in possession limits for U-235 in fuel at research reactor sites. In these licensing actions, the NRC has determined that there is no significant impact on the environment from normal operation or accidents associated with the increases in the possession limits for U-235 at those reactor sites. The possession or storage of fuel at the domestic research reactor sites is not considered by the NRC to be a significant activity as indicated by the following examples of their findings.

In 1993, the NRC performed a safety evaluation in response to the University of Missouri at Columbia request for a temporary increase in the license possession limit for U-235 from 45 to 60 kilograms. In regard to potential accidents the NRC determined: "There are no specific accidents in this type of research reactor associated with the storage of spent fuel in accordance with the Technical Specifications. The maximum hypothetical accident of complete fission product release of four fuel plates in the reactor core is not affected by increasing the amount of stored fuel. Because the fuel will be stored in accordance with the Technical Specifications, accidents previously evaluated are not changed and no new or different kind of accident is created. Therefore, the staff concludes that the temporary increase in the possession limit of U-235 is acceptable."

In regard to environmental considerations of this possession increase, the NRC stated: "The staff has determined that the amendment involves no significant increase in the amounts, and no significant change in the types, of any effluents that may be released offsite, and there is no significant increase in individual or cumulative occupational radiation exposure. Accordingly, this

amendment meets the eligibility criteria for categorical exclusion set forth in 10 CFR 51.22(c)(9).
Pursuant to 10 CFR 51.22(b), no Environmental Impact Statement or Environmental Assessment need be prepared in connection with the issuance of this amendment." (NRC 1993b)

In 1991, in performing a safety evaluation in response to an earlier University of Missouri request for a temporary increase in the license possession limit for a larger amount of U-235 from 60 to 75 kilograms, the NRC reached the same determinations and conclusions as in the 1993 licensing action. (NRC 1991b)

In response to the request from the Massachusetts Institute of Technology request in 1991 to extend a temporary increase in the possession limit of U-235 of 41 kilograms until January 1, 1994, the NRC performed an evaluation and made identically the same determination as that quoted above for the University of Missouri license amendment. (NRC 1991d)

The NRC, in its Environmental Assessment for the Training and Research Reactor of the University of Lowell, stated: "Accidents ranging from the failure of experiments up to the largest core damage and fission product release considered possible result in doses that are less than 10 CFR Part 20 guidelines and are considered negligible with respect to the environment.... The staff concludes that there will be no significant environmental impact associated with the licensing of research reactors or critical facilities designed to operate at power levels of 2 MWt or lower and that no environmental impact statements are required to be written for the issuance of construction permits or operating licenses for such facilities." (NRC 1985b)

In the Environmental Impact Statement for the University of Texas, TRIGA Mark II reactor, it was stated: "Storage, processing and disposal of fuel elements is not considered a significant activity of this facility." (NRC 1984)

Of the 11 domestic research reactors that are projected to exhaust their storage capacity, a few facilities indicated that they might take measures to physically expand their SNF storage capacity within their existing structures beyond what had been planned. Only one facility has indicated that it might elect to create an 18.6-square-meter (200-square-foot) storage area outside the existing structure. An addition of this small size would be expected to have a minuscule impact on the previously disturbed environment.

A small number of these facilities could request deferral of their directed conversion from highly enriched uranium fuel to low enriched uranium fuel. The environmental consequences of such an action would derive from extending the risks of theft or diversion of highly enriched uranium fuel which the U.S. Government has tried to reduce by mandating the conversion (Jentz 1993).

An unidentified number of the research reactors may elect to discontinue operation at some time during the next 40 years. Storage of the SNF onsite at a reactor facility that is undergoing decommissioning would interfere with the radiological surveys conducted to ensure that the reactor site is returned to the pristine conditions that existed before the reactor was constructed.

The consequences of premature shutdown of any of these reactors, attributable to implementation of the No Action Alternative, would include the loss of service which the reactors were scheduled to provide. These consequences of implementing the No Action Alternative could include, for example:

- Loss of education and training for some nuclear engineers and scientists
- Loss of trace analysis capability supporting solar cell material research, monitoring of atmospheric pollutants, detection of trace metals in foods, and analysis of criminal artifacts
- Loss of specific materials research capability relating to hydrogen in metals, metglasses, amorphous magnetic materials, and biomolecular polymers
- Loss of specific nuclear medicine and radiation therapy.

Any changes in radioactive (or other) releases or exposures to the public or to workers would be inconsequential. More detailed analyses of radiation exposures and other impacts would be provided in site-specific NRC licensing documents before implementation of any changes in these facilities that were made necessary by an SNF transportation moratorium.

4.1.3 Nuclear Power Plant Spent Nuclear Fuel

4.1.3.1 West Valley Demonstration Project. It has been determined that continued use

of the SNF storage pool in the Fuel Receiving & Storage building at the West Valley Demonstration Project is not a viable option for extended periods of time. Therefore, alternative concepts for storing West Valley Demonstration Project SNF are being evaluated by the Project. The options being considered at West Valley include dry storage, wet storage involving refurbishing of a portion of the existing spent fuel storage pool, and continued use of the present facility.

Dry storage is projected to require a maximum area of 0.003 square kilometer (0.72 acre) (i.e., a square plot of land about 54 meters [177 feet] on each side). This area would include the actual storage facility, approach pads, and perimeter fence. The largest base pad required for any of the dry storage concepts would measure 9.1 by 15.2 meters (30 by 50 feet) and be between 0.61 and 1.22 meters (2 and 4 feet) thick (WVDP 1993).

The wet storage concept and No Action Alternative assume the continued use (either modified or as is) of the existing spent fuel storage pool. These options should have no measurable impact on the West Valley Demonstration Project site. The actions taken to transfer the spent fuel from the storage pool to the on-site dry storage facilities would not differ from those taken to transfer this SNF to the INEL or any other DOE facility. Therefore, there would be no additional environmental impact resulting from these fuel transfer activities.

Potential impacts on the Cattaraugus Creek Basin Aquifer System as a result of SNF Management alternatives described in this EIS are expected to be small.

Keeping the SNF in dry storage on-site would result in both on-site and off-site exposures that would not occur if the fuel were shipped off-site once it was removed from the storage pool. Storing the fuel dry in sealed containers would not result in the production of radioactive liquid or gaseous effluents or solid radioactive wastes. The source of the on-site and off-site radiation doses is direct radiation from the dry spent fuel storage facility. Estimates have not yet been developed for these doses, because a storage concept has not been selected.

The 125 fuel assemblies in the Fuel Receiving and Storage Facility have been in storage for over 20 years. Their total heat generation rate is less than 9 kilowatt and fission product inventory should have reached a near steady state condition. Conservative calculations in safety analysis report estimate that failure of all 125 fuel assemblies would result in an off-site dose of 42 mrem and an on-site dose of 2.1 rem (DOE 1993c).

Doses and solid waste generation volumes resulting from implementation of the No Action Alternative would remain the same as the current operation at the West Valley Demonstration Project. The calculated annual effective dose equivalent resulting from the total site operations including wet storage of SNF at the West Valley Demonstration Project are as follows: (WVNS 1994)

Maximum individual off-site dose from gaseous releases	1.6 x 10-4 mrem/year
Maximum individual off-site dose from liquid releases	1.1 x 10-2 mrem/year

4.1.3.2 Fort St. Vrain. The Fort St. Vrain facility has already constructed an Independent Spent Fuel Storage Installation for interim storage (with a 40 year design basis) of the SNF from the Fort St. Vrain power plant. Onsite storage will have no additional impact on the Fort St. Vrain site (FSV 1990a). However, under this alternative, Public Service Company of Colorado would not achieve its goal of becoming free of radioactive materials by 1998 under this option.

4.1.3.3 B&W Lynchburg Technology Center. The Lynchburg Technology Center received the SNF between 1980 and 1987 as part of a "high-burnup" research program sponsored by the DOE Office of Nuclear Energy. The experiments were completed in 1989 and the program was officially terminated in 1992. Since that time, the Lynchburg Technology Center has stored this fuel under contract to DOE (DOE 1993c).

The DOE-owned spent fuel rods that are stored in the spent fuel storage pool are intact and in good condition. Water quality is also good and is maintained by passing through particulate filters and resin beds. No chemistry controls have been needed. In addition, sludge is not present in the pool and biological contamination has not been observed (DOE 1993c).

There are no routine inspections of the condition of spent fuel rods that have been sectioned and placed in dry storage. However, some of the fuel stored in this facility was recently repackaged and moved; this fuel and its containers are known to be in good condition. Other evidence that the integrity of spent fuel storage containers has been maintained in good condition is routine monitoring of groundwater, direct radiation, and smearable contamination, all of which indicate that leakage of radionuclides is not occurring (DOE 1993c).

Groundwater and other radionuclide monitoring have not indicated any radionuclide releases from the SNF storage facilities at the B&W Lynchburg Technical Center. There is currently no reason to suspect that spent fuel storage containers will degrade in the near term in a manner that would result in a release of fission products. This facility is routinely inspected and relicensed by the NRC every 5 years. Hence, any developing storage problems would most likely be dealt with and corrected under the direction of the NRC (DOE 1993c).

4.2 Decentralization

The Decentralization Alternative is similar to the No Action Alternative except that limited off-site shipments would occur from university and domestic non-DOE research reactors. Impacts of transportation are described in Appendix I to Volume 1. Some DOE facilities would be upgraded/replaced and additional on-site storage capacity would be required at several DOE facilities. Essentially, there are no differences from the No Action Alternative, except impacts from transportation, facility upgrade, and new construction.

At Brookhaven National Laboratory High Flux Beam Reactor, some land disturbance might be anticipated from the installation of additional SNF storage capacity, whether wet or dry. However, any such disturbance is expected to occur in previously disturbed on-site areas.

4.3 1992/1993 Planning Basis

The 1992/1993 Planning Basis Alternative would permit the shipment of the SNF currently in storage or being generated at the originating sites. With the implementation of the 1993/93 Planning Basis Alternative, as in past practice, SNF would continue to be shipped from the originating sites to a DOE receiving site. The 1992/1993 Planning Basis Alternative would be expected to have essentially no incremental impact on the originating sites. Impacts of transportation are described in detail in Appendix I to Volume 1. The alternative of transporting SNF by barge from Brookhaven National Laboratory is also described in Appendix I to Volume 1.

4.4 Regionalization

The Regionalization Alternative would be the same as the 1992/1993 Planning Basis Alternative, except for the difference in destinations. Implementation of the Regionalization Alternative would permit the shipment of SNF from originating sites to regional DOE interim storage facilities. The Regionalization Alternative would be expected to have essentially no incremental impact on the originating sites. Impacts of transportation are described in detail in Appendix I to Volume 1.

4.5 Centralization

The Centralization Alternative would be the same as the 1992/1993 Planning Basis Alternative, except for the difference in destinations. Implementation of the Centralization Alternative would permit the shipment of SNF from originating sites to a central DOE interim storage facility. The Centralization Alternative would be expected to have essentially no incremental impact on the originating sites. Impacts of transportation are described in detail in Appendix I to Volume 1.

5.0 CUMULATIVE IMPACTS

This section describes the cumulative environmental impacts of the alternatives for generating and storing SNF at the originating sites addressed in this Appendix. The emphasis is on DOE SNF Alternative 1, No Action, under which all SNF would remain at the originating facility. For the individual originating facilities, the cumulative impact is defined as the sum of the incremental impacts of SNF management under the No Action Alternative and the impacts of the other operations at the facility's reactor(s) or other activities involving radioactive materials. For the other alternatives, the SNF cumulative impact at the originating facilities essentially would end with the removal of the SNF from the site. The cumulative impacts of intersite SNF transportation alternatives on transportation routes and affected communities are analyzed programmatically in Volume 1, Appendix I. The cumulative impacts at the DOE facilities receiving SNF are addressed in Appendixes A, B, C and F.

5.1 DOE Test and Experimental Reactors

Under the No Action Alternative, the cumulative environmental impacts at DOE test and experimental reactors are derived from past environmental impacts as obtained from annual operating reports, and estimated future impacts based on extrapolation to the year 2035 of past impacts.

5.1.1 Brookhaven National Laboratory

It is expected that the High Flux Beam Reactor and Brookhaven Medical Research Reactor would continue to operate, for all SNF management alternatives except No Action. If additional storage were to be required on-site to accommodate High Flux Beam Reactor SNF through 2035, current impacts would be somewhat increased by the impacts of building and operating an additional facility. Although the nature of that facility has not been determined, the resulting impacts are expected to be negligibly small. Should the facility propose substantial changes, appropriate NEPA documentation would be prepared in accordance with existing environmental regulations.

5.1.2 Los Alamos National Laboratory

Omega West Reactor at the Los Alamos National Laboratory is permanently shut down and is being decommissioned. The spent fuel is in temporary dry storage at the Chemistry and Metallurgy Research complex, and resulting impacts are negligible. The spent fuel is awaiting relocation. Cumulative impacts would not change under any alternative.

5.1.3 Sandia National Laboratories

The cumulative environmental impacts would not change from those currently experienced at Sandia National Laboratories from the operation of the reactors and storage of small quantities of SNF.

5.1.4 Argonne National Laboratory - East

The cumulative environmental impacts would not change from those currently experienced from the storage of small quantities of SNF.

5.2 Domestic Research Reactors

Under the No Action Alternative, the cumulative environmental impacts at domestic research reactors are a composite of past environmental impacts as obtained from annual operating reports, and estimated future impacts based on extrapolation to the year 2035 of past impacts. The following facility-specific cumulative environmental impacts have been selected as representative of all domestic research reactor facilities that could be affected by Alternative 1.

5.2.1 National Institute of Standards and Technology

Implementation of the No Action Alternative would result in the shutdown of the National Bureau of Standards Reactor in October 1996 due to the inability to store additional SNF. The environmental radiological impact of such action would be a reduction of radioactive releases and doses below those of full power operation. On-site SNF storage would meet existing facility design criteria. There would be no other change in the cumulative environmental impact except for the adverse socioeconomic impacts as a result of the loss of services and knowledge from reactor operations.

A scenario of continued operation, assuming timely reissuance of the operating license, including compliance with the National Environmental Policy Act, would bound the cumulative environmental impacts under any of the DOE-postulated SNF alternatives.

5.2.2 Massachusetts Institute of Technology

As with the National Institute of Standards and Technology, the Massachusetts Institute of Technology research reactor would be expected to shut down in response to the No Action Alternative because of limited SNF storage capacity. Thus, a scenario of continued operation, assuming timely reissuance of the operating license, would bound the cumulative environmental impacts under any of the DOE-postulated SNF alternatives.

5.2.3 Conclusion

For all domestic research reactors, the SNF management alternatives, including the No Action Alternative, would not increase the cumulative impacts of the originating sites above current values. Some of the facilities could not be able to continue normal operation under the No Action Alternative and could be forced to shut down due to the lack of SNF storage capacity. Reactors licensed by the U.S. Nuclear Regulatory Commission are not under DOE control, and additional storage space could be constructed under the No Action Alternative. However, except for the negative socioeconomic impacts attributable to the loss of services and knowledge resulting from such shutdowns, other site-specific cumulative impacts would not be increased.

5.3 Nuclear Power Plant Spent Nuclear Fuel

The implementation of any one of DOE's five SNF management alternatives would have no additional environmental consequences beyond those already evaluated for the Fort St. Vrain and B&W Lynchburg facilities.

The situation is similar for the West Valley Demonstration Project, except that the DOE has entered into an agreement with the New York State Energy Research and Development Authority which calls for the removal of SNF from the West Valley Demonstration Project. Implementation of the No Action and Decentralization Alternatives would result in SNF remaining at the West Valley Demonstration Project. If the fuel remains at the West Valley Demonstration Project, the SNF may be managed in a new dry storage facility. Once the SNF is in dry storage, there will be no releases of radioactive effluents and an indistinguishable direct radiation exposure to the environs in excess of that which would occur were the SNF to be moved as scheduled, and in the payment of storage costs by DOE to the State of New York.

6.0 ADVERSE ENVIRONMENTAL EFFECTS

THAT CANNOT BE AVOIDED

Unavoidable adverse impacts addressed here are limited to those occurring as a result of DOE Alternative 1 (No Action) at the originating facilities discussed in this Appendix. All other alternatives consider normal shipment of SNF from the originating site, with only transportation routes and the receiving site possibly being subjected to unavoidable adverse impacts by transferred SNF. Any adverse impacts at the originating sites are thus precluded for all SNF transportation alternatives. Possible unavoidable adverse impacts on transportation routes are analyzed in Volume 1, Appendix I. Possible unavoidable adverse impacts at the DOE facilities that receive SNF are addressed in Appendixes A, B, C and F.

6.1 DOE Test and Experimental Reactors

The adverse effects that may be unavoidable caused by implementation of the No Action Alternative would be associated with the possible premature, long-term shutdown of the High Flux Beam Reactor at Brookhaven National Laboratory. The consequences of this shutdown would be cessation of site specific activities involving unique experiments. These experiments are needed for understanding materials structures, biological processes, and the behavior of super conducting materials. Shutdown would also cause the loss of jobs associated with these experiments and supporting site activities.

6.2 Domestic Research Reactors

The adverse effects that may be unavoidable at domestic research reactors caused by implementation of the No Action Alternative would be associated with the possible premature, long-term shutdown of several reactors. The consequences of these shutdowns, discussed in Section 4.1.2, would be cessation of site-specific research and education activities and could result in the loss of jobs associated with these activities at these sites.

6.3 Nuclear Power Plant Spent Nuclear Fuel

Implementation of the No Action Alternative could result in adverse consequences that may be unavoidable at West Valley Demonstration Project. Should this alternative be selected, the adverse impact that may be unavoidable would be continued on-site and off-site radiation exposures beyond the scheduled fuel removal date as a result of radioactive effluents and/or direct radiation.

Since the Public Services Company of Colorado has already responded to the No Action Alternative by licensing and constructing an independent spent nuclear fuel storage installation at its Fort St. Vrain site, no additional consequences or additional adverse consequences would be incurred there.

7.0 IRREVERSIBLE AND IRRETRIEVABLE

COMMITMENTS OF RESOURCES

The assessment of the activities undertaken at the SNF originating sites as a consequence of the implementation of all alternatives indicates that only minor irreversible and irretrievable commitments of resources would be required.

7.1 DOE Test and Experimental Reactors

If the Decentralization Alternative were to be implemented, the Brookhaven National Laboratory would expect to be required to identify some way to store the SNF generated by the High Flux Beam Reactor through the year 2035. Several scenarios are possible, but none has been decided upon at this time. One possible SNF management scenario is to install additional storage accommodations. Limited quantities of construction materials and fuel for construction equipment would be required if this scenario were selected.

Implementation of the No Action Alternative would not result in any irreversible and irretrievable commitments at the Los Alamos National Laboratory, Sandia National Laboratories or Argonne National Laboratory - East.

Implementation of any of the other proposed alternatives for SNF would not result in any additional irreversible and irretrievable commitments of resources at the DOE test and experimental reactors.

7.2 Domestic Research Reactors

There are no substantial new irreversible and irretrievable commitments of resources at the domestic research reactors with the implementation of any of the proposed SNF alternatives for generating and storing SNF. If, under the No Action Alternative, any NRC-licensed facility should elect to modify its SNF storage capabilities, a site-specific license amendment would be required. If the storage facilities were expanded, there would be a commitment of construction materials and fuel to operate construction equipment. The other DOE SNF alternatives would involve no commitment of resources at domestic research reactor facilities.

7.3 Nuclear Power Plant Spent Nuclear Fuel

Implementation of the Decentralization Alternative could result in irreversible and irretrievable commitments of resources at the West Valley Demonstration Project site. Should this alternative be selected, this commitment of resources would result from the construction materials and fuels used to provide alternative on-site SNF storage capability. The magnitude of these commitments cannot be quantified, however, until it is determined whether existing SNF storage capacity would be modified or a new SNF storage facility would be constructed and its type.

Implementation of any of the other proposed alternatives for SNF would not result in any additional irreversible and irretrievable commitments of resources at the commercial SNF storage facilities.

1. APPENDIX F INTRODUCTION

This appendix addresses the interim storage of spent nuclear fuel (SNF) at two U.S. Department of Energy sites, the Nevada Test Site (NTS) and the Oak Ridge Reservation (ORR). These sites are being considered to provide a reasonable range of alternative settings at which future SNF management activities could be conducted. These locations are not currently involved in management of large quantities of SNF; NTS has none, and ORR has only small quantities. But NTS and ORR do offer experience and infrastructure for the handling, processing and storage of radioactive materials, and they do exemplify a broad spectrum of environmental parameters. This broad spectrum of environmental parameters will provide a perspective on whether and how such location attributes may relate to potential environmental impacts. Consideration of these two sites will permit a programmatic decision to be based upon an assessment of the feasible options without bias to the current storage sites.

This appendix is divided into three parts. Part One is the Appendix F introduction. Part Two contains chapters one through five for the NTS, as well as the NTS references in chapter six and acronyms and abbreviations in Chapter 7. Part Three contains chapters one through five for the ORR, as well as the ORR references in chapter six and abbreviations and acronyms in Chapter 7. A Table of Contents, List of Figures, and List of Tables are included in Parts Two and Three. This approach permitted the inclusion of both sites in one appendix while maintaining chapter numbering consistent with Volume 1 and Appendices A, B, and C.

Currently, no SNF is stored at the NTS and only small quantities of SNF generated by research reactors at ORR are stored there. In order to receive, handle, and store spent nuclear fuel from other DOE sites on an interim basis, new facilities would need to be constructed at the NTS and ORR. Since the basic facilities to receive and handle the spent fuel, as well as any safety-related and emergency containment, cleanup, and recanning facilities, are approximately equivalent for all alternatives being considered, only the size of the storage facility will vary for each alternative, with the Centralization Alternative requiring the largest storage facility. As discussed in Chapter 3, only the Centralization Alternative for spent fuel storage at either the NTS or ORR is analyzed quantitatively in this volume; the Regionalization Alternative is evaluated qualitatively. The results of this appendix are then summarized in Volume 1.

NEVADE TEST SITE

FIGURES

TABLES

#1. INTRODUCTION

This part assesses the impacts of construction and operation of proposed spent nuclear fuel (SNF) facilities at the Nevada Test Site (NTS). The NTS is being evaluated for these facilities because of the area available, the isolation of population centers, the apparently suitable site environmental parameters, previous U.S. Department of Energy activities involving radioactive materials at the site, and the planned long-term government control of the site.

This part is organized as follows. Chapter 1 is the introduction, Chapter 2 sets the stage for the area under analysis by providing an overview of the NTS and discussions of the Regulatory Framework and SNF Management Program, and Chapter 3 explains the SNF alternatives being considered at the site.

Chapter 4 describes the human and natural environment that could be affected as a result of the introduction of an SNF facility at the NTS. Environmental parameters such as water resources, socioeconomics, biological resources and air quality are examples of those characterized.

Chapter 5 enumerates the environmental consequences that might be anticipated, the cumulative impacts, the unavoidable adverse impacts, the relationship between short-term use and long-term productivity, the irreversible and irretrievable commitment of resources, and possible mitigation measures that might be anticipated if an SNF facility were built at the NTS. Chapter 6 contains the references used to develop this part of the Environmental Impact Statement. Chapter 7 contains the abbreviations and acronyms used in this Part.

2. NEVADA TEST SITE BACKGROUND

2.1 Overview

2.1.1 Site Description

The Nevada Test Site (NTS), located in the southeastern portion of Nevada, is operated by the U.S. Department of Energy (DOE) as the on-continent test site for nuclear weapons testing. The site encompasses approximately 1,350 square miles (3,500 square kilometers). The NTS is surrounded on the north, east, and west by the Nellis Air Force Base (NAFB) Bombing and Gunnery Range. Together with the Tonopah Test Range, these three properties provide a 15- to 65-mile (24- to 104-kilometer) buffer zone between the test areas and public lands. The Bureau of Land Management owns land on the southern and southwestern borders of the NTS. Las Vegas is approximately 65 miles (104 kilometers) from the southeast corner of the site (Figure 2.1-1) (DOE/NV 1991a; USAF et al. 1991).

The NTS is a large, open area, tightly controlled, with the infrastructure to conduct tests with hazardous and radioactive materials. Security at the NTS consists of security guards, often using four-wheel drives, patrolling the site. The perimeter of the site is not fenced. Armed guards and electronic security measures are in place for secure areas. Approximately 25 percent of the site is unused or is used as a buffer zone for ongoing programs or projects (DOE/NV 1991a; USAF et al. 1991).

The NTS is broken into numbered test areas to simplify the distribution, use, and control of resources (Figure 2.1-2). Area 22, the site's main entrance, is located on the southeast corner of the site and contains the Desert Rock airstrip. Area 23, adjacent to Area 22, contains the Mercury base camp, which houses administrative operation and general support activities. Offices for the DOE, the U.S. Department of Defense (DoD), Defense Nuclear Agency, Lawrence Livermore National Laboratory (LLNL), Los Alamos National Laboratory (LANL), Sandia National Laboratories (SNL), and all supporting contractors of these organizations are located in this area. Other facilities in this area include the cafeteria, recreation, transportation, and housing. Area 5 (Frenchman Flat) was used in the past for nuclear testing. Area 6, north of Figure 2.1-1. Nevada Test Site regional map. Figure 2.1-2. Nevada Test Site map. Area 5, contains the Control Point One facility which overlooks Yucca Flat, where a large portion of the testing occurs. This facility provides control over and execution of nuclear detonations at the NTS. Also in Area 6 there is a new work camp which is used for construction and craft support. Other areas located on the NTS are the valley of the Yucca Flat (Areas 3, 7, and 9), the Rainier Mesa (Area 12), which is the center of DoD/Defense Nuclear Agency activities, and the Pahute Mesa (Areas 19 and 20) (DOE/NV 1991a; ERDA 1977; USAF et al. 1991). Area 5 will be housing the proposed spent nuclear fuel (SNF) facilities. Figure 2.1-2 shows the approximate location of the proposed SNF facility. The actual location will be determined for site-specific environmental documentation.

2.1.2 Site History

Prior to 1951, the land which is now occupied by the NTS was used for mining and grazing. Primarily, mining was for low grades of copper, lead, silver, gold, mercury, and tungsten. Although there were short periods of mining success at the site, the area was abandoned over time. Grazing ended in 1955 when the Federal government acquired the water and grazing rights of two ranches which were operating on what is now the NTS (ERDA 1977).

Since January 1951, the land now occupied by the NTS has been the primary location for nuclear weapons testing in the United States. Land was withdrawn from the NAFB Bombing and Gunnery Range in 1952 to form the NTS. Subsequent withdrawals occurred in 1958, 1961, and 1962. A Memorandum of Understanding between NAFB and the NTS in 1967 allowed the use of Pahute Mesa by the NTS (DOE/NV 1991a; USAF et al. 1991).

Most of the tests performed at the NTS in the 1950s were atmospheric tests. After 1951, nuclear tests were carried out intermittently until a voluntary moratorium ended testing in October 1958. The first full-scale nuclear detonation occurred in 1957 in a sealed tunnel. Testing resumed in September 1961 following the ending of the moratorium. Atmospheric testing ended in the summer of 1963 following the signing of the Limited Test Ban Treaty. Since 1962, all testing has occurred underground. Two methods have been used for underground testing since 1963: vertical shafts (from the valley of Yucca Flat to the top of Pahute Mesa) and horizontal tunnels (Rainer Mesa) (DOE/NV 1991a; ERDA 1977; USAF et al. 1991).

In addition to underground testing, between 1962 and 1968, earth-cratering tests were conducted as part of the Plowshare Program. This program explored peaceful means of using nuclear explosives. Other tests which have occurred on the NTS have included the Bare Reactor Experiment (1960s) and the open air nuclear reactor, nuclear engine, and nuclear furnace tests (1959-1973). Much of the nuclear testing has been conducted on the NTS by the LANL, LLNL, SNL and, through the Defense Nuclear Agency, the DoD. Non-nuclear testing has included hazardous material spills. Other activities which occur on the NTS are the storage and disposal of low-level radioactive wastes and mixed wastes (DOE/NV 1991a; ERDA 1977; USAF et al. 1991).

As part of DOE's program to establish a national repository for high-level radioactive waste, Lawrence Livermore National Laboratory conducted an evaluation of the effects of radiation and heat from radioactive decay on granite rock formations. The project, known as Spent Fuel Test - Climax, stored 11 spent fuel elements from the Florida Power & Light Company and 6 electric heat simulators in specially designed and constructed holes in the Climax tunnel, located in the northeastern corner of the NTS in Area 15. The SNF, in hermetically sealed canisters, was emplaced in the granite formation, stored for approximately 3 years, retrieved, and then transferred, in 1986, to INEL for further testing (DOE/NV 1983, 1986a).

2.1.3 Nevada Operations Office Mission

The missions of the NTS and/or the DOE Nevada Operations Office include:

- Maintaining the capability to conduct underground nuclear weapons tests.
- Conducting all programs related to nuclear emergencies and threats.
- Supporting arms control, treaty verification, and non/counter proliferation of nuclear weapons technology.
- Supporting research activities as part of being designated a National Environmental Research Park.
- Conducting tests for the Liquefied Gaseous Fuels Spill Testing Program.
- Supporting studies in alternate energy sources and environmental management, research and development, and testing.
- Ensuring that all operations are conducted in compliance with all environmental, safety, and health laws, regulations, standards, agreements, and DOE Orders (DOE/NV 1993b, 1992a, 1991a; ERDA 1977).

2.1.4 Nevada Test Site Management

The DOE Nevada Operations Office is currently administering NTS operations. The NTS has multiple contractor support. The major support contractors are Reynolds Electrical &

Engineering Co., Inc., the prime contractor; EG&G Energy Measurements, Inc., the electronic and instrumentation support contractor; Raytheon Services Nevada, the architect-engineering support contractor; and Wackenhut Services, Inc., the site security contractor.

2.1.5 Yucca Mountain Project

The DOE Office of Civilian Waste Management is conducting a program for siting the nation's first geologic repository for spent nuclear fuel and other high-level radioactive wastes.
The Yucca Mountain Site has been designated by the U.S. Congress as a candidate site. Although Yucca Mountain is located outside the western boundary of the NTS, a contiguous portion of the NTS has been assigned as part of the potential repository site. Access to the site is accomplished through the NTS and Yucca Mountain Project field offices and support facilities are located in Area 25 (DOE/NV 1993b). Currently, Yucca Mountain is being characterized to study its suitability as a geological repository. The characterization study includes exploratory borings and analyses of meteorological, geological, hydrological, geochemical, erosion, tectonics, and socioeconomics conditions. Upon completion of the characterization study, the Secretary may recommend Yucca Mountain to the U.S. President as viable site for a repository (DOE 1988b).

2.2 Regulatory Framework

The National Environmental Policy Act (NEPA) of 1969 (42 U.S.C. 4321-4347, as amended) provides Federal agency decision makers with a process to systematically consider the potential environmental consequences of agency decisions. The DOE has prepared this environmental impact statement (EIS) in conformance with the requirements of this Act to evaluate the potential impacts of programmatic decisions on the management of SNF. This EIS will provide the necessary background, data, and analyses to help decision makers understand the potential environmental consequences of each alternative.

On October 22, 1990, the DOE published a Notice of Intent in the Federal Register (FR 1990a) announcing its intent to prepare a programmatic EIS addressing environmental restoration and waste management (including SNF management) activities across the entire DOE Complex. On October 5, 1992, the DOE published a Notice of Intent in the Federal Register (FR 1992) announcing its intent to prepare an EIS addressing environmental restoration and waste management and SNF activities at the Idaho National Engineering Laboratory. For further programmatic discussion of this topic, see Volume 1.

Significant Federal and state environmental and nuclear materials management laws are applicable to the NTS. The Federal laws are listed in Volume 1, Section 7.3. The State of Nevada laws are listed alphabetically below:

- Air Pollution Control Law (Title 40 Chapter 445)
- Air Quality Regulations (Title 40 Chapter 445)
- Disposal of Hazardous Waste (Title 40 Chapter 444)
- Disposal of Radioactive Material (Title 40 Chapter 459)
- Facilities for the Management of Hazardous Waste (Title 40 Chapter 444)
- Regulation of Highly Hazardous Substances (Title 40 Chapter 459)
- Solid Waste Disposal Act (Title 40 Chapter 444)
- Storage Tanks (Title 40 Chapter 459)
- Underground Injection Control (Title 40 Chapter 445)
- Water Pollution Control Law (Title 40 Chapter 445)
- Water Pollution Regulations (Title 40 Chapter 445)

2.3 Spent Nuclear Fuel Management Program

Currently, spent nuclear fuel is not generated, received, reprocessed, or stored at the NTS; therefore, a SNF management program does not currently exist for activities at the NTS (DOE 1993). There are no current or foreseeable environmental, safety, or health vulnerabilities at the NTS associated with SNF (DOE 1993). Selection of the No-Action Alternative would not adversely affect the operations or any planned facility modifications at the NTS.

3. SPENT NUCLEAR FUEL ALTERNATIVES

3.1 Description of Management Alternatives

This chapter describes the spent nuclear fuel (SNF) management alternatives evaluated by the U.S. Department of Energy (DOE) for Appendix F that are applicable to the Nevada Test Site (NTS). DOE did not consider the Nevada Test Site to be a preferred site for the management of spent nuclear fuel in the Draft EIS because of the State's current role as the host site for the Yucca Mountain Site Characterization Project. DOE's identification of the preferred alternatives also indicates that DOE does not consider the Nevada Test Site as a preferred site for spent nuclear fuel management in the Final EIS. For the purposes of conducting a thorough NEPA analysis, the NTS provides a contrast to other potential sites because it represents a site that has no existing SNF management infrastructure. The NTS does not currently generate or store any SNF. Hence, of the five alternatives discussed in this Programmatic Environmental Impact Statement (EIS), only two, Regionalization and Centralization, are applicable to the NTS. The other three alternatives -- No Action, Decentralization, and the 1992/1993 Planning Basis -- are not applicable to the NTS since they affect or involve only sites which currently generate or store SNF.

3.1.1 Alternative 1 - No Action

The No Action Alternative is restricted to the minimum actions necessary for the continued safe and secure management of SNF. As defined, this alternative stipulates no SNF shipments to or from DOE facilities. The NTS does not currently generate or store any SNF and would not receive any SNF under this alternative. Therefore, this alternative is not applicable to the NTS and is not analyzed or discussed further in this or subsequent chapters for the NTS.

3.1.2 Alternative 2 - Decentralization

Decentralization involves storage of SNF at or close to generation sites, with limited shipments to the Idaho National Engineering Laboratory (INEL) and Savannah River Site (SRS) as necessary to permit continued operation. Since the NTS does not generate or store any SNF and would not receive any SNF under this alternative, it is not applicable to the NTS and is not analyzed or discussed further in this or subsequent chapters for the NTS.

3.1.3 Alternative 3 - 1992/1993 Planning Basis

The 1992/1993 Planning Basis Alternative is DOE's documented 1992/1993 plan for the management of DOE and Naval SNF. Since the NTS does not generate or store any SNF and would not receive any SNF under this alternative, it is not applicable to the NTS and is not analyzed or discussed further in this or subsequent chapters for the NTS.

3.1.4 Alternative 4 - Regionalization

3.1.4.1 Overview. The Regionalization Alternative consists of two subalternatives.

Subalternative A would distribute existing and new SNF between the Hanford Site, INEL, and SRS by SNF type. Under Subalternative B, SNF would be distributed to either an eastern or western regional site based on geographical location. SNF east of the Mississippi River would be shipped to the eastern region site (i.e., SRS or Oak Ridge Reservation (ORR)). SNF west of the Mississippi River would be shipped to the western regional site (i.e., Hanford, INEL, or NTS). Additionally, all Naval SNF would be shipped to only one of the sites, but not both. The ORR would be the alternative to the SRS as the eastern regional site, and the NTS would be the alternative to both the Hanford Site and INEL as the western regional site.

3.1.4.2 Regionalization Subalternative B. The following fuels would be transported to

the NTS for storage under the Regionalization Subalternative B:

- Naval-type SNF (if selected)
    - All, including from the INEL, shipyards, and prototypes
- Hanford Production SNF
    - From western sites including the Hanford Site
- Graphite SNF
    - From western sites including the INEL and Public Service of Colorado
- DOE-Owned Commercial SNF
    - From western sites including the Hanford and INEL
- Experimental - Stainless steel SNF

  - From western sites including the Hanford, INEL, Foreign Research Reactors, and non-DOE domestic research reactors
- Experimental - Zirconium SNF
  - From western sites including the INEL
- Experimental - Other
  - From western sites.
- SRS Production and Aluminum SNF
  - From western sites including INEL, Los Alamos National Laboratory (LANL), Foreign Research Reactors, and non-DOE domestic research reactors

All SNF presently in storage at DOE facilities would arrive at the NTS stabilized and canned to the extent necessary for safe transportation. However, this SNF might need to be uncanned, stabilized, prepared, and recanned at the NTS to ensure safe interim storage. New non-DOE domestic, Foreign Research Reactors, and Naval SNF would be shipped in the state necessary for safe transportation but not necessarily canned. This fuel would be stabilized, prepared, and canned at the NTS to ensure safe interim storage. All fuel would be cooled for a minimum of 120 days prior to shipping and 5 years before being placed in dry storage. Additionally, if the NTS is selected for the Expended Core Facility, Naval SNF would be examined at the NTS before being turned over for interim storage management.

The NTS currently has no facilities that are suitable for receiving, canning, storing, or supporting the research activities necessary for the safe management of SNF. As a result, a new SNF management complex would be built at the NTS under the Regionalization Subalternative B. The SNF management complex would include the following:

- SNF receiving and canning facility
- Technology development facility
- Interim dry storage area
- Expended Core Facility similar to the one at the INEL (if selected for Naval Fuel Receipt).

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before it is placed into dry storage, as necessary. The technology development facility would investigate the applicability of dry storage technologies and pilot scale technology development for disposal of the various types of SNF. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. If NTS is selected for Naval fuel receipt, Naval SNF would be examined at the Expended Core Facility prior to being turned over for interim storage management.

The SNF management complex which would be built at the NTS under the Regionalization Alternative would have the same components as that built under the Centralization Alternative. However, the dry storage component would be somewhat smaller due to the smaller SNF inventory that would be transported to the NTS under the Regionalization Alternative. The other components of the SNF management complex would be the same general size as those built under the Centralization Alternative. This is because the inventories of new uncanned fuel which would be sent to the NTS under the Regionalization and Centralization Alternatives would be very similar. Additionally, since the major portion of the potential radiological and chemical releases and waste generation rates are associated with these components, the Regionalization Alternative will not be analyzed separately. This alternative will be compared to the Centralization Alternative in a semiquantitative manner.

If the NTS is not chosen as the western regional site, the Regionalization Alternative would not be applicable to the NTS.

3.1.5 Alternative 5 - Centralization

3.1.5.1 Overview. Under Centralization, all existing and new SNF would be shipped to

one site. There are five Centralization options considered in this PEIS; Option A - Hanford Site, Option B - INEL, Option C - SRS, Option D - ORR, Option E - NTS. If the NTS was chosen as the centralization site, all SNF currently stored at the HS, INEL, SRS, ORR, and other sites currently storing DOE fuel would be transferred to the NTS.

3.1.5.2 Centralization Alternative Option E. The following fuels would be transported to

the NTS for storage under the Centralization Alternative Option E:

- Naval-type SNF
  - From the INEL and shipyards
- Hanford Production SNF
  - From the Hanford Site
- Graphite SNF
  - From the INEL and Public Service of Colorado
- DOE-Owned Commercial SNF

    - From Hanford, INEL, West Valley Demonstration Project, and B&W Lynchburg
- Experimental - Stainless Steel SNF
    - From Hanford, INEL, SRS, FRR, and non-DOE domestic research reactors
- Experimental - Zirconium SNF
    - From the INEL and SRS
- Experimental - Other
    - From the Oak Ridge National Laboratory (ORNL)
- SRS Production and Aluminum SNF
    - From the INEL, SRS, ORNL, LANL, Brookhaven National Laboratory, Foreign Research Reactors, and non-DOE domestic research reactors.

All SNF presently in storage at DOE facilities would arrive at the NTS stabilized and canned to the extent necessary for safe transportation. However, this SNF may need to be uncanned, stabilized, prepared, and recanned at the NTS to ensure safe interim storage. New non-DOE domestic research reactor, Foreign Research Reactor, and Naval SNF would be shipped in a state necessary for safe transportation but not necessarily canned. This fuel would be stabilized, prepared, and canned at the NTS to ensure safe interim storage. All fuel would be cooled for a minimum of 120 days prior to shipping and 5 years before being placed in dry storage. Additionally, Naval SNF would be examined at the NTS before being turned over for interim storage management.

The NTS currently has no facilities that are suitable for receiving, canning, storing, or supporting the research activities necessary for the safe management of SNF. As a result, a new SNF management complex would be built at the NTS under the Centralization Alternative Option E. The SNF management complex would include the following:

- SNF receiving and canning facility
- Technology development facility
- Interim dry storage area
- Expended Core Facility similar to the one at the INEL.

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before it is placed into dry storage, as necessary. The technology development facility would investigate the applicability of dry storage technologies and pilot scale technology development for disposal of the various types of SNF. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. Naval SNF would be examined at a new Expended Core Facility constructed at the NTS prior to being turned over for interim storage management.

The SNF management complex which would be built at the NTS under the Centralization Alternative would have the same components as those built under the Regionalization Alternative. However, the dry storage component would be somewhat larger under the Centralization Alternative due to the somewhat greater SNF inventory that would be transported to the NTS under this alternative. The other components of the SNF management complex would be the same general size as those built under the Regionalization Alternative. This is because the inventories of new uncanned fuel which would be sent to the NTS under the Regionalization and Centralization Alternatives would be very similar. Additionally, the major portion of the potential radiological and chemical releases and waste generation rates are associated with these components, and would not be significantly different for the two alternatives. Therefore, this alternative will be used as the basis for a semiquantitative comparison with the Regionalization Alternative.

If the NTS is not chosen as the centralization site, the Centralization Alternative would not be applicable to the NTS.

3.2 Comparison of Alternatives

Table 3.2-1 shows a comparison of the alternatives. The Regionalization Alternative column does not include the requirements of the Naval Expended Core Facility, although this facility may be constructed at the site under this alternative. The Centralization Alternative column does include the requirements of the Naval Expended Core Facility, which are presented in Volume 1, Appendix D, since this facility will be built at the site under this alternative.

Table 3.2-1. Comparison of alternatives for the NTS.

Parameter	Regionalization Subalternative B	Centralization Option E[a] at NTS
Land for new facilities (acres)	90	120
Site area (acres)	864,000	864,000
Percent of site area	0.01	0.01
SNF-related employment[b]	556	1,118
Baseline site employment	8,563	8,563
Percent of baseline site employment	6.5	13.1
Estimated cancer fatalities in 80-km population per year, SNF management	4.1 x 10^{-5}	

operationsc		4.1 x 10-5
Estimated cancer fatalities in 80-km population per year, other site operations	2.6 x 10-6	2.6 x 10-6
Estimated probability of cancer fatalities in a maximally exposed individual per year, SNF management operationsc	5.9 x 10-8	5.9 x 10-8
Estimated probability of cancer fatalities in a maximally exposed individual per year, other site operations	5.5 x 10-9	5.5 x 10-9
Estimated probability of cancer fatality in average worker per year, SNF management operationsc	1.6 x 10-5	1.6 x 10-5

Estimated maximum risk of worker cancer fatalities from maximum risk accident (cancer fatalities per year)d	1.9 x 10-7	

a. Centralization Option includes the Naval Expended Core Facility results from Volume 1, Appendix D.
b. Annual Average SNF direct construction and operation jobs over the 10-year period 1995 to 2005.
c. Excludes baseline site operations.
d. Centralization Option is the same as the Regionalization Option for the SNF Management Facility and does not include the Naval Expended Core Facility accident analyses results from Volume 1, Appendix D.

4. AFFECTED ENVIRONMENT

4.1 Overview

This chapter describes the existing environmental conditions in areas potentially affected by a programmatic decision to site spent nuclear fuel (SNF) facilities at the Nevada Test Site (NTS) under the Centralization and Regionalization Alternatives. Topics were selected for analysis based upon their potential to be affected by the alternatives. Each topic is addressed in the detail necessary to serve as a baseline for assessment of potential environmental consequences in Chapter 5.

4.2 Land Use

The NTS occupies an area of approximately 1,350 square miles (3,500 square kilometers) in southern Nevada, in a sparsely populated desert area approximately 65 miles (104 kilometers) northwest of Las Vegas. The NTS is almost entirely surrounded by other federally owned lands which buffer it from lands open to the public. The NTS is bordered by the Nellis Air Force Base (NAFB) Bombing and Gunnery Range on the north, east, and west, and by Bureau of Land Management (BLM) lands on the south and southwest (DOE/NV 1993a,b).

Existing land use on the NTS falls into four general categories: Testing Areas; Buffer/Reserved Areas; Industrial/Research Areas; and Waste Management Areas. According to the latest NTS land use map (Figure 4.2-1), approximately 50 percent of the land on the NTS is buffer/reserved area for ongoing programs or projects (DOE/NV 1993a).

Land bordering the site to the north, east, and west is located on the NAFB Bombing and Gunnery Range and is primarily vacant, unused, or used for a buffer zone. Land bordering the site to the south and southwest is owned by the BLM and is used for recreation, grazing, forest management, or wildlife management (DOE/NV 1993a,b).

The NTS is located in an area of sparsely vegetated desert. Beyond the federally owned lands which surround the NTS, principal land uses in Nye County in the vicinity of the NTS include mining, grazing, agriculture, and recreation (DOE/NV 1993a). Urban and residential land uses occur beyond the immediate vicinity of the NTS, in fertile valley regions such as the Owens and San Joaquin to the west of the site, the Virgin River to the east of the site, the Pahrump to the south of the site, the Moapa River to the southeast of the site, and the Hiko and Alamo to the northeast of the site (DOE/NV 1993b).

Figure 4.2-1. Land use at the Nevada Test Site.

Clark County, to the southeast of the NTS, consists of approximately 7900 square miles (20,220 square kilometers) of which about 95 percent is owned by the federal government (ULI 1992). Primary land uses on these federal lands include grazing, mining, and recreation. The remaining 5 percent of the county supports residential, state and local government, industrial, and retail land uses (Clark County Regional Transportation Commission 1992).

Currently, Nye County does not have a zoning ordinance; therefore, no zoning classification exists for NTS lands. The NTS is required to comply with State of Nevada regulations for air pollution, safety, and transportation, and with Nye County traffic regulations and safety codes (DOE/NV 1993b). Of the total area within Nye County, only a small number of isolated areas are under private ownership and therefore subject to general plan guidelines (NEEDA 1993).

Numerous national, state, and local public recreation areas exist within the NTS region (Figure 2.1-1). Outdoor recreational areas include the Death Valley National Monument, located 12 miles (19 kilometers) to the west/southwest, and the Desert National Wildlife Range, approximately 25 miles (40 kilometers) east. (Portions of the Desert National Wildlife Range are located within NAFB Bombing and Gunnery Range and are as close as 2 miles (3 kilometers) to the NTS). State parks near the site include; the Red Rock Canyon Recreation Lands, approximately 40 miles (64 kilometers) to the southeast; Spring Mountain Ranch State Park, approximately 50 miles (80 kilometers) southeast; and the Floyd R. Lamb State Park, approximately 45 miles (72 kilometers) southeast (BLM 1990).

Other recreational areas include numerous campsites, picnic areas, and sports grounds south of the site in the Toiyabe National Forest, approximately 25 miles (40 kilometers) southeast, and numerous camping and fishing sites north of the site which are used during the spring, summer, and fall months (DOE/NV 1993a,b,c).

The NTS is a controlled area with public access limited to through traffic on U.S. Route 95 and on Lathrop Wells Road (DOE/NV 1993b).

The proposed SNF site is in the northeast portion of Area 5, located in the southeastern part of the NTS. This area is currently designated as the Low-Level Waste Facility Management Area and Buffer/Reserved Area land use categories. This area was also designated as a Non-Nuclear Test Area in the latest NTS Future Land Use Plan (DOE/NV 1993a).

To the east of Area 5, the NTS is bordered by the NAFB Bombing and Gunnery Range, which provides a buffer zone of approximately 50 miles (80 kilometers) between the NTS and lands open to the public. Beyond the NAFB Bombing and Gunnery range land, land uses to the east of the NTS are primarily mining, grazing, and agriculture (BLM 1990; DOE/NV 1993a).

There are no onsite areas that are subject to Native American Treaty rights or contain any prime or unique farmland.

4.3 Socioeconomics

4.3.1 Region of Influence

The socioeconomic information presented in this Programmatic Environmental Impact Statement (PEIS) discusses the baseline conditions in a Region of Influence comprising of Nye and Clark Counties, Nevada. This is the region potentially affected by the principal direct and indirect socioeconomic effects of actions on the NTS. This Region of Influence includes the current residential distribution of the U.S. Department of Energy (DOE) and contractor personnel employed by the NTS, the probable location of offsite contractor operations, and the probable location of labor and capital supporting indirect economic activity linked to the NTS.

The residential distribution of most of the DOE and contractor personnel employed by the NTS reflects existing commuting patterns and attractiveness of area communities. A survey of NTS worker residential distributions in 1988 revealed that 86 percent lived in Clark County and 10 percent in Nye County (DOE 1988a). In Clark County, most NTS employees reside in the Las Vegas vicinity.

The two-county Region of Influence includes several communities located within a driving time of approximately 1 hour from the NTS, including Boulder City and the Las Vegas Valley (includes the "incorporated places" of Henderson, Las Vegas, and North Las Vegas; and the "census-designated places" of East Las Vegas, Enterprise, NAFB Bombing and Gunnery Range, Paradise, Spring Valley, Sunrise Manor and Winchester) in Clark County, and Pahrump and Beatty in Nye County (DOE/NV 1993a,b).

4.3.2 Regional Economic Activity and Population

Regional economic linkage supporting production activity at the NTS occurs primarily with Clark County, where most of the offsite supporting contractors and the labor and capital supporting indirect economic activity linked to the NTS are located.

4.3.2.1 Clark County (Las Vegas Metropolitan Statistical Area(1)). Clark County is

composed of five incorporated cities (Las Vegas, Henderson, North Las Vegas, Boulder City, and Mesquite) and large expanses of unincorporated land, some of which are experiencing strong growth. The area experiencing the majority of the county's development is the Las Vegas Valley (ULI 1992). In addition, 95 percent of the total area within the county is owned by the Federal government and includes several state parks, vast stretches of desert, and military installations.

Economic conditions in southern Nevada since the mid-1980s have grown continuously. Economic growth has accelerated relative to national trends due to an expansion in hotel and gaming markets, relocation of retirees to southern Nevada, expansion of local infrastructure, and additional unplanned investment to house new families in the region. The overall long-term growth pattern is forecasted to gradually change the current robust expansion to more stable growth conditions, as seen in the United States (The Center for Business and Economic Research 1992).

The economy in the Las Vegas Metropolitan Statistical Area is driven by growth in the hotel and gaming industry. Because of its orientation toward tourism and conventions, the economy is highly service oriented. Service employment in the Las Vegas area is substantially higher than the relative national share, accounting for nearly 45 percent of total employment, with hotels and gaming accounting for approximately 30 percent of the service factor. Trade employment accounts for 21 percent, and government and construction each account for an additional 10 percent (ULI 1992). Construction employment has increased over 130 percent since 1980, with 32,000 jobs in that sector in 1993 particularly due to the building and expansion of a number of casinos in Clark County (DOE/NV 1993a). The industrial market has also induced growth in the construction sector, causing a 50 percent increase in new construction activity between 1990 and 1992. Growth in the industrial market is expected to continue, with demand outpacing new construction (ULI 1992). Manufacturing employment is increasing steadily (7 percent from 1992 to 1993); however, this sector comprises only a 2.8 percent share of total employment (DOE/NV 1993a), still well below the national average.

Between 1980 and 1990, Clark County added an average of 15,000 jobs per year. By year-end 1991 another 19,000 jobs had been added to the employment base for 1990, for a total of 388,000 jobs (ULI 1992). In September 1992, employment in the Las Vegas area reached 399,900. Despite the national recession during 1990-1992, the number of existing jobs in the Las Vegas area increased rapidly, averaging an 8.1 percent gain during that period (DOE/NV 1993a).

The number of existing jobs in the Las Vegas area is projected to continue increasing for the next several years. The State of Nevada Employment Security Research Department estimated there would be a total of 125,190 new jobs in the Las Vegas area between 1991 and 1996, an increase of approximately 6 percent annually (DOE/NV 1993a).

The unemployment rate reached a low of 4.9 percent in 1990 and increased to 7.5 percent as of June 1993 (DOE/NV 1993a). The increase in unemployment reflected the fact that the in-migration of labor exceeded the growth in employment opportunities. However, the unemployment level is expected to decrease with new hotel, gaming, and amusement properties opening at the end of 1993 (DOE/NV 1993a).

Most of the population in the Las Vegas Metropolitan Statistical Area is centered in the

---

1. At the time of the 1990 census, CLark County and the Las Vegas Metropolitan Statistical Area were synonymous. The Census Bureau redifined the Las Vegas Metropolitan Statistical Area to include Mohave County, Arizona. However, the numbers provided here reflect the 1990 census definition.

Las Vegas Valley, with six population groupings in the area: the Las Vegas Valley, Boulder City, Indian Springs, Laughlin, Mesquite, and the Moapa Valley (DOE/NV 1993b). In 1990, the population of the metropolitan statistical area totaled 735,000, growing at a rate of 4.7 percent annually from 1980 (ULI 1992). This rate of growth, however, is lower than that near the end of the 1980s. The population of the metropolitan statistical area was estimated at over 900,000 as of August 1993, an increase of nearly 8 percent annually since 1990 (DOE/NV 1993b).

4.3.2.2 Nye County. The employment level in Nye County (11,310 jobs) is low relative

to Clark County, and includes opportunities in the services, mining, and government sectors (DOE/NV 1993b).

Nye County is sparsely populated, with the two largest population groupings being in the unincorporated communities of Pahrump and Tonopah. The populations of Pahrump and Tonopah in 1990 were 7,424 and 3,616 (62 percent and 20 percent of the county total), respectively (DOE/NV 1993b).

Tourist (and business traveller) activity is an important part of the Nye County economy in communities along U.S. Route 95; however, in each community, mining is the major, even dominant, economic force.

In the 1970s and 1980s, nuclear weapons testing at the NTS dominated the Nye County economy when described in terms of employment by place of work. Most of the NTS work force commutes to Mercury or forward areas from the Las Vegas Valley, and most food and other services are provided at federally subsidized facilities onsite. However, some Nye County businesses do provide NTS support services. In the context of the Yucca Mountain repository oversight program, Nye County and DOE have engaged in efforts that could lead to greater employment and procurement opportunities for Nye County residents and businesses (NEEDA 1993).

4.3.2.3 Nevada Test Site. The NTS work force supports engineering design,

construction, and operation of the site and includes people employed by DOE and people employed by DOE contractors. The total NTS work force in 1993 included nearly 4,000 jobs located at the NTS and an additional 5,000 jobs in the Nevada Operations Office (DOE/NV 1993a). As of January 1994, the work force totaled 8,563 (3,286 on NTS, 3,805 in Las Vegas, and 1,472 in the rest of Nevada or other areas). There is currently no SNF-related employment at NTS (DOE/NV 1994a).

4.3.2.4 Aggregate Regional Economic and Demographic Baseline. For the purposes of

establishing a regional baseline to assess potential impacts for the programmatic analyses in Section 5.3, regional economic and demographic data for Clark and Nye counties were aggregated to form one region (Table 4.3-1).

The total population of this Region of Influence is projected to be 998,093 persons in 1995 and to grow at an annual average rate of 2.7 percent, reaching 1,281,666 persons in 2004. The labor force of the Region of Influence is projected to grow at an annual average rate of 3.1 percent, reaching 792,309 persons in 2004. The total employment in the Region of Influence is projected to grow at an annual average rate of approximately 3.1 percent from 552,439 jobs in 1995 to 734,589 jobs in 2004.

4.3.3 Public Service, Education and Training, and Housing Infrastructure

4.3.3.1 Police and Fire. The NTS's fire protection capacity is structured to accommodate

current mission requirements, with a self-contained firefighting department responsible for suppression and prevention. Other services include rescue, hazardous material response, training of fire personnel, fire prevention inspections, installation of all fire extinguishers at the NTS, and fire prevention awareness programs. In addition, the DOE has signed an agreement whereby the Nye County Fire Department will assist the Clark County Fire Department in case of an emergency at the NTS (DOE/NV 1993a).

The Las Vegas Fire Department is spending $9.7 million to build three new fire stations in the northwest area of the city to support growing public service demand in this area. The Clark

Table 4.3-1. Aggregate regional economic and demographic indicators for the NTS.

Years	Regional employment	Regional labor force	Regional population
1995	552,439	595,851	998,093
1996	573,279	618,329	1,033,234

1997	594,916	691,666	1,069,422
1998	617,450	665,968	1,107,037
1999	640,822	691,175	1,145,711
2000	665,060	717,317	1,185,766
2001	681,956	735,538	1,209,316
2002	699,258	754,197	1,233,372
2003	716,971	773,299	1,257,672
2004	734,589	792,309	1,281,666
2005	752,356	811,483	1,305,461
Average Annual Growth Rate	3.1%	3.1%	2.7%

a. Sources: Nye County Board of Commissioners (1993); The Center for Business and Economic Research (1992).

Note: Aggregate region includes Clark and Nye Counties. Labor force projection developed for this study.

County Fire Department plans to add two new fire departments within the next 5 years. There is a mutual agreement between the Clark County Fire Department and all surrounding area departments to assist in any fire emergency when necessary (DOE/NV 1993a).

Law enforcement at the NTS is provided by the Nye County Sheriff. Security enforcement, established to accommodate the requirements of NTS's mission, is the responsibility of a private contractor. Regional law enforcement services are provided principally by the Las Vegas Metropolitan Police Department. Las Vegas ranks fourth nationally in metropolitan statistical areas in police per capita, with 1 per 277 population (DOE/NV 1993a).

4.3.3.2 Health Care. The NTS has a self-contained medical center that provides limited

emergency treatment. Health care in the Las Vegas metropolitan area is provided through 13 full-service hospitals, with 3.44 hospital beds per 1,000 population. A major proposed health care facility is scheduled to open in 1994 to accommodate demand (DOE/NV 1993a).

4.3.3.3 Education and Training. The Clark County School District provides education

services for the families of the majority of the employees who work at the NTS. Enrollment in the Clark County School District was approximately 122,000 student in 1992 and was projected to be 136,000 students in 1993. An average student/teacher ratio of 22.32 is reported for elementary school grades K-6; the student/teacher ratio is not reported for other grades (DOE/NV 1993a).

Higher education and training resources provided by the NTS include the support provided by the DOE Contractor Education and Training Departments, with technical training in areas such as Radiation Protection Training, Radiological Response Training, Environmental and Health Training (which includes Hazardous Waste, Site Operation, and Emergency Response) to support NTS's mission. In addition, there are a number of vocational, training, and higher education institutions in the Las Vegas metropolitan area (DOE/NV 1993a).

Since 1990, southern Nevada has experienced tremendous growth in school enrollment. To accommodate the influx of students, the school district was able to negotiate the largest bond sale in Nevada history along with regular allocations from the Nevada legislature (DOE/NV 1993a).

4.3.3.4 Housing. Between 1980 and 1990, the number of housing units in Clark County

increased by 84 percent, from approximately 174,000 to approximately 320,500. The housing market continues to flourish, as the demand for new housing has consistently exceeded the supply (ULI 1992). The increase in demand is attributable to the influx of retirees and other in-migrant population.

Residential building permits, which peaked in 1988 at 26,400 units, declined to 13,500 units in 1991. Between 1991 and 1995, the number of permits issued is expected to average 15,000 units per year (ULI 1992). Demand is projected to outpace supply over the next 5 years, given the strong projections for population and employment (ULI 1992).

4.4 Cultural Resources

4.4.1 Archaeological Sites and Historic Structures

For approximately 12,000 years, people have inhabited the lands now comprising the NTS site. The availability of surface water was the primary determinant governing the location of past human occupation on these lands. On what is now the NTS, access to surface water was through springs located in canyons and at the bases of mountains and mesas. Therefore, there is very little evidence of human occupation in valleys or playas where surface water sources were unavailable, including the Frenchman Flat area where the proposed SNF site would be located (DOE/NV 1993b).

Three cultural resource surveys were conducted in the vicinity of the proposed site. Two archaeological sites were recorded but neither was considered potentially eligible for listing on the National Register of Historic Places (DRI 1991, 1989, 1987). As a result, no prehistoric or historic resources are expected to be located on the proposed SNF site.

4.4.2 Native American Resources

The Southern Paiute and Shoshone Native American tribes are known to have inhabited southern Nevada including parts of what is now the NTS. These tribes are known to be affiliated with sites located in the northern portions of NTS including the Pahute and Rainier Mesas. However, no known Native American resources are located within the proposed SNF site (DRI 1986a).

4.4.3 Paleontological Resources

The NTS is characterized by alluvium-filled, topographically closed valleys surrounded by ranges composed of Paleozoic sedimentary rocks and Tertiary volcanic tuffs and lavas. Although igneous rocks do not contain fossils, the deposits might contain late Pleistocene terrestrial vertebrate fossils (Sandia National Laboratories 1982).

4.5 Aesthetics and Scenic Resources

Visual or scenic resources comprise the natural and manmade features that give a particular environment its aesthetic qualities. These features form the overall impression that a viewer receives of an area or its landscape character.

Scenic resources at the NTS are set in a landscape which is a transition area between the Mojave Desert and the Great Basin, with vegetation ranging from grasses and creosote bush in the lower elevations to juniper, pinyon pine and sagebrush in elevations above 5,000 feet (1,524 meters) (DOE/NV 1993b). The topography of the NTS consists of a series of mountain ranges arranged in a north-south orientation separated by broad valleys (DOE/NV 1993b). The topography is also characterized by the presence of numerous craters produced by past nuclear testing at the NTS. Of the three principal valleys located within the NTS, Frenchman Flat surrounds the proposed location of the SNF site (BLM 1990). Access to the NTS is from U.S. Route 95, which runs in an east-west direction along the south side of the NTS at Mercury Valley (BLM 1990). The Mercury Highway, which runs north from the Mercury Base Camp, is a restricted access road that is not available for public access (Figure 2.1-2).

The proposed SNF site at the NTS is set along the east side of the Mercury Highway in Area 5, within the Frenchman Flat. The proposed SNF site is located in the vicinity of the existing Radioactive Waste Management Site. The land cover in this area is typical desert vegetation.

The viewshed surrounding the NTS consists of unpopulated to sparsely populated desert and rural lands. Since the NTS is surrounded to the east, north and west by the NAFB Bombing and Gunnery Range and to the south by lands controlled by the BLM, the only public views into the interior of the NTS are from U.S. Route 95. Since the southern boundary of the NTS is ringed by various mountain ranges, including the Spector Range, Striped Hills, Red Mountain, and the Spotted Range, views to the interior of the site are generally limited to the Mercury Valley and the Mercury Base Camp (BLM 1990).

Low sensitivity exists when the public can be expected to have little or no concern about changes in the landscape. Little value may be ascribed to the views, or they may be similar to others in the area. In general, due to the mixture of industrial uses, open desert, and restricted access, the NTS could be classified as having low visual sensitivity.

4.6 Geologic Resources

This section provides a description of the general geology, geologic resources, and seismic and volcanic hazards at the NTS and surrounding area. This section also describes any existing impacts to the geology and geologic resources that have resulted from past and present activities conducted at the NTS.

4.6.1 General Geology

As shown on Figure 4.6-1, the NTS is located east and north of the Walker Lane-Las Vegas Valley Shear Zone (Eckel 1968). Walker Lane is a northwest-trending belt of right-lateral faults that disrupts the regional structural grain in the southwestern part of the Great Basin along the California-Nevada border. The Las Vegas Valley shear zone is a concealed zone of right-lateral faulting along the north side of the Las Vegas Valley (DOE 1988b). Whether the Walker Lane-Las Vegas Valley Shear Zone comprises a continuous single fault or two faults is debatable. Most geologists consider it to be a single fault system, which in the NTS area is buried beneath Figure 4.6-1. Location of Nevada Test Site in relation to regional fault zones. thick Tertiary strata (Eckel 1968). The NTS also lies in the southern part of the Great Basin Section of the Basin and Range Physiographic Province. The local geology of the NTS is characterized by mountain ranges composed of Precambrian and Paleozoic sedimentary rocks and Tertiary volcanic tuffs and lavas that surround alluvium-filled, topographically closed valleys.

A generalized stratigraphic column of the area is shown on Figure 4.6-2 (Sandia National Laboratory 1982). Figure 4.6-2 also shows the six aquifers and four aquitards of the NTS area (see Section 4.8). A schematic cross section illustrating NTS geology is shown on Figure 4.6-3 (DOE 1986). A geologic map of the NTS is shown as Figure 4.6-4 (DOE/NV 1993b).

The sedimentary rocks are complexly folded and faulted and are comprised mainly of carbonates (dolomite and limestone) in the upper and lower parts of the column and clastics (shale and sandstone) in the middle section. Above the approximately 4,000 meters (13,000 feet) of Precambrian to Cambrian clastic deposits are approximately 4,300 meters (14,000 feet) of Cambrian through Devonian carbonates, 2,400 meters (8,000 feet) of Mississippian shales and sandstones, and 900 meters (3,000 feet) of Pennsylvanian to Permian limestones (Sandia National Laboratory 1982).

The volcanic rocks in the NTS area are predominantly Tertiary tuffs that are high in silica. Although there are minor amounts of Tertiary basalts and a few scattered Mesozoic granitic plutons in the area (Sandia National Laboratory 1982), the Tertiary tuffs comprise approximately 70 percent of the rocks exposed at the surface (Eckel 1968).

The valleys formed between steeply dipping faults that have become filled with alluvium and comprise approximately 30 percent of the area (Eckel 1968). This generally unconsolidated alluvium is derived from erosion of nearby hills composed of Tertiary and Paleozoic rocks and ranges in thickness from 600 to 900 meters (2,000 to 3,000 feet) (DOE/NV 1992c). Some layers are cemented by calcium carbonate (caliche) and/or clays. The alluvial materials are better sorted and finer grained toward the center of the basins. The sediments in the playas (flat-floored undrained desert basins that, at times, become shallow lakes) consist of very fine-grained lacustrine deposits up to several tens of meters (feet) thick. Near the range fronts, alluvium is generally composed of angular rubble, with individual clasts commonly a foot or more in diameter surrounded by a matrix of silt, sand, and gravel (Sandia National Laboratory 1982).

Figure 4.6-2. Stratigraphic column of the Nevada Test Site. Figure 4.6-3. Schematic cross section portraying the geologic complexity of NTS. Figure 4.6-4. Geologic map of the NTS.(page 1) Figure 4.6-4. Geologic map of the NTS.(page 2) Faulting in the NTS area generally occurs as thrust faults (faults having shallow inclinations, mostly between 10 and 20 degrees), normal faults (faults with downward displacement of the face of the rock that lies above the fault), and strike-slip faults (nearly vertical faults characterized by shear zones) (DOE/NV 1992c). The faults located at NTS are shown on Figure 4.6-5 (DOE/NV 1993b). Thrust faulting in the NTS area occurs as three major thrust faults, with the total displacement along this fault system ranging from 40 to 48 kilometers (25 to 30 miles). Normal faults in the NTS area exist in both ranges and valleys and generally strike northeast and northwest, while a set of younger and potentially active faults strike north. The nearest strike-slip structure to the NTS is the Walker Lane-Las Vegas Valley Shear Zone (see Figure 4.6-1). Estimates of horizontal displacement along this shear zone range from 40 to 160 kilometers (25 to 100 miles) (Sandia National Laboratory 1982).

At the NTS, recent displacement has occurred along several faults as a consequence of underground nuclear explosions. This displacement is not attributable to naturally occurring seismic activity. Fault displacements are thought to have occurred as a result of the added stress produced by the explosion, the vibrations produced by the explosions, or a combination of both (Eckel 1968).

Faults are designated as capable if they have exhibited movement at or near the ground surface at least once within the past 35,000 years or movement of a recurring nature within the past 500,000 years (CFR 1993a). Almost all of the natural fault movement in the NTS area occurred several million years ago. However, movement along Yucca Fault, a north-south striking fault known in the northeast portion of the NTS (see Figure 4.6-5), is believed to have occurred sometime during the last tens of thousands to 250,000 years (Leedom 1994; Sandia National Laboratory 1982). Given the broad range of time during which displacement along Yucca Fault is believed to have occurred, Yucca Fault may or may not be an NRC capable fault (Leedom 1994).

4.6.2 Geologic Resources

Gold, tungsten, and molybdenum may exist in carbonate rocks near igneous intrusions, regional thrust faults, or other faults at the NTS. In other areas, these deposits have been found

Figure 4.6-5. Approximate location of proposed facility in relation to major faults at NTS.

in carbonate rocks associated with this type of terrane. However, based on available information, the NTS is assessed as having only a low to moderate potential for the occurrence of tungsten skarn (contact metamorphic rock rich in iron) deposits and/or polymetallic replacement deposits, and very low potential for the discovery of gold in these types of rocks. Magnetite deposits exist in rocks at the NTS, but they are not extensive and have very low resource potential. Figure 4.6-6 shows the possible location of the SNF storage facility in relation to the types of terrains associated with geologic resources as well as to locations of mining districts (USAF et al. 1991).

Gold and silver may exist at NTS in Tertiary volcanic rocks or in sedimentary rocks near volcanic or intrusive centers. Based on limited information, however, NTS is assessed as having a low to moderate potential for the development of precious metal deposits in these rocks. It is estimated that one small to medium-sized precious metals deposit might have been developed within the NTS had the area remained open to mineral development (USAF et al. 1991).

Much of the alluvial areas along the lower flanks of the ranges within the NTS contain sand and gravel reserves. These materials, however, do not have any unique value over similar material occurring in other areas throughout southern Nevada (USAF et al. 1991).

Zeolitized rocks (various hydrous silicates occurring as secondary minerals in cavities of lavas) underlie most of the volcanic rocks and the alluvial basins at the NTS. Clinoptilolite and mordenite, either alone or in mixtures, are the most common zeolites in these deposits, but ferrierite, chabazite, and analcime also occur. Zeolite deposits in Nevada that have been developed for exploitation are lakebed deposits that have been altered to zeolites under saline water-saturated conditions. Zeolites are used in water softeners, detergent builders, and cracking catalysts. Very little information is available on the tonnage and grade of these deposits. The widespread occurrence of zeolite deposits, however, requires that the deposits at NTS be assigned a low to moderate potential for development (USAF et al. 1991).

Barite is also known to occur at the NTS. The barite occurs in veins associated with quartz and mercury, antimony, and lead mineralization. These veins cut Devonian carbonate rocks. However, the barite veins at the NTS are small and impure, and do not represent a potential barite resource (USAF et al. 1991).

Figure 4.6-6. Geologic terrains and mining districts of the Nevada Test Site.

Fluorite is also reported to be present at the NTS, occurring in veins and replacement bodies within Paleozoic sedimentary rock. However, little is known about this occurrence; therefore, the NTS is assumed to have a very low to moderate potential for the development of fluorite resources (USAF et al. 1991).

4.6.3 Seismic and Volcanic Hazards

The NTS lies on the southern margin of the Southern Nevada East-West Seismic Belt. This belt connects the north-trending Nevada Seismic Belt, about 160 kilometers (100 miles) west of the site with the north-trending Intermountain Seismic Belt about 240 kilometers (150 miles) to the east. The location of these seismic belts are shown on Figure 4.6-7. The pattern of historic earthquakes in the western United States is marked by relatively brief episodes of intense activity in areas that may have been relatively inactive for hundreds and perhaps thousands of years (DOE 1986).

The southern Nevada region is generally characterized as an area of moderate seismic activity (DOE/NV 1993b). The proposed SNF management site is located on the eastern NTS in a region considered to have a moderate seismic-activity level. Earthquakes in southern California and the California desert have registered on the NTS seismic network.

Prior to the installation of a seismic network within a 160-kilometer (100-mile) radius of the site in 1978 and 1979, 12 earthquakes (including one series of earthquakes) with Richter magnitudes (M) of equal to or greater than 6.5 were reported within a 400-kilometer (250-mile) radius of the site (DOE/NV 1994b). One of the largest and nearest of the earthquakes relative to NTS was the 1872 Owens Valley shock (M = 8.25), located approximately 150 kilometers (100 miles) from the site. Figure 4.6-8 shows the location of the pre-network earthquakes with M greater than or equal to 5 that have occurred near the NTS (DOE 1988b). Recorded seismic activity prior to 1978 in the vicinity of the NTS also includes two earthquakes with M equals 4.3 and M equals 4.5 near Massachusetts Mountain (located just north of the proposed SNF storage site) and in Frenchman Flat (located in the southeast corner of the NTS, an area that includes the proposed SNF storage site) (DOE/NV 1994b).

Figure 4.6-7. Location of the NTS in relation to the Nevada Seismic Belt, the Intermountain

Seismic Belt, and the Southern Nevada East-West Seismic Belt.

Figure 4.6-8. Historical Seismicity of the Southern Great Basin from 1868 through 1993 for M>5.

Between 1978 and 1981, no earthquakes with magnitudes greater than 4.3 were recorded. Since 1981, a magnitude 5.6 earthquake was recorded near Little Skull Mountain (located near the southwest corner of the NTS) in 1992 at a depth of 12 kilometers (7.5 miles). In 1993, a magnitude 3.5 earthquake was recorded southeast of the town of Mercury on the NTS (DOE/NV 1994b). However, there is some uncertainty in the seismic sources for many signals recorded by the seismic monitoring network in the area, because underground nuclear explosions, surface drilling, and explosions to support geophysical investigations may produce earthquake-like signals (DOE 1986).

The most probable source for seismic activity within the area where the SNF storage facility would be located is the Cane Spring Fault (see Figure 4.6-5). This fault is thought to be the source of the magnitude 4.3 Massachusetts Mountain earthquake discussed above. The maximum credible earthquake associated with the Cane Springs Fault is expected to be a magnitude earthquake of 6.7. The recurrence interval for this magnitude earthquake is estimated at 10,000 to 30,000 years (DOE/NV 1993a).

Predictions of future seismicity and faulting, however, are complicated by a number of factors. Because the recurrence interval for large earthquakes on a Basin and Range fault may be thousands of years, epicenter maps of historic earthquakes or evidence of Holocene faulting alone may not be reliable indicators of future or long-term seismicity. Another complication is that when long fault zones in normal fault regimes fail, they may break along segments rather than along the entire length. Large (M greater than 7) earthquakes in the western Great Basin tend to be followed by aftershocks lasting about a century and then seismic activity stabilizes at a low level for centuries or thousands of years. Based on this concept, recurrence estimates based on historic or current earthquake distributions may not be directly applicable to the problem of identifying the most likely locations of future large earthquakes (DOE 1986).

From the historical seismicity of the southern Great Basin (two earthquakes of M equals 6) and length of active faults, a maximum magnitude of M equals 7 to 8 is inferred for earthquakes in the Yucca Mountain region. Estimates of recurrence intervals for major earthquakes in the region (M is greater than or equal to 7) are on the order of 25,000 years; for magnitudes of greater than or equal to 6, recurrence intervals are on the order of 2,500 years; and for magnitudes of greater than or equal to 5, recurrence intervals are on the order of 250 years (DOE 1986).

Ground motion acceleration resulting from earthquakes may cause damage to buildings and other structures. Ground motion acceleration is represented by the unit (g), which is the acceleration due to the force of the earth's gravitational field and is approximately equal to 986 centimeters per square second (DOE/NV 1993a). A maximum horizontal ground surface acceleration of 0.34g at the NTS is estimated to result from an earthquake that could occur once every 2,000 years (DOE 1994). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility specific basis consistent with DOE orders and standards and site specific procedures.

The Massachusetts Mountain earthquake associated with the Cane Spring Fault (the most probable source for seismic activity in the area of the proposed SNF storage facility) discussed above occurred on August 5, 1971 and produced a peak ground motion acceleration of 0.05 g. The maximum credible earthquake associated with the Cane Spring Fault is expected to produce a peak acceleration of 0.67 g (DOE/NV 1993a).

Volcanic activity in the area is evident in the geologic record by the presence of widespread tuffs and scattered granitic plutons deposited during the Tertiary period and basalts deposited during the late Pliocene and Pleistocene epochs (DOE 1988b).

The potential for renewed silicic volcanism is suggested by the youngest (7- to 8-million year old) major silicic volcanic center in the area, the Black mountain center, located just west of the northwest corner of the NTS. However, the occurrence of silicic volcanism near the NTS during the next 10,000 years is considered unlikely due to: no silicic volcanism in the south-central Great Basin during at least the past 6 million years, the decrease of silicic volcanism throughout the central and southern parts of the Great Basin during the past 10 million years, and the restriction of silicic volcanism to the margins of the Great Basin during the Quaternary (the past 2 million years). If silicic volcanism were to occur, the most likely effect at NTS would be the deposition of air-fall tuff from eruptions of silicic centers near the western margin of the Great Basin, as happened at least twice during the Pleistocene. Such volcanism could result in the deposition of fine-grained volcanic ash in layers ranging from a few millimeters to tens of centimeters thick (DOE 1988b).

The possibility of future basaltic volcanism near the NTS is suggested by Quaternary basaltic volcanism, notably in the Crater Flat basalt field, just west of the southwest corner of the NTS. However, future basaltic eruptions would likely be small and short-lived judging from the Quaternary record of basaltic volcanism due to: magma volumes for eruptions in the vicinity of the NTS during the past 8 million years being generally less than 1.0 x 108 cubic meters (3.5 x 109 cubic feet), and of short duration; a low rate of magma generation in the south-central Great Basin during the late Cenozoic as reflected by the small-volume, basalt eruptive cycles in the region; and the lack of geologic or geochemical patterns indicating that the rates of volcanism in the southern Great Basin are increasing, that such rates might increase in the future, or that basaltic activity could evolve into more voluminous types of basalt fields. The probability for the penetration of a repository at Yucca Mountain by basaltic volcanism was calculated based upon studies of volcanic deposits in the vicinity. According to these calculations, the annual probability is estimated as 3.3 x 10-10 to 4.7 x 10-8 (DOE 1988b).

4.7 Air Resources

Because the transport of airborne effluents is affected by meteorological conditions, the climatology at the NTS is discussed in this section. A summary of air monitoring networks is then included. Finally, the most recent air quality data available are presented.

4.7.1 Climatology

The climate at the NTS and the surrounding region is characterized by high solar radiation, limited precipitation, low relative humidity, and large diurnal temperature ranges. The lower elevations have a climate typical of the Great Basin.

NTS is situated at the edge of the Mojave Desert, and the arid climate is typical of the Great Basin. The Sierra Nevada Mountains of California and the series of mountains exceeding 1,830 meters (6,000 feet) in height immediately west and north of the NTS have a marked influence on the climate. The prevailing upper level winds are from the west; most of the moisture associated with Pacific Ocean storms falls on the western slopes of the Sierra Nevada. East of the Sierra Nevada, at locations such as the NTS, very little precipitation occurs.

The Weather Services Office at the NTS monitors meteorological data from numerous observation sites within and in the vicinity of the NTS. The nearest National Weather Service full-time meteorological monitoring station is at McCarran International Airport, Las Vegas.

At Area 6 of the NTS, the average daily maximum/minimum temperatures during the month of January are 10.6yC/-6.1yC (51yF/21yF). The average daily maximum/minimum temperatures are 35.6yC/13.9yC (96yF/57yF) in July. At Las Vegas, the coldest temperature on record is -13.3yC (8yF) and the warmest temperature on record is 46.7yC (116yF).

The average annual precipitation at Area 6 is 15 centimeters (6 inches). Precipitation amounts for each month are generally less than 1.3 centimeters (0.5 inch). At Las Vegas, the greatest precipitation recorded in a 24-hour period is 6.6 centimeters (2.59 inches). An average of 14 thunderstorm days occur each year, with maximum occurrence in July and August. Thunderstorms occasionally become severe. Tornadoes are extremely rare in Nevada. The average relative humidity at 4 AM in Las Vegas is 40 percent. The average relative humidity at 4 PM is 20 percent.

Low-level surface winds at the NTS are influenced by the large-scale weather patterns interacting with the mountain ranges, which generally run from north to south. Predominant winds are from the south during the summer and north during the winter. The general downward slope in the terrain from north to south across the NTS results in a diurnal wind reversal from the south during the day to the north during the night. At Area 6, the average annual wind speed is 11 kilometers per hour (7 miles per hour). Occasionally, strong winds associated with storms will exceed 82 kilometers per hour (50 miles per hour). These events are most common in the spring. At Las Vegas, the peak wind gust on record is 145 kilometers per hour (90 miles per hour). Strong winds interacting with dry soil conditions are responsible for occasional duststorms or sandstorms.

Wind direction and speed are major factors in planning and conducting nuclear tests, where atmospheric transport is the primary potential route of contamination to onsite workers and offsite populations. Figure 4.7-1 presents 10-meter (33-feet) wind roses for the NTS in 1990. A wind rose presents the frequency distribution of wind directions at a particular location. The wind roses indicate that there are differences in prevailing wind directions across the NTS. Mountain slopes and valleys are major determinants in these localized variations (DOE/NV 1993c; National Climatic Data Center 1991).

Atmospheric dispersion improves as the wind speed increases, conditions become more unstable, and the depth of the mixing height increases. The transport and dispersion of airborne material are direct functions of air movement. Transport directions and speeds are governed by the general patterns of air flow (and by the nature of the terrain), whereas the diffusion of airborne material is governed by small-scale, random eddying of the atmosphere (i.e., turbulence). Turbulence is indicated by atmospheric stability classification. Data collected at Desert Rock for calendar year 1990 indicated that atmospheric conditions were unstable (i.e., Stability Classes A through C) approximately 25 percent of the time, neutral (Class D) approximately 37 percent of the time, and stable (Classes E through G) approximately 37 percent of the time for that year.

4.7.2 Air Monitoring Networks

4.7.2.1 Radiological Monitoring Network. DOE Order 5400.1, General Environmental

Protection Program, established the onsite environmental protection program requirements, authorities, and responsibilities for DOE operations. At the NTS, radiological effluents may originate from tunnels, underground test sites, and facilities where materials are used, processed, stored, or discharged. Airborne radiological effluents at the NTS have the greatest potential for reaching the public. There are two radiological monitoring programs for potential airborne radioactive effluents associated with the NTS, one onsite and the other offsite (DOE/NV 1993c). Figure 4.7-1. 1990 10-meter (33 foot) wind rose patterns for the NTS. The onsite environmental surveillance program consists of 52 air sampling stations collecting particulates and reactive gases; 17 samplers collecting atmospheric moisture for tritium analysis; 10 samplers collecting air samples for noble gas analysis; 63 water sampling locations that include wells, springs, reservoirs, and ponds onsite; and 187 locations where thermoluminescent dosimeters are positioned for measurement of external gamma exposures (DOE/NV 1993c).

The offsite radiological monitoring program is conducted around the NTS by the U.S. Environmental Protection Agency's (EPA's) Environmental Monitoring Systems Laboratory, Las Vegas, under an interagency agreement. This program consists of several extensive environmental sampling, radiation detection, and dosimetry networks. In 1992, the Air Surveillance Network was made up of 30 continuously operating sampling locations surrounding the NTS and 77 standby stations (operating one week each quarter) in all states west of the Mississippi River. During 1992, no airborne radioactivity related to current nuclear testing at the NTS was detected on any sample from this network (DOE/NV 1993c).

4.7.2.2 Nonradiological Monitoring Network. Nonradiological environmental monitoring

of NTS operations involved only onsite monitoring because there were no nonradiological hazardous material discharges offsite.

4.7.3 Air Releases

4.7.3.1 Radiological. The majority of radioactive effluents at NTS in 1992 originated

from underground nuclear tests designed and conducted by two national laboratories and the Defense Nuclear Agency. The Los Alamos National Laboratory of Los Alamos, New Mexico and the Lawrence Livermore National Laboratory of Livermore, California conducted tests in support of DOE nuclear testing program objectives. Sandia National Laboratories of Albuquerque, New Mexico supported tests conducted by the Defense Nuclear Agency, which uses the NTS as a nuclear testing facility under an agreement with DOE (DOE/NV 1993c).

The presence of plutonium as an airborne, radioactive effluent at NTS in 1992 is primarily due to previous atmospheric tests and tests in which nuclear devices were detonated with high explosives (called "safety shots"). These latter tests spread low-fired plutonium in the eastern and northeastern areas of the NTS. Three decades after the conclusion of the atmospheric test program, higher than normal levels of plutonium in the air are still detected in several areas. Because of operational activities and vehicular traffic in Area 3 some of the plutonium becomes airborne and elevated levels of plutonium have been detected in Area 3 for several years (DOE/NV 1993c).

Six underground nuclear tests were conducted at the NTS during 1992. A list of these tests and a summary of environmental monitoring observations for each of these are provided in Table 4.7-1.

Air emissions from nuclear testing operations consisted primarily of radioactive noble gases and tritium released during posttest drillback, mineback, or sampling operations following each of **the 1992 underground nuclear tests.** None of the tests resulted in a prompt release or venting (release of radioactive materials within 60 minutes of the nuclear test). Onsite radiological safety support included monitoring emissions during the six nuclear tests. Testing included detecting, recording, evaluating, and reporting radiological conditions prior to, during, and for an extended period after each test with provisions for aerial monitoring teams to detect airborne releases (DOE/NV 1993c).

Following each test, when control of the test area was released by the DOE Controller, survey personnel obtained radiation measurements using portable detection instruments. During the postevent drillback and mining activities, continuous environmental surveillance was maintained in the work area. For containment of radioactive releases to the atmosphere during drillback, systems were employed to trap radioactive particles.

Radioactive waste management sites are located in Areas 3 and 5. These sites serve as DOE defense waste disposal sites (DOE/NV 1993c).

NTS airborne radionuclide emissions for 1992 are presented in Table 4.7-2.

4.7.3.2 Nonradiological. Air emissions from the NTS originate from concrete batch plants, aggregate crushing and processing, surface disturbance, fire training exercises, motor

vehicle operations, boilers, and fuel storage. The concrete batch plants, aggregate crushing and processing facilities, and surface disturbance activities are sources of particulate matter. These activities are largely intermittent and occur in support of specific testing programs on the NTS. Fire training exercises consist of periodic open burning in designated areas with approved fuel materials conducted by fire and emergency personnel several times per year. Motor vehicle operations and boilers are the largest sources of air pollutants at the NTS; motor vehicles consume gasoline, while boilers, construction equipment, and other diesel engines consume diesel fuel. A continuous, nonradiological air monitoring network is not in place at the NTS (USAF et al. 1991). Table 4.7-3 presents the maximum allowable nonradiological emission rates for those NTS sources which require permits.

4.7.4 Air Quality

4.7.4.1 Radiological. Onsite surveillance of airborne particulates, noble gases, and

tritiated water vapor indicated onsite concentrations that were generally not statistically different from background concentrations. External gamma exposure monitoring in 1992 indicated that the gamma environment within the NTS remained consistent with that of previous years. All gamma monitoring stations displayed expected results, ranging from the background levels predominant throughout the NTS to the types of exposure rates associated with known contaminated zones and radiological material storage facilities. Results of 1992 offsite environmental surveillance indicated no NTS-related radioactivity was detected at any air sampling station, and there were no apparent net exposures detectable by the offsite dosimetry network (DOE/NV 1993c).

The GENII environmental transport and dose assessment model (PNL 1988) was used to calculate the effective dose equivalents (EDE) resulting from the airborne radionuclide emissions presented in Table 4.7-2. These results are summarized in Table 4.7-4. The maximum EDE at the NTS boundary is 1.1 x 10-2 millirem. This is 1.1 x 10-1 percent of the corresponding National Emissions Standard for Hazardous Air Pollutants. The collective EDEs to the estimated population of 15,100 persons within 80 kilometers (50 miles) of the proposed SNF facility is 5.2 x 10-3 person-rem, which is 1.2 x 10-4 percent of the natural background radiation dose affecting this population. Background radiation doses are presented in Figure 4.7-2.

Figure 4.7-2. Sources of radiation exposure, unrelated to NTS operations, to individuals in the vicinity of NTS.

4.7.4.2 Nonradiological. Air quality rules and regulations applicable to the NTS are governed by the Clean Air Act, the Nevada Revised Statutes, and the Nevada Administrative Code. The EPA administers the Federal regulations developed to implement the Clean Air Act, and the Nevada Department of Conservation and Natural Resources is responsible for enforcing the Federal and state regulations. Air quality in a given location is described as the concentration of various pollutants in the atmosphere, generally expressed in units of micrograms per cubic meter (-g/m3).

The Clean Air Act directed the EPA to set National Ambient Air Quality Standards (NAAQS) for those pollutants, termed criteria pollutants, that pose the greatest threat to air quality in the United States. The six criteria pollutants are ozone, carbon monoxide, sulfur dioxide, lead, nitrogen dioxide, and particulate matter with an aerodynamic particle diameter less than or equal to 10 microns, referred to as PM10. The Clean Air Act Amendments authorized the EPA to designate geographic regions not in compliance with NAAQS as nonattainment areas. The NTS is located within the Nevada Air Quality Control Region 147, which is in attainment with respect to the NAAQS for the criteria pollutants (CFR 1993b; Engineering Science, Inc. 1990). The nearest nonattainment areas to the Nevada Test Site Spent Nuclear Fuel site are in Clark County, which includes an area in the Las Vegas planning area that is designated serious for PM10 and an area in Las Vegas that is designated moderate for carbon monoxide (CFR 1993b).

Under the Clean Air Act, clean air areas are divided into classes. National parks and wilderness areas receive mandatory Class I protection. Very little pollution increase is allowed in Class I areas. The only Class I area in Nevada, the Jarbridge Wilderness Area, is located approximately 480 kilometers (300 miles) from the NTS, in the northwest corner of Nevada. The nearest Class I areas to the NTS are the Grand Canyon National Park, approximately 275 kilometers (171 miles) to the southeast, and Sequoia National Park approximately 175 kilometers (109 miles) to the west-southwest. The NTS is located in a Class II area, as are most areas across the country.

In addition to the criteria pollutants which are regulated under the National Ambient Air Quality Standards and under various emission standards, hazardous air pollutants are regulated. Title III of the Clean Air Act Amendments of 1990 directed the EPA to determine maximum available control technologies which would be used as the basis for emission limits for the hazardous air pollutants.

Engineering Science, Inc. of Pasadena, California conducted an air quality study at the NTS in 1990. The study examined air quality compliance of the NTS with applicable Federal and state air quality standards. The study encompassed an air emissions inventory, ambient air monitoring, and air pollution source testing at various sources. Based on the data collected at the ambient air monitoring stations established for the study, air quality at the NTS is within applicable Federal and state standards. The results of background monitoring performed by Engineering Science, Inc. are summarized in Table 4.7-5. This is the most recent comprehensive analysis of NTS ambient air quality.

Air dispersion modeling was performed to determine the maximum concentrations of the criteria pollutants. These results are also summarized in Table 4.7-5. The "total existing maximum concentrations" in Table 4.7-5 would result if all permitted sources at the NTS operated at the maximum allowable capacity. All pollutant concentrations from this worst-case scenario of existing emissions at the NTS are below applicable regulations.

4.8 Water Resources

This section provides a description of the surface water and groundwater at the NTS and surrounding area. The section also describes the existing impacts to surface water and groundwater that have resulted from past and present operations at the NTS.

4.8.1 Surface Water

The drainage basins and the generalized directions of surface water flow near the NTS are shown in Figure 4.8-1 (USAF et al. 1991). The boundary lines of the drainage basins occur principally along topographic divides (DOE 1988b). Figure 4.8-1 also shows other surface water features.

Table 4.7-5. Comparison of baseline concentrations with most stringent applicable regulations and guidelines at the NTS.

Criteria pollutant	Averaging time	Most stringent regulation or guideline (-g/m3)	Maximum background concentration (-g/m3)	Maximum existing DOE site contribution (-g/m3)	Total existing maximum concentration (-g/m3)
Carbon monoxide	8-hour	10,000	2,290	b	2,290
	1-hour	40,000	2,748	b	2,748
Nitrogen dioxide	Annual	100	c	b	b
Lead	Calendar quarter	1.5	c	b	b
Particulate matter (PM10)d	Annual	50	c	0.43	0.43
	24-hour	150	78.3	6.6	84.9
Sulfur dioxide	Annual	80	c	1.07	1.07
	24-hour	365	39.3	15.9	55.2
	3-hour	1,300	65.4	104.9	170.3
Hazardous air pollutants	b	b	b		b

a. Sources: Maximum background concentration provided by Engineering Science, Inc. (1990). Maximum existing DOE site contribution computed by Halliburton NUS.

b. No sources indicated.

c. Not measured.

d. All suspended particulate matter is assumed to be PM10.

Figure 4.8-1. NTS hydrologic basins and surface drainage direction.

Almost all stream flow in the NTS area is ephemeral, and therefore almost no streamflow data have been collected. The average annual runoff within the hydrographic areas in the Death Valley Basin in Nye County was estimated at less than 164 million gallons (620,000 cubic meters) per area (DOE 1988b).

The ephemeral character of streamflow has also limited the onsite monitoring of surface water quality. Water samples were, however, collected from the main channel of Fortymile Wash and two of its principal tributaries (Drill Hole Wash and Busted Butte Wash) during periods of runoff and flooding in 1984. Due to unknown factors such as compositional variability of storms, any quantitative interpretation is unwarranted (DOE 1988b).

Throughout the NTS, perennial surface water originates solely from springs, and it is restricted to source pools at some large springs. Because of the extreme aridity of this region, most of the spring discharge travels a short distance before evaporating or infiltrating back into the ground (DOE 1986). Thus, dry washes may be the principal sources of potential groundwater recharge inputs in the area (DOE 1988b). In addition, playas on NTS, including Frenchman Lake located in Area 5 and Yucca Lake to the northwest of Area 5, may retain standing water for hours to weeks following intense precipitation events. These playas represent the only natural surface water features in the vicinity of Frenchman and Yucca Flats. The direction of movement of water accumulated in playas is generally upward due to high evapotranspiration (DOE/OFE 1994). However, accumulated runoff in Frenchman Lake and Yucca Lake reportedly serves to recharge the valley fill aquifer (DOE 1988b).

Despite the arid climate, which includes high annual average potential evaporation, low average annual precipitation, and infrequent storms, surface runoff does occur. Runoff results from storms that occur most commonly in winter and occasionally in autumn and spring, and from localized thunderstorms that occur mostly during the summer (DOE 1988b). The ephemeral streams resulting from heavy precipitation fill the normally dry washes. Local flooding may occur where the water exceeds the capacity of the channels. In contrast to the washes, the terminal playas may retain standing water for days or weeks after severe storms (DOE 1986). Playas in Kawich Valley and Gold Flat collect and dissipate the runoff from the northern part of Pahute Mesa (ERDA 1977). Summer floods usually do not accumulate to cause regional floods, but their intensive character renders them potentially destructive over limited areas (DOE 1988b).

The western half and southernmost part of the NTS have channel systems which carry runoff beyond NTS boundaries during infrequent, very intense storms. Fortymile Canyon is the largest of these systems, originating on Pahute Mesa in the northwestern part of the NTS and draining into the normally dry Amargosa River channel about 20 miles (32 kilometers) southwest of the NTS. Within the NTS, Fortymile Canyon and its tributaries are restricted to well-incised canyons. Flood-prone areas surround Fortymile Wash, a major tributary within Fortymile Canyon. The other major NTS tributaries to the Amargosa River are Tonopah Wash, which runs southwesterly from Jackass Divide in the south-central part of the NTS into the Amargosa Desert near Amargosa Valley, and Rock Valley, which drains from the southernmost part of the NTS westward and then southward to Ash Meadows in the east-central portion of the Amargosa Desert (ERDA 1977).

The Amargosa River originates in Oasis Valley and continues southeastward through the Amargosa Desert past Death Valley Junction, then southward another 45 miles (82 kilometers), where it turns northwestward and terminates in Death Valley. The river carries floodwaters following cloudbursts or intense storms but is normally dry, except for a few short reaches that contain water from springs (DOE 1988b).

Two watersheds, Fortymile Canyon and Jackass Flats, have the potential of endangering offsite public health and safety due to flooding. Regional peak-flood flow equations for the southern Nevada area indicate that the 100-year peak flow from the Fortymile Canyon drainage is approximately 13,000 cubic feet (370 cubic meters) per second and 8,200 cubic feet (230 cubic meters) per second from the Jackass Flats drainage (USAF et al. 1991).

In summary, the potential exists for sheet flow and channelized flow through ephemeral washes from intense precipitation events to cause localized flooding throughout the NTS; however, no comprehensive floodplain analysis has been conducted on the NTS to delineate the 100- and 500-year floodplains associated with NTS drainages. No flood studies are known to have been conducted for the proposed SNF facility in Area 5; a flood assessment was conducted for the Radioactive Waste Management Site in NTS Area 5 on Frenchman Flat, located southwest of the proposed SNF Site. This study determined that the southwest corner of the Radioactive Waste Management Site is located in Federal Emergency Management Agency Zone AO (100-year flood zone with depths between 1 and 3 feet [0.3 and 0.9 meter]) of the Barren Wash Alluvial Fan. The remainder of the Radioactive Waste Management Site is located in Zone X of the Halfpint Alluvial Fan (100-year flood zone with depths less than 1 foot [0.3 meter]). Areas to the north, south, and east of the Radioactive Waste Management Site are in Zone X or Zone AO (DOE/NV 1993d). These suggest that the proposed SNF facility area may encompass areas in Zone X and/or areas in Zone AO associated with the Halfpint Alluvial Fan. Probable maximum flood analyses are known to have been performed only for areas in the vicinity of Yucca Mountain to aid in flood protection design for Yucca Mountain facilities (DOE 1988b).

Underground nuclear testing has resulted in the release of radioactive materials at the land surface. There is the potential for 100-year floods to transport these contaminants beyond the boundaries of the NTS. Quantitative estimates of this potential cannot be determined without additional studies (USAF et al. 1991).

There are no National Pollutant Discharge Elimination System (NPDES) permits for the NTS, as there are no wastewater discharges to onsite or offsite surface water. NTS sanitary wastewaters are discharged to sewage lagoons or to septic tank/leach field systems. All wastewater discharges at NTS are conducted in accordance with permits issued by the State of Nevada (DOE/NV 1993c).

4.8.2 Groundwater

Generally, the hydrogeology at the NTS is characterized by great depths to the groundwater table and slow velocity of movement of water in the saturated and unsaturated zones (DOE/NV 1992c). Depth to groundwater varies from about 660 feet (200 meters) beneath valleys in the southern part of the NTS to more than 1,640 feet (500 meters) beneath Pahute Mesa. The depth of the water table below Area 5 is approximately 800 feet (244 meters) below land surface (DOE/NV 1993c). Locally, there are perched water tables at shallow depths (USAF et al. 1991). Perched aquifers have been reported at depths of 70 feet (21 meters) in the southwestern part of Frenchman Flat (RSN 1993). In the eastern portions of the NTS, the water table occurs generally in the alluvium and volcanic rocks above the regional carbonate aquifer (DOE/NV 1993c).

The NTS lies within the Death Valley Groundwater System, which is a large and diverse area encompassing southern Nevada and adjacent parts of California composed of many mountain ranges and topographic basins that are hydraulically connected at depth. In general, groundwater within the system travels toward Death Valley, although much of it discharges before reaching it. Groundwater in the Death Valley system does not enter neighboring groundwater systems (DOE 1986). The Death Valley Groundwater System is divided into several groundwater subbasins. The boundaries of these subbasins have been estimated from potentiometric levels, geologic controls of subsurface flow, discharge areas, and inferred flow paths (DOE 1988b). As shown in Figure 4.8-2, the three groundwater subbasins of the system beneath the NTS are Ash Meadows, Alkali Flat Furnace Creek Ranch, and Oasis Valley. Groundwater beneath the eastern part of the NTS is in the Ash Meadows Subbasin. Most of the western NTS is in the Alkali Flat Furnace Creek Ranch Subbasin. Groundwater beneath the far northwestern corner of the NTS occurs in the Oasis Valley Subbasin (DOE/NV 1993c, 1992b).

Six major aquifers occur in the area. In decreasing order of age of the geologic units in which they are found, they are: Cambrian through Devonian lower carbonate aquifer, Pennsylvanian and Permian upper carbonate aquifer, Tertiary bedded tuff aquifer, Tertiary welded tuff aquifer, Tertiary lava flow aquifer, and Tertiary and Quaternary valley fill aquifer (Eckel 1968) (see Figure 4.6-2). The hydrologic and geologic properties of these aquifers vary (see the Yucca Mountain Site Characterization Plan [DOE 1988b] for a thorough description of the hydraulic properties of the major hydrostratigraphic units based on studies at Yucca Mountain). For example, the carbonate aquifers and the welded tuff aquifer store and transmit water chiefly along fractures. In contrast, the valley fill aquifer stores and transmits water chiefly through interstitial openings. Additionally, in places in the lower carbonate aquifer, groundwater flow is diverted laterally and vertically because of fault displacements that have juxtaposed the lower carbonate aquifer against less permeable rocks. Where the flow is blocked, intersection of the water table with the land surface causes springs (DOE 1986).

Figure 4.8-2. Groundwater hydrologic units, hydrgraphic areas, and well locations of the Nevada Test Site.

The lower carbonate and valley fill (alluvial) aquifers are the main sources of groundwater in the eastern part of the NTS (DOE 1986). Groundwater withdrawals in the area of the proposed SNF management facilities are principally from the valley fill aquifer of the Frenchman Flat hydrographic area (DOE 1988b). The other four units in the area have relatively low permeabilities that tend to retard the flow of groundwater. These units are called aquitards (DOE 1986). In decreasing order of age of the geologic units that form them, these aquitards are: Precambrian through lower Cambrian lower clastic aquitard, Devonian through Mississippian upper clastic aquitard, Tertiary tuff aquitard, and Tertiary lava flow aquitard (Eckel 1968) (see Figure 4.6-2).

Figure 4.8-3 is a regional groundwater potentiometric surface map of the NTS (DOE/NV 1993d). The map does not show perched groundwater. However, perched groundwater does occur at NTS, principally associated with the aquitards underlying the ridges (Eckel 1968).

In general, regional groundwater flow is from the north and northeast toward the regional discharge area near Ash Meadows in the Amargosa Desert (see Figure 4.8-2 and 4.8-3). In the western portions of the area, the regional flow is from the northwest to the south and southwest (DRI 1986b). Deep regional movement of groundwater south of the NTS occurs chiefly through the lower carbonate aquifer. Because of geologic structure, flow paths in the lower carbonate aquifer are complex and poorly defined. Groundwater from the Ash Meadow Subbasin supplies the water entering Devil's Hole, which supports the only known population of the Devil's Hole pupfish, a federally listed endangered species. The decline of the species has been attributed to low water levels caused by decreasing groundwater levels (ERDA 1977).

Groundwater recharge to the Ash Meadows Subbasin occurs primarily from precipitation over the mountainous areas in the northern, eastern, and southern portions of the basin (DOE 1988b). As mentioned above, this recharge generally travels vertically through the vadose zone (unsaturated zone) and the overlying aquifers to the underlying carbonate aquifers. Specifically, in the eastern half of the NTS, groundwater flows toward the major valleys before deflecting downward to join the regional flow in the carbonate aquifers. Beneath Yucca and Frenchman flats, vertical flow through the underlying volcanic rocks is impeded by bedded and zeolitized tuffs, resulting in a downward flow rate of less than 0.2 foot (0.06 meter) per year.

Figure 4.8-3. NTS regional potentiometric surface map.

Vertical flow in the uppermost portions of the vadose zone in the area of Frenchman Flat is generally upward toward the surface, due to an evapotranspiration rate which is 15 times higher than precipitation (DOE/OFE 1994). Site characterization data for Area 5 indicate that the vertical flow direction in the vadose zone is upward from 0 to 250 feet (0 to 75 meters) below land surface. In the next interval (250 to 600 feet [75 to 180 meters]), a downward flow rate of 10 feet/1,000 years (3 meters/1,000 years) has been calculated. At a depth of 600 to 800 feet (180 to 250 meters), a zone of equilibrium (a zone of no vertical movement) is present above the water table (Johnejack et al. 1994).

Analyses have also been conducted in order to determine the travel time of water from the vicinity of Area 5 and Frenchman Flat to the regional water table. Modeling studies for the Radioactive Waste Management Site at Area 5 indicate that the travel time from the surface to the water table is on the order of thousands of years (DOE/NV 1993c). Specifically, the travel time from Area 5 to the regional water table is estimated to range from 19,000 to more than 113,000 years (USAF et al. 1991). The Yucca Mountain Site Characterization Plan (DOE 1988b) describes in detail the hydraulic properties of the various units comprising the unsaturated zone, based on studies at Yucca Mountain.

Three types of groundwater chemistry exist at the NTS and in its vicinity: (1) sodium and potassium bicarbonate, which generally occurs in the tuff and valley fill aquifers composed chiefly of tuff detritus; (2) calcium and magnesium bicarbonate, which generally occurs in the carbonate and the valley fill aquifers composed chiefly of carbonate detritus; and (3) mixed, which is defined as having the chemical characteristics of both type 1 and type 2 (DOE 1986).

The hydrogeologic units which supply potable water to the NTS have been classified as

Class IIA (currently a source of drinking water) and IIB (potentially a source of drinking water) in accordance with the EPA's guidelines for groundwater classification (DOE/NV 1993d). No aquifers at the NTS have been designated as sole source aquifers.

In general, the quality of NTS groundwater is suitable for most purposes and generally meets EPA secondary standards for major cations and anions and the primary standards for deleterious constituents. Specifically, groundwater in the Ash Meadows Subbasin has a total dissolved solids concentration ranging between 275 and 450 milligrams per liter (mg/L) (DOE/NV 1993a). Summary groundwater quality data for the period 1957 to 1990 for Well 5b, 5c, Well UE5c, and Army Well 1 which serve Area 5 reveal a pH range of 7.6 to 8.7; calcium (2.4 to 44.0 mg/L); sodium (38.1 to 129.0 mg/L); chloride (9.1 to 23.2 mg/L); sulfate (26 to 58 mg/L); and silica (0 to 55.1 mg/L) (DRI 1993).

Contamination by radionuclides occurs below the water table as well as in the unsaturated zone above it. This contamination is a result of underground nuclear testing. A preliminary environmental survey of the NTS also identified a number of potential sources of groundwater contamination. These included wastewater discharges, hazardous- or mixed-waste discharges, solid waste landfills and trenches receiving potentially hazardous waste, and over 50 inactive waste spill or release sites (USAF et al. 1991).

Underground nuclear testing has primarily occurred in the areas of Yucca Flat, Frenchman Flat, Pahute Mesa, Rainier Mesa, and Shoshone Mountain. Nuclear detonations at or near the water table have resulted in groundwater contamination. The principal confirmed or suspected contaminants from these tests include various radionuclides (primarily tritium) and heavy metals. A number of NTS waste disposal and testing facilities, including injection wells, leach fields, and various waste storage facilities or disposal sites, have caused contamination of the vadose zone. Contaminants of concern include radionuclides, organic compounds, heavy metals (primarily lead), and hydrocarbons as well as various residues from plastics, drilling muds, and epoxy (DOE/NV 1993e). Figure 4.8-4 depicts the areas with known or suspected groundwater and/or vadose zone contamination. Groundwater contamination characterization activities are in progress at NTS; at present, no contaminant plume maps are available, and available groundwater quality data are not useful for the purposes of site-wide characterization or for comparison with established criteria.

Groundwater contamination could be transported toward the NTS boundary by one of the regional groundwater flow systems. Groundwater flow velocities in these systems range between 6 and 600 feet (1.8 and 183 meters) per year. Because of sorption, however, most nuclides (other than tritium) would move at a much slower rate. The groundwater travel time from the NTS to the Ash Meadows Discharge Area of the Ash Meadows Subbasin Flow System is approximately 300 years. Radioactive decay during this time, coupled with dilution and sorption, should reduce radioactivity concentrations to well below regulatory limits (USAF et al. 1991). Thus, there are no effects on public health and safety, nor are any expected in the foreseeable future.

Figure 4.8-4. Areas of potential groundwater contamination at the NTS.

The NTS derives its complete water supply from the groundwater aquifers underlying the site. Water supply has been developed and is managed on the basis of five service areas that support the different NTS operating areas. Given the wastewater disposal practices on the NTS and the depth to the groundwater system, it is reasonable to assume that all of the water pumped on the NTS is consumed (USAF et al. 1991). Recent annual water use at the NTS has declined substantially from the 1980's. In 1989, NTS annual water withdrawal was 1.117 billion gallons (4.22 million cubic meters) (Leppert 1993). In 1992, NTS annual water withdrawal was 0.595 billion gallons (2.25 million cubic meters) (Leppert 1993).

In 1993, 14 wells were utilized for the NTS water supply (DOE/NV 1994c). A small portion of the NTS receives its water from 5 onsite wells drilled in the Alkali Flat-Furnace Creek Ranch Subbasin (DOE 1988b). Most of the NTS receives its water from 9 onsite wells drilled in the Ash Meadows Subbasin, which encompasses Area 5 (DOE/NV 1994c). These 9 wells have a combined production capacity of 1,813 billion gallons per year (6.86 million cubic meters per year) (DOE/NV 1993a).

Area 5, which encompasses the proposed SNF facility site, is located within NTS water service area C. Wells 5b, 5c, and UE5c serve the fire protection, construction, and potable water needs of Area 5 facilities (DOE/NV 1993b). Wells 5b and 5c are completed in alluvial materials (valley fill aquifer) with total completion depths of 900 and 1,200 feet (274 and 366 meters) below land surface, respectively. Well UE5c is completed in volcanic rock (exact aquifer unknown) with a total depth of 2,682 feet (817 meters) below land surface (DOE 1988b; DOE/NV 1993b; DRI 1993).

Groundwater for construction and operation of the SNF management facilities would likely be drawn from the Frenchman Flat hydrographic area of the Ash Meadows Subbasin. Much of the land within the Ash Meadows Subbasin is under Federal jurisdiction and has been withdrawn from the public domain (DOE 1988b). Little of the total groundwater of the subbasin is privately appropriated or used.

The perennial yield of the Ash Meadows Subbasin greatly exceeds water withdrawals by DOE and all other users. For more than thirty years water withdrawals from the Frenchman Flat hydrographic area had exceeded the estimated precipitation recharge for that area (DOE 1988b). This study also indicates that withdrawals have caused no decline in the static water level (DOE 1988b). However, it should be noted that numerous conditions on the NTS preclude the accurate measurement of static water levels (Winograd 1970). Because of hydrogeologic complexities, regional groundwater flow at the NTS is not constrained by the hydrographic basins which are defined by local topography (USAF et al. 1991). Therefore any potential groundwater overdrafts in the Frenchman Flat basin indicated by previous yield estimates are likely made up by untapped groundwater from neighboring hydrographic basins.

Water in southern Nevada (excluding the Las Vegas area) is used chiefly for irrigation and to a lesser extent for livestock, municipal needs, and domestic supplies. Almost all the required water is pumped from the ground, although some springs supply water to establishments in Death Valley and other areas south of the NTS. Springs in Oasis Valley near Beatty, Nevada are a significant source of water for public and domestic needs and for irrigation (DOE 1986). The City of Las Vegas obtains approximately 80 percent of its water from the Colorado River; the remaining 20 percent is withdrawn from groundwater sources. There are no plans to change the water supply sources in the near future. (Las Vegas Valley Water District 1994).

The principal water users in the area closest to the NTS are in the Amargosa Desert in and around the Town of Amargosa Valley and in the Pahrump Valley. Aquifers in the Pahrump Valley could support up to about 16,900 residents with no decline in usable storage, although local effects, such as land subsidence and well interference, could result from sustained development. The mining industry in southern Nevada also uses a small amount of water for processing. Water for this purpose is supplied from nearby shallow wells or trucked in from nearby towns. Many of the mines currently recycle process water, which reduces their water demand (DOE 1986).

The volume of groundwater underlying the NTS (as well as the estimated volume of contaminated groundwater) that has been removed from direct access to the general public is rather large. The impaired groundwater will likely remain unusable for an extended period. The significance of the loss of access to the NTS groundwater is diminished by the fact that even if access were provided, the water underlying portions of the NTS might not be usable for domestic purposes (USAF et al. 1991).

4.9 Ecological Resources

NTS lies within the transition area between the Mojave Desert and the Great Basin. As a result, flora and fauna characteristics of both occur on the NTS. The NTS covers about 3,500 square kilometers (1,350 square miles) of which only 0.55 percent is developed (DOE/NV 1988).

NTS has completed numerous studies on the effects of nuclear testing on the ecology of the area, and an extensive bibliography of these studies has been prepared (ERDA 1976). In summary, studies (including ongoing surveys) have shown that there may be a correlation between radioactive testing and the decline of vegetation present in an area. As a result, animals may not have the necessary vegetation for food and cover, thus changing the fauna diversity in those areas (USAF et al. 1991).

The following section describes the ecological resources at the NTS, including terrestrial resources, wetlands, aquatic ecology, and threatened and endangered species. Information is also presented on special status species other than threatened and endangered species such as Federal Candidate and state-listed species.

4.9.1 Terrestrial Resources

Plant communities on the NTS have been classified according to the dominant shrub. Approximately 700 taxa, representing about 70 families, have been identified on the NTS (ERDA 1976; DOE/NV 1993b, 1991b). Figure 4.9-1 presents the general plant communities identified there.

Figure 4.9-1. Plant communites on Nevada Test Site.

The Mojave Desert is located at elevations ranging up to 1,219 and 1,524 meters (4,000 and 5,000 feet). The dominant plant community is creosote bush (Larrea tridentata). Areas in which this community occurs are located within much of the southern portion of the NTS, including Jackass Flats and Frenchman Flat (DOE/NV 1991b, 1986b; ERDA 1976; FWS 1992).

The transitional zone between the Mojave Desert and the Great Basin occurs at elevations between 1,219 and 1,524 meters (4,000 and 5,000 feet). The dominant plant communities associated with the transition zone are: blackbrush (Coleogyne ramosissma), desert thorn (Lycium pallidum), and hopsage (Grayia spinosa). In general, these communities are found in upper bajadas and in closed basins within Jackass Flats and Yucca Flat (DOE/NV 1991b, 1986b; ERDA 1976).

The Great Basin is located within the northern two-thirds of NTS at elevations above 1,524 meters (5,000 feet). The dominant plant communities are big sagebrush (Artemisia tridentata) and black sagebrush (Artemisia nova), saltbush (Atriplex canescens), and desert thorn (Lycium shockleyi). In areas with elevations above 1,830 meters (6,000 feet), collectively labeled as mountains, hills, and mesas, the dominant plant communities are singleleaf pinyon (Pinus monophylla) and Utah juniper (Juniperus osteosperma). In general, these communities are found at Thirsty Canyon, Yucca Playa, Rainier Mesa, and Yucca Mountain (DOE/NV 1991b, 1986b; ERDA 1976).

There is a recent trend of nonnative plant species establishing themselves in areas of disturbance at the NTS. Cheatgrass (Bromus tectorum), an annual grass, occurs at elevations above 1,524 meters (5,000 feet). Downey chess (Bromus rubens), another annual grass, is becoming established in the mid-elevations. Russian thistle (Salsola iberica and S. paulsennii) appears in areas where the native vegetation has been removed and the soil composition has changed (DOE/NV 1991b, 1988; ERDA 1976).

Like vegetation, animals on the NTS are representative of both the Mojave Desert and the Great Basin and the associated transition zone. There are over 30 species of reptiles and amphibians, 190 species of birds, and 50 species of mammals on the NTS (DOE/NV 1993b; ERDA 1976). Many animals utilize man-made reservoirs and natural springs and seeps on the NTS. Sewage ponds have also become an important resource for wildlife.

Reptiles and amphibians on the NTS include 1 species of desert tortoise, 14 species of lizards, and 17 species of snakes. In addition, the NTS is within the range of the Great Basin spadefoot toad (Scaphiopus intermontanus), but this amphibian has not been identified on the NTS (DOE/NV 1993b; ERDA 1976; Medica 1990).

Birds on the NTS are often migratory and seasonal residents. The most widely distributed species include the black-throated sparrow (Amphispiza bilineata), house finch (Carpodacus mexicanus), red-tailed hawk (Buteo jamaicensis), common raven (Corvus corax), loggerhead shrike (Lanius ludovicianus), mockingbird (Mimus polyglottos), ash-throated flycatcher (Myiarchus cinerascens), and mourning dove (Zenaida macroura) (DOE/NV 1993b; ERDA 1976; Greger 1991).

The most abundant group of mammals on the NTS are rodents. Carnivores include coyote (Canis latrans), kit fox (Vulpes macrotis), badger (Taxidea taxus), bobcat (Lynx rufus), mountain lion (Felis concolor), and long-tailed weasel (Mustella frenata). Large mammals on NTS include the mule deer (Odocoileus hemionus), pronghorn (Antilocapra americana), desert big horn sheep (Ovis canadensis), and wild horse (Equus caballus). Hunting, grazing, and fishing are not allowed on the NTS (DOE/NV 1993b, 1986b; ERDA 1976; Medica and Saethre 1990).

In general, the portion of Frenchman Flat in Area 5 (i.e., north and east of Mercury Highway) within which the proposed SNF facility would be located is within the creosote bush community. This plant community is characteristic of the Mojave Desert. Pre-activity surveys completed for the Radioactive Waste Management Site, which is in the general area of the proposed SNF facility, found the dominant vegetation to include creosote bush, spiny hopsage, white bursage, desert thorn, and Nevada joint-fir (Ephreda nevadensis) (EG&G 1993, 1991, 1990, 1989).

The distribution of animals within the portion of Area 5 being considered for the proposed SNF facility is not as well documented as for the rest of the NTS. However, species identified within 5 kilometers (3.1 miles) of the Liquefied Gaseous Fuels Spill Test Facility include 8 reptiles, 17 bird species, and 14 mammals (Hunter et al. 1991). The Liquified Gaseous Fuels Spill Test Facility is located within similar habitat approximately 7.6 kilometers (5 miles) south of the proposed facility. There are no water sources located within the portion of Area 5 being considered for the proposed SNF facility.

4.9.2 Wetlands

There are several natural springs on the NTS that feed flowing streams (Greger and Romney nda). Some of these extend for 91 meters (300 feet) before infiltration and evaporation cause them to dry up. Vegetation along these channels consists of willow (Salix sp.) and tamarisk (Tamarix sp.). Reservoirs on the site which are fed by groundwater from wells have developed wetland vegetation such as tamarisk, cattail (Typha sp.), and bulrushes (Scirpus sp.) (Elle 1992). A wetland delineation, as defined by the 1987 U.S. Army Corps of Engineers wetlands Delineation Manual (U.S. COE 1987), has not been performed for any of these areas (DOE/NV 1993b; Elle 1992), and National Wetlands Inventory maps are not available for the NTS.

The portion of Area 5 under consideration for the SNF facility does not have any known springs, seeps, or wetland vegetation (DOE/NV 1993b; Greger and Romney nda).

4.9.3 Aquatic Resources

Potential aquatic habitat on the NTS includes surface drainages, playas, man-made reservoirs, and springs. Permanent surface water sources are limited to a few small springs.

There are two dry lake beds (playas) located in the eastern (Yucca Flat) and southeastern (Frenchman Flat) portions of the NTS. Runoff from the eastern half of the NTS flows through surface drainages to onsite playas and can collect for a few days to a few months. The remaining areas of the NTS drain offsite via arroyos and dry stream beds that carry water only during intense or persistent rainstorms. These surface drainages and playas are unable to support permanent fish populations (ERDA 1976; Greger and Romney nda).

Reservoirs resulting from discharge of well water located on the NTS support three introduced species of fish: bluegill (Lepomis macrochirus), goldfish (Carassius auratus), and golden shiner (Notemigonus crysoleucas). Springs located throughout the site do not support fish populations (Elle 1992). There are no springs, seeps, or other permanent water bodies on the proposed SNF Site; however Cane Spring is located in Area 5, southwest of the proposed SNF Site (Greger and Romney nda).

4.9.4 Threatened and Endangered Species

Table 4.9-1 presents a list of federally and state-listed species that may be found in the vicinity of NTS.

There are no known plants which have been listed as threatened or endangered under the

Endangered Species Act (16 USC 1531-1534) on NTS. However, the U.S. Fish and Wildlife Service has identified candidate species for listing, 11 of which may occur on or in the vicinity of the NTS. Ten of these are Candidate Category 2 species, meaning that information indicates that they may be appropriate for listing as endangered or threatened but more information is needed. One species, the Beatley milk-vetch, is a Candidate Category 1 species (DOE/NV 1993b, 1991c; EG&G 1993; USAF et al. 1991). This species has been identified on Pahute Mesa (Hunter et al. 1988). A Candidate Category 1 species is one for which there is substantial information indicating that it is appropriate for listing as endangered or threatened Four Candidate Category 2 species (camissona, black wooly-pod, cymopterus, and Beatley phacelia) have been identified in Frenchman Flat, although none of these was identified during surveys conducted near the proposed SNF facility site (EG&G 1993; Tetratech 1993).

Two listed reptile species on or in the vicinity of NTS are of concern. The chuckwalla is a Federal Candidate Category 2 species which may occur on NTS. The desert tortoise is the only federally listed threatened species known to occur on NTS (DOE/NV 1993b; EG&G 1993). Both the desert tortoise and the chuckwalla are listed as reptile species of Frenchman Flat (DOE/NV 1986b).

Table 4.9-1. Federally and state-listed threatened, endangered, and other special status species that may be found in the vicinity of the Nevada Test Site.

		Statusb	
Common name	Scientific name	Fed.	State
	Plants		
Amargosa penstemon	Penstemon fruticiformis ssp. amargosae	C2	NL
Beardtonguec	Penstemon pahutensis	C2	NL
Beatley milkvetchc	Astragalus beatleyae	C1	CE
Beatley phaceliac	Phacelia beatleyae	C2	NL
Black wooly-podc	Astragalus funerus	C2	NL
Camissoniac	Camissonia megalantha	C2	NL
Cymopterusc	Cymopterus ripleyi var. saniculoides	C2	NL
Green-gentianc	Frasera pahutensis	C2	NL
Kingston bedstrawc	Galium hilendiae ssp. kingstonense	C2	NL
Mojave fishook cactusc	Sclerocactus polyancistrus	NL	CY
White bear desert-poppyc	Arctomecon merriamii	C2	NL
	Birds		
Bald eagled	Haliaeetus leucoephalus	E	E
Golden eaglec	Aquila chrysaetos	NL	P
Ferruginous hawkc	Buteo regalis	C2	NL
Loggerhead shrikec	Lanius ludovicianus	C2	NL
Mountain ploverc	Charadrius montanus	C2	NL
Peregrine falcond,e	Falco peregrinus	E	E
Western least bittern	Ixobrychus exilis hesperis	C2	NL
Western snowy ploverc	Charadrius alexandrinus nivosus	C2	NL
White-faced ibisc	Plegadis chihi	C2	NL
	Reptiles		
Chuckwalla	Sauromalus obesus	C2	NL
Desert tortoisec	Gopherus agassizit	T	T
	Mammals		
Spotted bat	Euderma maculatum	C2	NL
Pygmy rabbit	Branchylqus idahoensis	C2	NL
	Fish		
Devils Hole pupfishd,f	Cyprinodon diabolis	E	E

b. Status codes:
C1 Federal candidate - Category 1 (probably appropriate to list)
C2 Federal candidate - Category 2 (possibly appropriate to list more study required)
CE State critically endangered by authority of NRS 527.270 (State Division of Forestry)
CY State protected by authority of NRS 527.60-.120 under the Nevada Cacti and Yucca Law
E Endangered
NL Not listed
T Threatened
P State protected by NAC 503.050

c. Species recorded on the NTS.

d. U.S. Fish and Wildlife Service Recovery Plan exists for this species.

e. Peregrine falcon seen on the NTS; however not identified to subspecies level.

f. Only known location of this species is outside the NTS 24 miles (39 km) southwest of Mercury. This species is included here due to potential offsite groundwater impacts.

Note: Nevada Department of Wildlife utilizes the Federal threatened and endangered species list.

The distribution and abundance of the desert tortoise have been extensively researched; the latest research for the NTS as a whole was completed in 1991 (DOE/NV 1991c). A biological opinion from the U.S. Fish and Wildlife Service was completed in 1992 for NTS activities planned for 1992 through 1995 (FWS 1992). The desert tortoise is known to exist in the southern portion of the NTS, but its abundance on the NTS is considered to be very low to low (DOE/NV 1991c). The northern extent of its range is from Massachusetts Mountain through Control Point Hills and Mid Valley to Topopah Valley and west to the NTS boundary (DOE/NV 1991c).

Two bird species which could occur on or within the vicinity of NTS are federally listed endangered species. These are the American peregrine falcon and the bald eagle. The American peregrine falcon has been sighted on the NTS in the past but not recently (DOE/NV 1991c; ERDA 1976). Bald eagles may also occur on the NTS, but sightings have not been reported in recent literature (DOE/NV 1986b; EG&G 1993; ERDA 1976; Hunter et al. 1991). Six other bird species, all of which are Federal Candidate Category 2 species, are known to occur on or within the vicinity of NTS (DOE/NV 1991c; EG&G 1993). Recent surveys of Area 5 (which contains the proposed SNF Site) have not identified any of these species (DOE/NV 1986b; EG&G 1993, 1991, 1990, 1989). However, birds listed as common to Frenchman Flat include the golden eagle and loggerhead shrike (DOE/NV 1986b; Tetratech 1993).

There are two Federal Candidate Category 2 mammal species identified as potentially occurring in the vicinity of the NTS. Neither the spotted bat nor the pygmy rabbit has been observed during recent pre-activity surveys for the area (EG&G 1993; USAF 1993). They are also not listed as mammals occurring in Frenchman Flat (DOE/NV 1986b; Tetratech 1993).

There are no known fish species indigenous to the NTS. However, it is important to note that the only known location of the Devils Hole pupfish, a federally listed endangered species, is approximately 39 kilometers (24 miles) southwest of the NTS. The decline of this species has been attributed to low water levels caused by decreasing groundwater levels (ERDA 1977; USAF et al. 1991).

Pre-activity surveys for threatened and endangered species have recently been completed for the Radioactive Waste Management Site located in Area 5 near the proposed SNF facility. The primary purpose of these surveys was to identify live tortoise, scat, burrows, and remains. Although these surveys have found few tortoise or their sign, each new activity on NTS must undergo pre-activity surveys for the desert tortoise (DOE/NV 1991c; EG&G 1993, 1991). In addition, these surveys look for other listed species. Recent surveys have not identified any other listed or candidate species in the portion of Area 5 surrounding the Radioactive Waste Management Site, which is near the proposed SNF Site (EG&G 1993, 1991).

4.10 Noise

The major noise sources at the NTS occur primarily in developed operational areas and include various facilities, equipment and machines (e.g., cooling towers, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles), aircraft operations, and testing. No NTS environmental noise survey data are available.
At the NTS boundary, away from most facilities, noise from most sources is barely distinguishable from background noise levels. Some disturbance of wildlife activities might occur within the NTS as a result of operational activities and construction activities.

Existing NTS-related noise sources of importance to the public are those from transportation of people and materials to and from the NTS. These sources include trucks, buses, private vehicles, helicopters, and airplanes. In addition, some air cargo and business travel via commercial air transport through the McCarren International Airport in Las Vegas can be attributed to the NTS operations.

The State of Nevada and Nye County have not established any regulations that specify acceptable community noise levels with the exception of prohibitions on nuisance noise.

During a normal week, about 3,300 employees travel to the NTS each day. Most employees commute using the contracted bus service and a small portion commute in government or private vehicles. Both government-owned and private trucks pick up and deliver materials at the site. Most of the private vehicles, buses, and trucks travel to and from the site each day using U.S. Route 95. The contribution of the NTS operations to traffic volumes along U.S. Route 95, especially during peak traffic periods, affects noise levels at residences along this route.

4.11 Traffic and Transportation

Traffic congestion is measured by level of service. Level of Service A represents free flow of traffic. Level of Service B is in the range of stable flow, but the presence of other users in the traffic stream begins to be noticeable. Level of Service C is in the range of stable flow, but marks the beginning of the range of flow in which the operation of individual users becomes significantly affected by interactions with others in the traffic stream. Level of Service D represents high-density but stable flow. Level of Service E represents operating conditions at or near the capacity level. Level of Service F is used to define forced or breakdown of flow of traffic. The calculated Level of Service are for discrete locations along a segment. Level of Service will most likely be worse in urban areas and better in rural areas along with the segment.

The Region of Influence for the following analysis includes site roads and regional roads in Nye and Clark counties.

Vehicular access to the NTS is provided by U.S. Route 95 to the south, with off-road access to the northeast provided via Nevada State Route 375. Baseline traffic along segments providing access to the NTS contributes to differing service level conditions. Nevada State Route 375 and U.S. Route 95 are projected to remain at Level of Service A. No major improvements are presently scheduled for those segments providing immediate access to the NTS (NDOT 1992). Regional roads and local roads providing access to NTS are presented in Figures 2.1-1 and 2.1-2, respectively.

Future background traffic (defined as all future traffic not attributable to the proposed SNF facilities) is projected to contribute to differing service-level conditions for local roads in 2001.
The year 2001 was selected for analysis because that is when the impacts from the proposed SNF facilities would be highest. All local and regional roads are projected to operate at Level of Service A.

The Level of Service was calculated using average daily traffic counts (NDOT 1992) and standard parameters (ITE 1991; Rand McNally 1993; TRB 1985).

The public transit serves the heavily populated regions of Clark County. Contract buses run to the NTS. There is no public transportation system serving the NTS; however, approximately 70 buses a day transport employees to and from the site. The nearest major railroad is the Union Pacific, located approximately 50 miles (80 kilometers) east of the NTS. A 9-mile (15-kilometer) standard-gauge railroad serves Area 25 of the NTS but does not connect with the Union Pacific (ERDA 1977). No navigable waterways within the Region of Influence are capable of accommodating waterborne transportation of material shipments to the NTS.

McCarran International Airport in Las Vegas provides jet air passenger and cargo service from both national and local carriers. It is outside the Region of Influence. Smaller private airports are located throughout the Region of Influence. Desert Rock Airstrip, the onsite airport, is located near Mercury.

4.12 Occupational and Public Health and Safety

Health impacts to the public from activities on the NTS are minimal as a result of administrative and design controls to minimize releases of pollutants to the environment and to achieve compliance with permit requirements, e.g., air emissions and National Pollutant Discharge Elimination System permit requirements. The effectiveness of these controls is verified through the use of monitoring and inspections. Health impacts to the public may occur during normal operations at the NTS via inhalation of air containing radioactive and chemical pollutants released to the atmosphere, immersion in this air, and ingestion of food contaminated by these pollutants. Risks to public health from other possible pathways such as exposure to contaminated soil are low relative to these pathways.

Health impacts to NTS workers during normal operations may include those from inhalation of the workplace atmosphere, consumption of potable water, direct exposure, and possible other contact with hazardous materials associated with work assignments. The potential for health impacts varies from facility to facility and from worker to worker, and available information is not
sufficient to allow a meaningful estimation and summation of these impacts. However, workers are protected from hazards specific to the workplace through appropriate training, protective equipment, monitoring, and management controls. NTS workers are also protected by occupational standards that limit atmospheric and drinking water concentrations of potentially hazardous chemicals and that also limit radiation exposure. Monitoring ensures that these standards are not exceeded. Additionally, DOE requirements (DOE Order 3790.1B) ensure that conditions in the workplace are as free as possible from recognized hazards that cause or are likely to cause illness or physical harm. Therefore, worker health conditions at the NTS are expected to be substantially better than required by standards.

Health effects from radiation are presented here as the risk of fatal cancer. This risk is in
the ratio of the health risk estimator (risk of fatal cancer per rem of exposure). The value of this
estimator for exposures to the public is 5.0 x 10-4 for fatal cancers. The corresponding estimator
for exposures to workers is 4.0 x 10-4.

The DOE Nevada Field Office published a Waste Minimization and Pollution Prevention Awareness Plan in June 1991 to reduce the quantity and toxicity of hazardous, mixed, and radioactive wastes generated at DOE/NV facilities. The plan is designed to reduce the possible pollutant releases to the environment and thus increase the protection of employees and the public. All DOE/NV contractors and NTS users that exceed the EPA criteria for small-quantity generators are establishing their own waste minimization and pollution prevention awareness programs that are implemented by the DOE/NV plan. Contractor programs ensure that waste minimization activities are in accordance with Federal, state, and local environmental laws and regulations, and DOE Orders (DOE/NV 1993c).

Additional goals include the promotion and use of nonhazardous materials, establishment of a baseline of waste generation data, calculations of annual reductions of wastes generated, and implementation of recycling programs. Goals also include incorporation of waste minimization concepts and technologies in planning and design of new processes and facilities, and in upgrades of existing facilities. A waste minimization task force composed of representatives from each contractor and NTS user has been established to coordinate DOE/NV waste minimization and pollution awareness activities (DOE/NV 1993c).

4.12.1 Doses

4.12.1.1 Radiological Doses. Every individual is affected by natural and other

background radiation. The major sources of background radiation exposure to individuals in the vicinity of the NTS are shown in Figure 4.7-2. All annual doses to individuals from background radiation are expected to remain constant over time.

Releases of radionuclides to the environment from NTS operations provide another source of radiation exposure to people in the vicinity of the NTS. Table 4.7-2 summarizes the airborne radionuclides and quantities released in curies during baseline NTS operations. The annual committed doses to the public resulting from these release are given in Table 4.7-4. Compared to those from natural background radiation, these doses are very small. The doses are all less than 1 percent of the most restrictive standard given in DOE Order 5400.5.

Workers at the NTS receive the same dose as the general population from background radiation but also receive an additional dose from working in the facilities. The doses to the average and maximally exposed workers due to operation in 1991 (assumed representative of 1995 operations), were approximately 5 and 500 millirem, respectively; the total dose to all workers was about 4 person-rem (DOE/NV 1992c). The maximum dose is well within the limit of 5,000 millirem per year specified in DOE Order 5480.11 and in 10 CFR 835.

4.12.1.2 Nonradiological Doses. Every individual is also affected by background

concentration of nonradiological pollutants. The maximum background concentrations for those criteria pollutants which have been measured is provided in Table 4.7-5. The maximum existing DOE site contribution concentration was then computed, as discussed in Section 4.7.

4.12.2 Health Effects

4.12.2.1 Radiological. The fatal cancer risk to the maximally exposed member of the

public due to the radiological emissions from NTS baseline operations in 1995 would be 5.5 x 10-9. The same risk estimator projects 2.6 x 10-6 excess fatal cancer to the population within 80 kilometers (50 miles) of the NTS. These values would be approximately 2.2 x 10-7 and 1 x 10-4, respectively, during the 40 years of SNF facility operations.

Because of the different age distribution of a working population, the health risk estimators for workers are somewhat lower than for members of the general public. As a result of 1995 baseline operations at the NTS, these estimators predict a fatal cancer risk of 2.0 x 10-4 to the maximally exposed worker, and 1.6 x 10-3 excess fatal cancer among all workers. The risk faced by an average worker would be 2.0 x 10-6. Over the 40-year operating life of the proposed SNF facility, and assuming a particular worker during this time, these values would be 8.0 x 10-3, 6.4 x 10-2, and 8.0 x 10-5, respectively.

4.12.2.2 Nonradiological. As discussed in Section 4.7, the maximum existing DOE site

contribution of criteria nonradiological air pollutants were computed. In Table 4.7-5 the total existing maximum concentration (which adds the maximum existing DOE site contribution to the maximum background concentration) is presented. The total existing maximum concentration values represent the highest concentrations to which members of the public would be exposed. In every case where information was available, the highest concentration was less than the applicable health-based standard.

4.12.2.3 Health Effects Studies. The epidemiologic studies concerning the NTS have

concentrated on the health effects in soldiers and children associated with nuclear testing rather than on plant emissions (Beck and Krey 1983; Bross and Bross 1987; Caldwell et al. 1980; Lyon et al. 1979; Rallison et al. 1990; and others). The results regarding the observed leukemia incidence and deaths in exposed children are contradictory, with some studies reporting an excess and others reporting no excess. The validity of the analytical methods used in some of these studies are subject to various opinions. For soldiers, the results regarding leukemia and polycythemia vera differed between two studies relating to nuclear test explosions, but reanalyses showed leukemia, respiratory, and other cancers to be associated only with exposure to higher doses, e.g., more than 300 millirem for leukemia cases.

In March 1990, the Secretary of Energy announced that DOE would turn over responsibility for analytical epidemiologic research on long-term health effects on workers at DOE facilities and surrounding communities to the Department of Health and Human Services and directed that worker health and exposure data be released. A Memorandum of Agreement with the Department of Health and Human Services was signed in January 1991. The Department of Health and Human Services is now conducting the ongoing health effects research program. To develop a data base on workers, DOE has initiated an Epidemiologic Surveillance Program and a Health-Related Records Inventory.

4.13 Utilities and Energy

4.13.1 Water Consumption

There are 14 active wells which supply water to the NTS. Figure 4.8-2 in Section 4.8 shows the location of these wells. These 14 wells combined had a capacity of 387 liters per second (6,139 gallons per minute) in 1993 (DOE/NV 1993a). From 1988 to 1993, water use at the NTS varied from a high of 134 liters per second (2,125 gallons per minute) in 1989 to a low of 60 liters per second (949 gallons per minute) in 1993 (DOE/NV 1994c; Leppert 1993). Water usage projections to 1995 are unavailable; however, significant changes in the water consumption level are not anticipated.

There are also a number of deactivated wells located on the NTS. These wells could add additional water supply capacity if they were reactivated (Leppert 1993). It has been estimated that the activation of these wells could increase the available water supply by 85 liters per second (1,342 gallons per minute). Other methods to increase production of water could include increasing pump sizes or installing new wells (DOE/NV 1993a).

The proposed SNF site would be located in Area 5. There are four wells located in Area 5, two of which supply potable water. These two wells have a capacity of 38 liters per second (595 gallons per minute) (DOE/NV 1994c; 1993b). A third well in the area is currently being used to supply water for construction activities. The fourth well has been deactivated (DOE/NV 1993b). In 1993, Area 5 used approximately 12 liters per second (191 gallons per minute) of water, including the well used for construction purposes. Water usage for Area 5 is not expected to change substantially from 1993 to 1995 (DOE/NV 1994c; Leppert 1994).

4.13.2 Electrical Consumption

The NTS obtains electrical power from the Nevada Power Company and Valley Electric Association. Each company provides an independent 138 kilovolt transmission line to the site. The capacity of these transmission lines, with scheduled upgrades, is approximately 40 to 45 megavolt-amperes. The local utilities' 138 kilovolt transmission grids have adequate capacity within a 80-kilometer (50-mile) radius of the NTS to serve an additional 75 megavolt-amperes of load. In addition, the local utilities' proposed expansion of their existing 230 kilovolt transmission systems would make capacity in excess of 200 megavolt-amperes available within an 80-kilometer (50-mile) radius (DOE/NV 1993a).

From 1989 to 1993, the annual consumption of electricity ranged from a high of 183,118 megawatt hours in 1989 to a low of 144,521.5 megawatt hours in 1993. The peak demand varied from a high of 38.4 megavolt-amperes in 1989 to a low of 30.9 megavolt-amperes in 1993 (Leppert 1993; Thornton 1994). In 1995, the annual consumption of electricity is projected to be 176,440 megawatt hours, with a peak demand of 39.5 megavolt-amperes. The institution of energy management practices can regulate the peak demands of various NTS activities so that the maximum peak capacity is not exceeded. The predicted increase in overall electricity usage for 1995 is attributable to the increased requirements for the Yucca Mountain Site Characterization Project; the usage for the rest of the NTS is predicted to continue its downward trend (Thornton 1994).

The Frenchman Flat Substation, located in Area 5, has a capacity of 12.5 megavolt-amperes (Thornton 1994). A 34.5 kilovolt line from this substation feeds the loads at Area 6, Well C, the Tweezer facility, and the east side of the test areas used by LANL (DOE/NV 1993b). In 1993, the peak demand on the substation was 5.2 megavolt-amperes. This demand is not anticipated to change substantially from 1993 to 1995 (Thorton 1994).

4.13.3 Fuel Consumption

The majority of the energy used at the NTS is provided by electricity, but diesel fuel and fuel oil are used to provide heat in some facilities and backup power.

4.13.4 Wastewater Disposal

Currently, there are no wastewater disposal facilities in Area 5. Septic systems are used in parts of the NTS for sanitary wastewater disposal. These septic systems discharge to percolation/evaporation stabilization ponds. These ponds, however, are only used for the disposal of wastewater not generated by any manufacturing processes.

4.14 Materials and Waste Management

The operations conducted at the NTS have resulted in generation of low-level radioactive waste, hazardous waste, mixed waste (radioactive and hazardous combined), and sanitary waste (nonhazardous, nonradioactive solid waste). In addition, the NTS stores mixed transuranic waste received from Lawrence Livermore National Laboratory. This section discusses the treatment, storage, and disposal of waste at the NTS.

DOE currently operates two disposal facilities in Areas 3 and 5 at the NTS for low-level radioactive waste generated by DOE defense facilities. The Area 5 Radioactive Waste Management Site also serves as a interim storage area for LLNL transuranic wastes which will be shipped to the Waste Isolation Pilot Plant in New Mexico for final disposal. The Area 5 facility also accepts mixed waste, which contains both low-level radioactive waste and hazardous waste only if the waste was generated on the NTS.

All hazardous wastes generated at the NTS are disposed of offsite at commercial facilities approved and permitted by the EPA. Hazardous wastes are temporarily stored at the NTS in full compliance with Federal, state, and local requirements.

Mixed waste disposal facilities are presently operating under interim status, pending completion of the Resource Conservation and Recovery Act (RCRA) permitting process. Operation of the low-level radioactive waste and mixed waste disposal sites and the temporary transuranic waste storage site are supported by an environmental monitoring program that indicates waste is being safely contained in the near-surface environment in which it is emplaced.

The radioactive and mixed-waste disposal facilities are mainly shallow land burial areas. Figure 4.14-1 shows the location of the waste management facilities at the NTS (DOE/NV 1993b, 1992b).

The DOE Nevada Operations Office developed and implemented a Waste Minimization and Pollution Prevention Awareness Plan to reduce the quantity and toxicity of hazardous, mixed, and radioactive wastes generated at the NTS. The plan is designed to reduce the possible pollutant releases to the environment. The objectives of the waste minimization and pollution program are to:

- Identify processes generating waste streams
- Characterize and track each waste stream
- Identify, evaluate, and implement applicable waste minimization technologies
- Set numerical goals and schedules after the initial assessment of technological and economic feasibility
- Establish an employee pollution prevention awareness and training program.

Additional goals include the promotion and use of nonhazardous materials, establishment of a baseline of waste generation data, calculations of annual reductions of wastes generated, implementation of recycling programs, and incorporation of waste minimization concepts and technologies in planning and design of new processes and facilities and in upgrades of existing facilities.

The NTS manages the following waste categories: mixed transuranic waste, mixed low-level waste, low-level waste, hazardous waste, sanitary waste, and nonhazardous waste. The NTS does not currently manage high-level waste or SNF. The NTS waste management activities include onsite treatment, onsite storage, onsite disposal, and preparation for appropriate offsite disposal.

Additionally, the NTS uses and manages an onsite inventory of hazardous materials, including
Figure 4.14-1. Existing treatment, storage, and disposal units at the NTS. some managed in underground storage tanks. Figures 4.14-2 and 4.14-3 present flow diagrams of onsite generated waste management and waste shipment, receipt, and disposal, respectively.

Waste generation rates presented for each of the waste categories for the NTS represent 1993 waste generation rates unless otherwise stated and are assumed representative of the 1995 baseline year. Table 4.14-1 presents the baseline waste management for 1995 for those waste categories currently managed at the NTS. In addition, the table presents available disposal/ storage capacity and waste disposition.

4.14.1 Transuranic Waste

Transuranic waste from the Rocky Flats Plant and mixed-transuranic waste from LLNL are stored at the NTS at the transuranic waste storage cell located in Area 5 Radioactive Waste

Management Site. The transuranic waste has been characterized and repackaged, and the mixed-transuranic waste has been placed in a RCRA-permitted storage area consisting of 55-gallon drums and steel boxes stored on wooden pallets fixed upon a curbed asphalt pad. Approximately 204,663 kilograms (451,201 pounds) with a total volume of 612 cubic meters (800 cubic yards) of transuranic waste are stored at the NTS (DOE/NV 1994d). The NTS expects no additional transuranic or mixed-transuranic wastes to be stored at this unit.

4.14.2 Mixed Low-Level Wastes

The Area 5 Radioactive Waste Management Site contains Pit 3, which is an active mixed low-level waste management unit. Pit 3 is the only active landfill cell within the Area 5 Radioactive Waste Management Site for which a RCRA permit is being sought. Pit 3 is an unlined, trapezoidal shaped pit occupying 3.42 x 104 square meters (8.46 acres) with a process capacity of 1.29 x 105 cubic meters (1.69 x 105 cubic yards). The estimated disposal space for mixed low-level waste remaining at this facility is 9.03 x 104 cubic meters (1.19 x 105 cubic yards) (DOE/NV 1992b).

A RCRA permit is being sought for a proposed Mixed Waste Disposal Unit in the area immediately north of Pit 3 in the Area 5 Radioactive Waste Management Site. This Mixed Waste Disposal Unit would occupy 2.1 x 105 square meters (52 acres) and consist of ten landfill cells. The estimated disposal space for mixed waste in this proposed unit is approximately 1.20 x 105 cubic meters (1.58 x 105 cubic yards) (DOE/NV 1992b).

Figure 4.14-2. Flow diagram for waste generation at the NTS. Figure 4.14-3. Flow diagram for waste shipment, receipt, and disposal at the NTS.

Table 4.14-1. Baseline waste management for 1995 at the NTS.

Waste type	Volume generated or disposed of (m3)	Available disposal space (m3)	Disposition
Transuranic waste and mixed-transuranic waste	0	8,296	Interim onsite storage
Low-level waste	10,845	438,359	Onsite disposal
Mixed low-level waste	0	90,240	Onsite disposal
Hazardous waste	252	91	90-day pad
Sanitary waste	1.1 x 104b	c	Onsite disposal

a. Sources: DOE/NV (1994d, 1992c).

b. 1992 data.

c. Current disposal space adequate.

In May 1990, mixed waste disposal operations ceased due to EPA issuance of the Land Disposal Restrictions of RCRA. Active mixed waste disposal operations will commence under interim status in Pit 3 upon completion of NEPA documentation and an approved Waste Analysis Plan (DOE/NV 1993c). No mixed low-level waste has been received, generated, or disposed of at the NTS since 1991 (DOE/NV 1994d, 1993c,f).

4.14.3 Low-Level Waste

Two low-level waste disposal facilities are in operation at the NTS: Area 5 Radioactive Waste Management Site and the Area 3 Radioactive Waste Management Site (DOE/NV 1992c). The Area 5 Radioactive Waste Management Site receives low-level waste generated at the NTS and other DOE facilities and occupies approximately 2.9 square kilometers (730 acres) of land. The waste is disposed of in large-diameter shafts, trenches, and shallow pits. The total volume of low-level waste disposed of at the Area 5 Radioactive Waste Management Site between 1961 and 1991 was 3.96 x 105 cubic meters (5.8 x 105 cubic yards). Average annual low-level waste disposal for this period was 1.3 x 104 cubic meters (1.7 x 104 cubic yards). During 1993, approximately 1.1 x 104 cubic meters (1.4 x 104 cubic yards) of low-level waste was disposed of at the NTS (DOE/NV 1994d).

4.14.4 Hazardous Waste

The primary facilities that generate or manage nonradioactive hazardous wastes and/or use or store nonradioactive hazardous materials are the Liquified Gaseous Fuels Spill Test Facility, the Hazardous Waste Accumulation Site, the tunneling facilities and operations, and various underground storage tanks.

The Liquified Gaseous Fuels Spill Test Facility is located on Frenchman Lake in Area 5.

This location provides a remote, environmentally acceptable setting for atmospheric release of hazardous materials and toxic substances for investigative purposes. The facility consists of a tank farm, spill area, wind tunnel, and pads for conducting small volume spill tests. The facility also includes a control building that houses data acquisition and recording instruments, a command and control computer, and support personnel. A total of 17 spill tests were conducted at the facility in Area 5. Discharges from the test facility occur at a controlled rate and consist of a measured volume of hazardous test fluid released on a surface especially prepared to meet the test requirements. Personnel monitor and record operating data, close-in and downwind meteorological data, and downwind gaseous concentration levels. Spills involving hydrofluoric acid were conducted in 1991 and the results monitored (DOE/NV 1992c).

The Hazardous Waste Accumulation Site consists of an impervious concrete pad with 15-centimeter (6-inch) curbs to contain spillage and to protect the pad from precipitation runon and runoff; a separate curbed area is provided for noncompatible wastes. A roof protects the wastes from rain and weathering effects; there is also a fire detection system (DOE/NV 1992d). Each operating entity at NTS is a potential satellite accumulation area for hazardous waste. Each satellite accumulation area is allowed to accumulate up to 208.2 liters (55 gallons) of hazardous waste or 0.95 liter (1 quart) of acutely hazardous waste. Within 3 days of reaching these quantities, the waste is transferred to the Hazardous Waste Accumulation Site. If the material is unknown or if an offsite treatment, storage and disposal facility wishes to confirm the contents of a waste stream, samples are collected for characterization (DOE/NV 1992d).

When the waste containers are transferred to the Hazardous Waste Accumulation Site, they are checked for proper labeling and an accumulation date is assigned to each container. An EPA-permitted treatment, storage, and disposal facility is contacted prior to the 90-day storage limit to collect and remove the accumulated wastes from the NTS (DOE/NV 1992d).

Nuclear devices were tested in horizontal tunnels mined into Rainer Mesa at the NTS. The tests were conducted in zeolitized volcanic tuffs, which act as a perching layer for waters infiltrating from the mesa surface. During normal tunneling operations, fractures containing water are intercepted creating artificial springs in the tunnels. Periodically, these waters contain radionuclides from previous underground nuclear tests and are drained out of the tunnels into evaporation ponds or washes. Tunneling and related operations also may have released organic compounds and heavy metals to the tunnel effluent. Presently, sampling of the tunnel effluent is being conducted to characterize the effluent. The objectives of the project include identifying the types and concentrations of radionuclides, metals, and organic compounds in the effluent of U12t, U12e, and U12n tunnels. Variations of discharge volumes and chemical contaminants over time are also being examined (DOE/NV 1992c).

There is a site-wide inventory of 115 underground storage tanks at the NTS. These include 24 underground storage tanks containing petroleum products that were removed, closed in place, or temporarily taken out of service in 1991 in accordance with state statutes as well as 17 underground storage tanks which were temporarily closed in 1991 while awaiting upgrades (DOE/NV 1992c).

As part of the 1991 underground storage tank activities, all tanks to be upgraded had soil samples taken from the tank ends to identify any soil contamination prior to redesign and construction. To date, overfill releases from underground storage tanks located at the Areas 6, 12, and 23 gasoline stations were observed and necessitated additional soil sampling. All underground storage tanks that were planned to be upgraded (except a tank containing asphaltic material) were also pressure tested for leaks. All tanks passed the test limit of 0.76 liter per hour (0.2 gallon per hour) (DOE/NV 1992c).

Numerous underground storage tanks have been identified throughout the site as "Undetermined Activity Status." The contents of some of these underground storage tanks is classified as "H?" which indicates that the contents are presumed to be hazardous.

The types of possible wastes found on the surface of the NTS include radionuclides, organic compounds, metals, hydrocarbons, and residues from plastic, epoxy, and drilling muds (not petroleum production related and therefore considered hazardous under Subtitle C of RCRA). A wide variety of surface facilities, such as injection wells, leach fields, sumps, waste storage facilities, tunnel ponds and muck piles, and storage tanks, may have contaminated the local soil and the shallow unsaturated zone of the NTS. Because of the great depths to groundwater and the arid climate, it is assumed that the potential for mobilization of surface and shallow subsurface contamination is minimal. However, contaminants entering carbonate bedrock from Rainier Mesa tunnel ponds, contaminated wastes injected into deep wells, and wastes disposed into subsurface craters have the potential to reach the regional water table. Pilot wells were to be installed during 1992 to support the RCRA permitting process (DOE/NV 1992c).

Annual generation or disposal of hazardous waste at the NTS was approximately 252 cubic meters (329.6 cubic yards) during 1993. Available storage space on the 90-day pad is approximately 91 cubic meters (119 cubic yards) (DOE/NV 1994d).

4.14.5 Sanitary Waste

Sanitary wastes are expected to be generated at the current rates for several years into the future, then decline assuming the present moratorium on underground weapons testing. Liquid sanitary wastes are disposed of in septic tanks/leach fields, sumps, or in ponds, and solid sanitary wastes are disposed of in landfills at various locations on the site. The NTS currently maintains 13 sewage discharge permits: Area 2, Area 6 (5), Area 22, Area 23, Area 25 (4), and Area 12 (DOE/NV 1993c). Approximately 9.1 x 103 cubic meters (11,902 cubic yards) of sanitary waste were generated at the NTS during 1991 and 1.1 x 104 cubic meters (14,388 cubic yards) during 1992 (DOE/NV 1993c). Sufficient disposal space is available at the NTS for current needs.

4.14.6 Hazardous Materials

Polychlorinated biphenyls, pesticides, and asbestos have been or currently are managed at the NTS. These wastes and materials are managed in addition to the approximately 90,000 kilograms (100 tons) of RCRA-regulated nonradioactive hazardous wastes generated annually at the NTS, the approximately 218,000 kilograms (240 tons) of non-RCRA-regulated hazardous waste generated annually at the NTS, and the wastes and materials managed at the facilities discussed previously.

By the end of 1991, all known polychlorinated biphenyl transformers and other electrical equipment had been either reclassified or appropriately disposed of, and three polychlorinated biphenyl-contaminated transformers and regulators were under the 90-day period for reclassification. Successful reclassification of these three polychlorinated biphenyl-contaminated transformers will complete the reclassification or disposal of all known polychlorinated biphenyl and polychlorinated biphenyl contaminated transformers at the NTS (DOE/NV 1992c).

No unusual environmental activities relating to the Federal Insecticide, Fungicide, and Rodenticide Act occurred in 1991 at the NTS. Pesticides are stored in an approved storage facility located in Area 23. Pesticide usage includes insecticides, herbicides, and rodenticides. Insecticides are applied twice a month at the food service areas, herbicides are applied once a year, and all other pesticides are applied on an as-requested basis. General-use pesticides are used for most applications, although restricted-use herbicides and rodenticides are used on occasion (DOE/NV 1992c).

The Area 11 Explosive Ordnance Disposal Facility is a thermal treatment unit for disposal of conventional explosives. Explosives detonated at the facility include Defense Nuclear Agency materials and waste explosives from Reynolds Electrical and Engineering Co., Inc. tunnel operations, the Wackenhut Firing Range (used by the NTS security force), and the resident national laboratories. No radioactive or radioactive-contaminated materials are accepted or detonated at the Area 11 Explosive Ordnance Disposal unit.

The unit encompasses approximately 0.08 square kilometer (20 acres) of land located between Frenchman Flat and Yucca Flat, with four graded areas. Only one of these graded areas is used for detonation. Magazines are used to store detonation materials and waste explosives. Approximately 80 to 90 percent of the explosives detonated at the Explosive Ordnance Disposal unit during the past 10 to 12 years have been water-gel explosives; earlier, the primary waste was gelatin-based dynamite. Other explosives detonated include small amounts of trinitrotoluene (TNT), RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine) pellets, small arms ammunition (from past military operations at NTS), and black powder (DOE/NV 1992b).

4.14.7 Non-hazardous Waste

Solid wastes are regulated through State of Nevada regulations NAC 444 and Federal regulations 40 CFR 241, 257, and 258. Solid wastes generated include used petroleum products, uncontaminated tunnel muck, drilling fluids, cement and grout wastes, construction debris, refuse, sludge from wastewater lagoons, septic tank and chemical toilet sludge, and animal carcasses. The NTS has several sanitary landfills and construction landfills in operation; several landfills have been closed or abandoned (DOE 1990).

Some wastes not regulated under RCRA will be stored at the Hazardous Waste Accumulation Site. These nonregulated wastes are shipped offsite along with the RCRA wastes to a treatment, storage, and disposal facility. Only non-RCRA hazardous wastes that cannot be disposed of at the NTS landfill will be stored at the Hazardous Waste Accumulation Site for offsite shipment. Any drum containing nonregulated wastes will carry a label so specifying. The contents of the drum will be entered on a space provided on the label. Wastes in this category include but are not limited to epoxies, photochemicals, spent antifreeze, and oils and solvents that do not carry EPA codes.

Recycling of paper, metals, glass, plastics, and cardboard has already resulted in some decrease in quantities of waste and is expected to result in significant decreases over the next few years (DOE/NV 1992b).

5. ENVIRONMENTAL CONSEQUENCES

5.1 Overview

This chapter describes the potential environmental consequences from the construction and operation of spent nuclear fuel (SNF) facilities at the Nevada Test Site (NTS) under the Centralization and Regionalization Alternatives. Potential environmental consequences are assessed to the extent necessary to support a programmatic decision concerning the siting of the proposed SNF facilities. More detailed considerations of potential environmental consequences would be performed as necessary prior to initiating construction or operation of the facilities.

5.2 Land Use

5.2.1 Centralization Alternative

Construction and operation of SNF facilities under this alternative would require the disturbance of approximately 90 acres (0.36 square kilometer), including buffer areas. Use of the proposed SNF site for program activities would be consistent with existing nearby land uses and land use policies and plans. The current land use designations for this area are Low-Level Waste Facility Management and Buffer/Reserved Area. Use of this area for program activities would also be consistent with future land use plans (DOE/NV 1993a).

Use of the proposed site for the construction and operation of SNF facilities could result in irreversible or irretrievable land use impacts in those areas currently under Buffer/Reserved use. However, the placement of SNF facilities at this location would be consistent with DOE's 1994 draft future land use plan, which designates this portion of Area 5 as a Non-Nuclear Test Area (DOE/NV 1993a). Therefore, no mitigation measures are proposed.

5.2.2 Regionalization Alternative

As under the Centralization Alternative, use of the proposed site for construction and operation of SNF facilities under the Regionalization Alternative would be consistent with existing land uses and with all applicable land use policies and plans. Impacts would be similar in character to those described for the Centralization Alternative, except that there could be reduced land requirements under this alternative.

5.3 Socioeconomics

Socioeconomics as addressed in this Programmatic Environmental Impact Statement (PEIS) encompasses the interaction of economic, demographic, and social conditions. Economic consequences (e.g., capital requirements to support SNF research and development activities) affect business activities, market structures, procurement methods, and dissemination of commodities within and between regions. Demographic consequences (e.g., in-migration of specialized human resources to support the SNF Management Program) affect size, distribution, and composition of the population, labor force, and the housing market in the regions. Social consequences (e.g., capacity modifications of public infrastructure to support SNF activity) affect the overall quality of life enjoyed by the residents of a community (Murdock and Leistritz 1979). These conditions are potentially affected either directly or indirectly by actions proposed under the U.S. Department of Energy (DOE) SNF Management Program.

The importance of actions is relative to the affected region. A region can be described as a dynamic socioeconomic system, where physical and human resources, technology, social and economic institutions, and natural resources interrelate to create new products, processes, and services to meet consumer demands. The measure of a region's ability to support these demands depends on its ability to respond to changing economic, demographic, and social conditions.

Potential socioeconomic effects are addressed only to the extent that they are interrelated with the natural or physical environment. Direct effects include those impacts that are caused by the action and occur at the same time and place. Indirect effects include those impacts caused by the action that are later in time or farther removed in distance but still are reasonably foreseeable (i.e., offsite) (CFR 1993e). Direct and indirect effects are presented quantitatively from 1995 through 2005, and qualitatively through 2035.

Socioeconomic effects are quantified for regional economic activity and population. Other potential socioeconomic impacts to individual communities, such as public infrastructure and housing, are discussed qualitatively to address programmatic issues.

Economic impact projections include direct and indirect jobs. Direct jobs are those jobs needed to construct or support the operation of the SNF management complex at the NTS.

Indirect jobs are created throughout the regional economy within the Region of Influence as a result of procurement for materials, services, and other commodities, and induced effects from consumer spending. These direct and indirect impacts reflect both construction and operation phase demands, which may occur concurrently or independently throughout the project planning period. Indirect jobs were projected using parameters from the U.S. Bureau of Economic Analysis Regional Input-Output Modeling System.

Two scenarios were analyzed to account for two potential distributions of the SNF facility construction efforts. The construction effort consists of fabricating various structures, each with its own construction labor need and a duration of either three or five years. The Peak Scenario accelerates the construction labor requirements into the first two years of construction. The Average Scenario averages the labor requirements of a structure for the duration of construction. The total construction effort for all structures, in labor years, is the same for each scenario. Therefore, for structures with a three year construction duration, the Peak Scenario has high labor needs for the first two years and then a substantial reduction for the third year, while the Average Scenario has a constant labor requirement for the three years. Likewise, for structures with a five year construction duration, the Peak Scenario has a high labor need for the first two years, then a lower need for the remaining three years, while the Average Scenario has a constant requirement for all five years. Because the total construction labor years for each structure is the same for both scenarios, the Average Scenario will have a lower requirement than the Peak Scenario in the first two years, then will have a higher requirement then the Peak Scenario in the remaining construction years.

Regional population projections reflect the potential change in population resulting from an increase in regional economic activity. Detailed assumptions regarding in-migration associated with the SNF Management Program were not developed, given the programmatic scope of this analysis. Potential in-migration effects resulting from direct job creation are presented qualitatively where appropriate.

5.3.1 Centralization Alternative

The upper and lower bounds of construction and operation-related jobs generated by SNF facilities for both scenarios under the Centralization Alternative from 1995 to 2005 are illustrated in Figure 5.3-1 and tabulated in Table 5.3-1. In its initial phase, the Centralization Alternative may create 54 jobs (25 direct, 29 indirect) over a 5-year period beginning in 1995 and continuing through the year 1999 to support project planning, engineering design, personnel operations training, and environmental permitting and compliance. Construction is expected to begin in the year 2000, requiring a total of 4,351 direct jobs (5,041 indirect jobs). In that year and 2001, the Peak Scenario requires 1,587 construction laborers, while the Average Scenario needs 1,346. There is no operational labor required for this time period. In 2002, after two years of construction, the Peak Scenario decreases its construction labor requirements to 928 workers, while the Average Scenario maintains its 1,346 laborers. Additionally, 300 operational personnel are needed, raising the total of SNF workers to 1,228 for the Peak Scenario and 1,646 for the Average Scenario. By 2003, the buildings with three year construction durations have been completed; therefore, both the Peak and Average Scenario construction labor requirements decline to 125 and 157, respectively. Operation labor requirements remain at 300 workers. Total SNF labor requirements are 425 workers for the Peak Scenario and 457 for the Average Scenario. In 2004, construction labor needs for both scenarios remains at their previous level, but operational personnel increase. Total SNF labor requirements are 612 workers in the Peak Scenario and 644 workers in the Average Scenario. By 2005, all construction has been completed and operational personnel have increased to the full staff labor requirement of 800 workers.

The Peak Scenario reaches its maximum construction labor with 1,587 direct jobs (3,426 total jobs created) over a 2-year period from years 2000 through 2001. The Average Scenario would have its maximum construction labor with 1.346 direct jobs (2,906 total jobs created) in a

Figure 5.3-1. Total employment effects, NTS centralization alternative.

Table 5.3-1. Socioeconomic effects - centralization of SNF at Nevada Test Site.

	Time period					
Years	1995 - 1999	2000, 2001	2002	2003	2004	2005 +
			Operations			
Direct jobs	25	0	300	300	487	800
Indirect jobs	29	0	344	344	559	918
Total jobs	54	0	644	644	1,046	1,718
			Construction			
Direct jobs						
Peak	0	1,587	928	125	125	0
Average	0	1,346	1,346	157	157	0
Indirect jobs						
Peak	0	1,839	1,076	145	145	0
Average	0	1,560	1,560	182	182	0
Total jobs						
Peak	0	3,426	2,004	270	270	0
Average	0	2,906	2,906	339	339	0
			Total			

Direct jobs						
Peak	25	1,587	1,228	425	612	800
Average	25	1,346	1,646	457	644	800
Indirect jobs						
Peak	29	1,839	1,420	489	704	918
Average	29	1,560	1,904	526	741	918
Total jobs						
Peak	54	3,426	2,648	914	1,316	1,718
Average	54	2,906	3,550	983	1,385	1,718
Population Change						
Peak	91	5,664	(1,084)	(2,379)	547	540
Average	91	4,804	896	(3,522)	547	447

3-year period from years 2000 through 2002. Operation requirements would be minor until 2002, when engineering and administrative services are assumed to be in demand to accommodate project requirements. Ancillary SNF complex operations, such as utilities and research and development activities, are assumed to begin in 2004, taper off into 2005, and remain relatively constant through 2035. The maximum total SNF management direct jobs under either construction scenario would occur in 2002 with 1,346 construction jobs for the Average Scenario and 300 operation jobs. Implementation of the Centralization Alternative would increase the projected average annual rate of growth rate for both regional population and employment from 1995 through 2005 by 0.02 percent.

Regional businesses and the work force would benefit from increased competition for contract procurement and jobs. Most of this activity is anticipated to be captured by Clark County, with a smaller share occurring in Nye County. However, the impact to the regional economy represents only a portion of the total economic activity generated by the Centralization Alternative. For instance, purchases of specialized materials and technology acquisition may occur even outside the State of Nevada. It has been estimated that about 50 percent of total NTS expenditures occur within the State of Nevada (Nye County Board of Commissioners 1992). This leakage would result in the associated economic benefits accruing outside of the regional economy.

Most of the population change in the Region of Influence above the baseline forecast would be due to in-migration of labor and households to support SNF management activity at the NTS. It is likely that most of the SNF operation work force would be supplied by SNF personnel relocating from DOE sites where SNF inventories were stored before shipment to the NTS, since they are familiar with the processes, technologies, and research. Other demands for operational jobs not related to SNF management would be accommodated by the regional labor market. The regional labor market could accommodate most of the construction requirements, with the exception of very specialized tasks. Construction employment in Clark County is twice that of the national average. As the population continues to grow, demand on public infrastructure grows as well. These projects will result in continued growth in construction activity (Las Vegas Review Journal et al. 1993).

To assess potential population and housing impacts, an in-migration rate per job was estimated using a ratio between projected employment and population figures (Table 4.3-1). This ratio was applied to the number of total (direct and indirect) jobs created by SNF management activities at the NTS, resulting in the total estimated number of persons in-migrating into the Region of Influence per job created (Table 5.3-1).

With initial operation in 1995 under the both scenarios (Table 5.3-1) a total of 91 persons could migrate into the Region of Influence. The number of persons coming in would be at its largest for the years 2000 through 2001, (5,664 in-migrants for the Peak Scenario and 4,804 for the Average Scenario) the period when construction starts. In the final phases of construction, people would migrate out of the Region of Influence. However, the number of in-migrants would increase in the years 2004 and 2005, as more of the SNF management operations start. After 2005, in-migration due to SNF management activities would cease, since SNF management activities would not create any more jobs.

Construction of the SNF complex could result in a temporary increase in housing demand in Nye County. The demand for both the rental market and short-term lodging could increase. The demands on housing would fluctuate over time, based on the various construction phases, peak employment levels, the level of local sub-contracting, and any decision by a contractor to develop temporary housing arrangements near the job site. Within Nye County, the communities of Tonopah and Beatty would probably experience the most impacts related to housing demand. Both communities support fairly large inventories of temporary housing. While such demands are favorable for local lodging operators and landlords, they could compete with tourism demands (Nye County Board of Commissioners 1992).

Overall socioeconomic impacts to Clark County could be absorbed within the projected expansion of the county's economy, local infrastructure, public service, and real estate development.

5.3.2 Regionalization Alternative

Socioeconomic impacts resulting from the Regionalization Alternative are expected to be similar to those for the Centralization Alternative. The construction and operation cycles for each alternative would be the same; therefore, the same issues identified for the Centralization Alternative would apply. Labor requirements might be reduced slightly for the Regionalization Alternative. Although the volume of SNF stored would be less for the Regionalization Alternative, an economy of scale occurs for both alternatives, so that differences in labor and capital between the two alternatives would be minimized.

5.3.3 Mitigation Measures

5.3.3.1 Coordination with Local Jurisdictions. To reduce construction- and operation-

related impacts, possible coordination with local communities could address potential impacts from increased labor and capital requirements. The knowledge of the extent and effect of growth due to SNF management activities could greatly enhance the ability of affected jurisdictions to plan effectively. Effective planning would address changes in levels of service for housing, infrastructure, utilities, transportation, and public services and finances.

5.3.3.2 Enhance Labor Force Availability. To alleviate potential impacts associated with

the in-migration of labor, local labor force availability could be increased through various employment training and referral systems currently provided by the NTS. The goal of these systems would be to reduce the potential for in-migration of labor to support SNF management activities.

5.4 Cultural Resources

5.4.1 Centralization Alternative

Under the Centralization Alternative, the construction of SNF facilities is not expected to require the disturbance of more than 90 acres (0.36 square kilometer) on the NTS. There are no known historical, archeological, paleontological, or Native American traditional sites in the proposed area or its vicinity. Therefore, no impacts to cultural resources are expected due to ground disturbance, noise, or air emissions during construction and operation of the SNF facilities. Consultation with the Nevada State Historic Preservation Office (SHPO) prior to project implementation is required under Section 106 of the National Historic Preservation Act of 1966. The SHPO may recommend that further archaeological studies be conducted throughout the construction area to verify that there are no archaeological sites subject to disturbance.

5.4.2 Regionalization Alternative

Under the Regionalization Alternative, the location of the SNF facilities would remain the same but could be reduced in area. As with the Centralization Alternative, impacts are not anticipated.

5.5 Aesthetics and Scenic Resources

5.5.1 Centralization Alternative

The proposed SNF facilities under the Centralization Alternative, when fully constructed and under operation, would consist of a series of industrial buildings set within a security fence on the proposed 90-acre (0.36 square-kilometer) site. The facility would have the appearance of industrial buildings ranging in height from one to three stories. The maximum height of the buildings contained within the site would not exceed 42 feet (13 meters) above ground level. The proposed SNF site is located within a valley over 10 miles (16 kilometers) from U.S. Route 95, separated by intervening hills and mountains, including Red Mountain, the Spotted Range, the Specter Range, Hampel Hill and Skull Mountain. The site would not be visible from areas outside the NTS or the Nellis Air Force Base Bombing and Gunnery Range. Therefore, impacts to aesthetics and scenic resources are not anticipated.

5.5.2 Regionalization Alternative

Under the Regionalization Alternative, proposed SNF facilities could be reduced in area and intensity of operations from the Centralization Alternative. Environmental effects to aesthetics and scenic resources could also be less than that of the Centralization Alternative.

5.6 Geologic Resources

This section describes any incremental or additional impacts on geology and geologic resources that would result from the construction and operation of the new facilities associated with the storage of SNF at the NTS. Seismic and volcanic hazards are discussed in Section 4.6.

5.6.1 Centralization Alternative

As discussed in Section 4.6.2, precious metal deposits may exist in certain carbonate rocks and volcanic or sedimentary rocks at the NTS. Figure 4.6-5 shows the proposed SNF site in relation to these types of geologic terranes as well as to the locations of mining districts. Although the proposed SNF facilities would not be located within a mining district, they would be situated on Tertiary volcanic or sedimentary rocks near volcanic or intrusive centers (the type of geologic terrane where small to medium-size precious metal deposits could be developed). However, because the NTS would likely remain closed to mining operations, the impact on any precious metal deposits that might exist at the NTS would not change if the proposed storage facility were to be sited there.

In addition, destruction of unique geologic features are not expected to occur as a result of construction and operation of a new SNF storage facility nor are mass movement and subsidence and sediment runoff from land disturbances.

5.6.2 Regionalization Alternative

Impacts to geology and geological resources under the Regionalization Alternative would generally be as described for the Centralization Alternative.

5.7 Air Resources

Both radiological and nonradiological air emissions impacts from the proposed SNF facilities are discussed in this section.

5.7.1 Centralization Alternative

5.7.1.1 Emissions.

5.7.1.1.1 Radiological Emissions-There would be no radiological emissions from

construction of the proposed SNF facilities.
The total annual airborne radionuclide releases from operation of the proposed SNF facilities are provided in Table 5.7-1.

5.7.1.1.2 Nonradiological Emissions-During construction of the proposed SNF

facilities, short-term emissions, such as fugitive dust and heavy equipment exhaust emissions, would be temporary and only affect receptors close to construction areas.
Fugitive dust emissions would be minimized by curtailing soil-disturbing activities during high winds. During operation of the proposed SNF facilities, criteria and hazardous air pollutants would be emitted.

The total annual emissions from all modules associated with the proposed SNF facilities are listed in Table 5.7-2.

5.7.1.2 Air Quality.

5.7.1.2.1 Radiological-The GENII environmental transport and dose assessment

model (PNL 1988) was used with 1990 meteorological data from Desert Rock Army Airfield to determine effective dose equivalents from the radiological emissions listed in Table 5.7-1. A population of 15,100 persons was estimated to be within 50 miles (80 kilometers) of the proposed SNF facilities. It was also assumed that 1995 operations at the NTS would result in the same baseline radiological emissions as the 1992 operations at the NTS. The most recent comprehensive radiological emissions report at the NTS was based on 1992 operations.

Table 5.7-1. Annual airborne radionuclide emission source terms for proposed NTS SNF facility operational phase.

Isotope	Release rate (Ci/yr)b,c
Tritium	7.9 x 10-1
Carbon-14	1.2 x 100
Manganese-54	2.2 x 10-8
Cobalt-60	4.2 x 10-8
Krypton-85	1.0 x 104
Strontium-90	3.3 x 10-6
Yttrium-90	2.0 x 10-6
Ruthenium-106	1.1 x 10-5
Antimony-125	3.4 x 10-4
Iodine-129	1.0 x 10-1
Cesium-134	6.2 x 10-8
Cesium-137	4.8 x 10-5

a. Source: Johnson (1994).

b. 2.0 x 10-6 Ci/yr of Barium-137m, from Wet Storage, is not in GENII. Barium-137m, with a half-life of 2.55 min, decays to Barium-137, which is stable.

c. 7.5 x 10-8 Ci/yr of Thallium-208, from Wet Storage, is not in GENII. Thallium-208, with a half-life of 3.10 min, decays to Lead-208, which is stable.

Table 5.7-2. Total annual nonradioactive emissions for the SNF storage facility at NTS.

Criteria pollutants	Release rate (kg/yr)
Carbon monoxide	1.7 x 103
Particulate matter (PM10)b	1.0 x 10-3
Nitrogen oxides	5.5 x 103
Sulfur dioxide	1.3 x 102
Lead	5.0 x 10-9
Hazardous air pollutants	Release rate (kg/yr)
Selenium compounds	1.6 x 10-4
Mercury compounds	5.1 x 10-1
Chlorine	3.5 x 103
Hydrogen fluoride	1.6 x 101
Cadmium compounds	2.9 x 10-7
Cobalt, chrome, antimony, and nickel compounds	2.0 x 10-10

a. Source: Johnson (1994).

b. All suspended particulate matter is assumed to be PM10.

Table 5.7-3 summarizes the sum of the baseline and the incremental contribution from the proposed SNF facilities to the effective dose equivalents of the maximum site boundary individual and, collectively, to the population within 50 miles (80 kilometers) of the proposed facility. These combined effective dose equivalents for operation of the proposed SNF facilities would be less than 1 percent of the National Emissions Standards for Hazardous Air Pollutants (NESHAP) standard and less than 1 percent of the natural background radiation.

5.7.1.2.2 Nonradiological-The Industrial Source Complex Short Term air

dispersion model (EPA 1992) was used with 1990 meteorological data from Desert Rock Army Airfield to determine pollutant concentrations resulting from the Centralization Alternative nonradiological emissions listed in Table 5.
7-2. A maximum emissions baseline was established to characterize conditions that could result if all sources operated to the maximum extent allowed by permit conditions. It was also assumed that 1995 operations at the NTS would result in the same baseline nonradiological emissions as the 1990 operations at the NTS. The most recent comprehensive nonradiological emissions report at the NTS was based on 1990 operations. The results of modeling are in Table 5.7-4, where a comparison of the existing DOE site contribution concentration is compared to the existing DOE site contribution concentration plus the proposed SNF contribution. The increases in pollutant concentrations from operation of the proposed SNF facilities would be negligible in magnitude. The concentrations of pollutants at the NTS with the inclusion of the proposed SNF facilities would remain within regulatory guidelines.

The calculated atmospheric maximum concentrations at the site boundary and offsite for the proposed SNF facilities are presented in Table 5.7-5. The maximum concentrations at the site boundary reflect exposure to a maximally exposed individual, whereas the maximum onsite concentrations reflect exposure to a worker.

5.7.2 Regionalization Alternative

As with the Centralization Alternative, construction of the proposed SNF facilities under the Regionalization Alternative would not result in radiological air emissions, but could result in minor, temporary emissions of fugitive dust. These emissions could be slightly less than under the Centralization Alternative, since the extent of construction disturbance would be less.

Table 5.7-3. Summary of effective dose equivalents to the public from proposed SNF storage facility plus 1995 baseline operations at NTS.

	Maximally exposed individual doseb	Collective dose to population within 80 km of NTS sources
Dose	1.3 x 10-1 mrem per yearc	8.7 x 10-2 person-remd
NESHAP standard	10 mrem per year	--
Percentage of NESHAP standard	1.3	--
Natural background dose	278 mrem per year	4190 person-rem per year
Percentage of natural backgroun dose	4.7 x 10-2	2.1 x 10-3

a. Effective dose equivalents computed using GENII (PNL 1988).

b. The maximum boundary dose is to the hypothetical individual who remains in the open continuously during the year at the NTS boundary.

c. The SNF facility contributes 1.2 x 10-1 millirem to this dose.

d. The SNF facility contributes 8.2 x 10-2 person-rem to this dose.

Table 5.7-4. Comparison of baseline concentrations with most stringent applicable regulations and guidelines at NTS for proposed SNF facility plus current operations.

Criteria pollutant	Averaging time	Most stringent regulation or guidelined (-g/m3)	Maximum background concentration (-g/m3)	Total existing maximum concentratione (-g/m3)	Total projected maximum concentrationf (-g/m3)	Increase in maximum concentration (-g/m3)
Carbon dioxide	8-hour	10,000	2,290	2,290	2290.8	0.80
	1-hour	40,000	2,748	2,748b	2754.0	6.03
Nitrogen dioxide	Annual	100	a	b	0.20	0.20
Lead	Calendar quarter	1.5	a	b	3.7 x 10-12	3.7 x 10-12
Particulate matt (PM10)c	Annual	50	a	0.43	0.43	0
	24-hour	150	78.3	84.9	84.9	0
Sulfur dioxide	Annual	80	a	1.1	1.1	0
	24-hour	365	39.3	55.2	55.2	0
	3-hour	1,300	65.4	170.3	170.3	0

Hazardous air pollutants						
Selenium	8-hour	4.8	a	b	2.18 x 10-7	2.18 x 10-7
Mercury compounds	8-hour	0.2	a	b	2.18 x 10-3	2.18 x 10-3
Chlorine compounds	8-hour	71.4	a	b	1.52	1.52
Hydrogen fluorid	8-hour	59.5	a	b	3.70 x 10-3	3.70 x 10-3
Cadmium compounds	8-hour	1.2	a	b	1.81 x 10-9	1.81 x 10-9
Cobalt, chromium antimony, and nickel compoundsg	8-hour	1.2	a	b	5.5 x 10-10	5.5 x 10-10

a. Not measured.

b. No sources indicated.

c. All suspended particulate matter is assumed to be PM10.

d. Criteria pollutant regulations are National Ambient Air Quality Standards. Hazardous air pollutant regulations are Nevada Ambient Air Quality Standards.

e. Includes background concentration plus existing DOE facilities impact concentration. This is the baseline concentration.

f. Includes background concentration plus existing DOE facilities impact concentration plus SNF facilities impact concentration.

g. Individual emission rates were not specified for each of cobalt, chrome, antimony, and nickel compounds. Only a total emission rate for all four was provided. Therefore, the most stringent standard for any of the four compounds, 1.2 -g/m3 for cobalt, was used.

Table 5.7-5. Calculated annual maximum concentrations for hazardous air pollutants at NTS, onsite and offsite.

Hazardous air pollutant	Maximum annual average concentration onsite (-g/m3)	Maximum annual average concentration offsite
Selenium compounds	6.03 x 10-8	1.20 x 10-8
Mercury compounds	6.03 x 10-4	1.20 x 10-4
Chlorine compounds	4.2 x 10-1	8 x 10-2
Hydrogen fluoride	1.02 x 10-3	2.04 x 10-4
Cadmium compounds	5.01 x 10-10	1.0 x 10-10
Cobalt, chromium, antimony and nickel compounds	1.50 x 10-10	3.00 x 10-11
Lead	1.21 x 10-11	2.40 x 10-12

a. All impacts from proposed source only. No hazardous air pollutant emissions information available for existing sources.

The same types of radiological and nonradiological air emissions from operation of the proposed SNF facilities would occur under the Regionalization Alternative as under the Centralization Alternative. However, the magnitudes could be lower. As with the Centralization Alternative, the combined dose equivalents from the operation of the proposed SNF facilities would be less than 1 percent of the NESHAP and less than 1 percent of the natural background radiation. The concentrations of non-radiological air emissions from the operation of the proposed SNF facilities under this alternative would remain within all applicable regulatory guidelines (EPA 1992; PNL 1988).

5.8 Water Resources

Construction and operation of the SNF modules could affect surface and groundwater resources. Potential environmental impacts to surface water and groundwater resources during construction include depletion of groundwater supplies, floodplain encroachment, and surface water sedimentation from erosion runoff occurring after land clearing. Potential normal operational impacts could include depletion of groundwater supplies and diminished surface water and/or groundwater quality resulting from wastewater discharges from normal operations.

5.8.1 Centralization Alternative

Separate discussions are provided for surface water quantity, surface water quality, groundwater quantity and groundwater quality.

5.8.1.1 Surface Water Quantity. Existing activities on the NTS derive their water supply

from groundwater sources, and the same would be true for construction and operation of the proposed SNF facilities. Therefore, construction and operation of the proposed SNF facilities would have no impact on surface water availability in the region. In addition, under normal operating conditions, there would be no wastewater discharges to Area 5 watercourses which could affect surface water flow characteristics.

Stormwater runoff associated with construction and operation of the proposed SNF facilities is expected to have a negligible impact on surface water quantity. During construction, standard stormwater management techniques would be employed to attenuate runoff. The impact of stormwater runoff on the ephemeral character of Area 5 watercourses during operation of the SNF facilities is also expected to be negligible. A site drainage and stormwater management system consisting of a perimeter drainage ditches and a retention pond would be included as part of the SNF facilities (Johnson 1994). This system would provide for control of runoff and erosion, which otherwise could affect Area 5 watercourses or the SNF facilities.

As discussed in Section 4.8.1, analyses of available data indicate that the areas encompassed by the proposed SNF facility may lie in flood Zone X (100-year flood zone with depths less than 1 foot [0.30 meter]) and/or Zone AO (100-year flood zone with depths between 1 and 3 feet [0.30 and 0.9 meter]) associated with the Halfpint Alluvial Fan. Accordingly, the SNF facilities would have to be located and constructed to minimize floodplain impacts and to avoid floodplains to the maximum extent possible, as required by Executive Order 11988 (Floodplain Management) and DOE Orders. Site-specific surveys would be performed to determine locations of flooding elevations more accurately.

5.8.1.2 Surface Water Quality. The proposed SNF facility in the northeast portion of

Area 5 is not served by the NTS sanitary sewer system. A number of NTS facilities have self-contained sanitary sewer systems. The nearby Radioactive Waste Management Site does have its own septic tank and leach field system to dispose of sanitary wastewater (DOE/NV 1993a). The proposed SNF facilities would have a sanitary sewer system comprised of a sewage treatment facility equipped with a sewage treatment and ejection pump system with a programmable controller and software. A pressurized sanitary sewer line would be provided to run to a sewage lagoon at the facility (Johnson 1994). This system would be adequate to accommodate the estimated 9,863 gallons (37,335 liters) per day of sanitary wastewater generated by the SNF facilities and personnel. This system would be operated in accordance with State of Nevada permitting requirements.

The proposed SNF facilities are designed to generate no liquid releases of wastewater with hazardous chemicals or radiological characteristics related to SNF management operations. These facilities would be constructed using state-of-the art technologies including secondary containment, and leak detection and water balance monitoring equipment. The normal operation of the proposed SNF facilities is not expected to affect the quality of any surface water
on or near the NTS.

During construction, 90 acres (0.36 square kilometer) would be disturbed, all of it in previously undisturbed areas. This would create the potential for increased sediment runoff into dry washes and shallow drainages or to spread out overland as a result of sheetflow. However, sediment runoff from construction activities would be controlled by implementing soil erosion control measures, which would result in negligible effects to surface water quality.

In addition, as stated in Section 4.8.1, existing onsite contaminants may be transported and dispersed beyond the facility boundary during flooding (USAF et al. 1991). Therefore, the potential exists for some incremental transportation and dispersion of any additional contaminants that might result from the construction or operation of the SNF facilities. Although
this potential cannot be determined without additional studies, any additional contamination would be unlikely, due to the design of the containment structures and leak detection system of the SNF facilities.

5.8.1.3 Groundwater Quantity. Operation of the SNF facilities would require

approximately 9,863 gallons (37,335 liters) per day. This translates to an additional 3,600,000 gallons (13,627 cubic meters) of water used at the NTS per year. It is assumed that the water demand of the SNF facilities would be supplied via the existing NTS Area 5 supply wells and water distribution system. If this scenario should be demonstrated to be infeasible or impractical,
a water supply and distribution system consisting of two 8-inch-diameter wells supplying two

250,000-gallon (946,333-liter) aboveground storage tanks would be constructed to service the SNF facility complex (Johnson 1994).

Water withdrawals to support the proposed SNF facilities would likely be from the Frenchman Flat hydrographic area of the Ash Meadows Subbasin. In 1993, 176 million gallons (666,000 cubic meters) of groundwater was withdrawn by DOE from the Frenchman Flat hydrographic area. An additional 3.6 million gallons (14,000) cubic meters) per year would be required for SNF operations. The recharge due to precipitation in the Frenchman Flat hydrographic area was estimated to be 32.6 million gallons (123,000 cubic meters) (Rush 1970). This recharge estimate was exceeded for more than thirty years with no decline in static water levels (DOE 1988b). Accurate measurement of static water levels are, however, precluded by numerous conditions on the NTS (Winograd 1970). More detailed analyses of perennial yield and total water withdrawal from the hydrographic area would be required if the NTS were chosen as a site for SNF management facilities, but because the estimated perennial yield has been exceeded for more than thirty years with no measurable decline in static water levels, it is likely that increased water use for the SNF Management Facility could be sustained.

Because of hydrogeologic complexities, a regional groundwater flow at the NTS is not constrained by the hydrographic basins which are defined by local topography (USAF et al. 1991). Therefore any potential groundwater overdrafts in the Frenchman Flat hydrographic area indicated by previous yield estimates are likely made up by untapped groundwater from neighboring hydrographic areas. Localized impacts could occur if the perennial yield of Frenchman Flat hydrographic area is exceeded. Potential impacts include depletion of water stored locally in the regional aquifer, removal of that groundwater from other potential uses, and the potential modification of the rate and direction of contaminant migration resulting from underground nuclear testing. The complex issues of groundwater contamination and use are being addressed in the Resource Management Plan being prepared in conjunction with the NTS site-wide EIS.

The vast majority of groundwater not withdrawn from the Frenchman Flat hydrographic area, and the Ash Meadows Subbasin as a whole, is discharged at Ash Meadows. Using 1993 water withdrawal data, NTS annual withdrawal from the Ash Meadows Subbasin would only increase by 1% or 3.6 million gallons (14,000 cubic meters) to approximately 370 million gallons (1.4 million cubic meters) if the proposed SNF facilities were sited on NTS. This increase in withdrawal would have little impact on the subbasin as a whole as its perennial yield is estimated to be 12 to 18 billion gallons (46 to 68 million cubic meters) (DOE 1988b; USAF et al. 1991). Water from the groundwater systems which pass beneath the NTS annually discharge approximately 8.8 billion gallons (33 million cubic meters) to the deserts southwest of the NTS (DOE/NV 1993b). Annual groundwater withdrawal for SNF operations would amount to 0.04 percent of this discharge. No impacts to down-gradient users and discharge areas would be expected due to the small volume of water required and the vast amount of water in the regional groundwater system.

Dewatering is not expected to be necessary to construct the SNF facility complex, due to the relatively great depth to groundwater across the NTS. Although perched water table conditions at depths of 70 feet (21 meters) have been reported for Frenchman Flat, all excavation activities are expected to occur in the vadose zone. Consequently, there would be no effect on groundwater quantity due to construction dewatering of wastewater with hazardous chemical or radiological characteristics related to SNF management activities.

5.8.1.4 Groundwater Quality. As previously mentioned, the proposed SNF facilities are

designed to have no liquid release to the environment. However, for the purpose of this water resource analysis, a conservative release scenario was evaluated to identify the potential environmental consequences of a liquid release to the environment under normal operating conditions. The release scenario was evaluated for information purposes only, as no normal operating releases are planned for the proposed facility. The scenario consisted of a maximum potential liquid release to the environment under normal operating conditions such as an undetected secondary containment failure or piping leak. The scenario was evaluated using conservative estimates of the sensitivity of actual leak detection systems and operational source term data from similarly functioning facilities at the Idaho National Engineering Laboratory (INEL). The conservative estimates for the hypothetical release included a point release of 5 gallons (19 liters) per day to the environment over the course of 1 month. The release volume and durations were considerably greater than existing leak detection system sensitivities, surveillance activities, and radiological surveys. Source terms were derived at the 95 percent confidence level from 8 years of operational data at the INEL Fluorinel and Storage Facility at the Idaho Chemical Processing Plant.

The point source release as described above has been conservatively assumed to occur at a depth of 40 feet (12 meters) below land surface (the bottom of the Wet Storage Basin for the Receiving/Canning Facility). As detailed in Section 4.8.2, this is well within the vadose zone underlying Area 5 at Frenchman Flat. Vertical flow in the uppermost portions of the vadose zone at Area 5 is generally upward toward the surface, due to an extremely high evapotranspiration rate relative to precipitation. Site characterization data for Area 5 indicate that the vertical flow direction in the vadose zone is upward from 0 to 75 meters (0 to 250 feet) below land surface. In the next interval (75 to 180 meters [250 to 600 feet]), a downward flow rate of 3 meters/1,000 years (10 feet/1,000 years) has been calculated. At a depth of 180 to 250 meters (600 to 800 feet), a zone of equilibrium is present above the water table (a zone of no vertical movement). These data, combined with the relatively extensive depth to the water table (244 meters [800 feet]) and extreme travel times to the water table, indicate that the release described above would be highly unlikely to reach the saturated zone. The release would likely remain indefinitely in the vadose zone beneath the proposed SNF facilities, where it would present a persistent source of contamination but would not affect groundwater quality.

5.8.2 Regionalization Alternative

Potential impacts to surface water and groundwater from construction and operation of the proposed SNF facilities under the Regionalization Alternative would generally be as described for the Centralization Alternative. However, the quantity of groundwater withdrawn to support operation of the proposed facilities could be less.

5.9 Ecological Resources

The Centralization and Regionalization Alternatives could potentially affect ecological resources primarily through the alteration or loss of habitat. Potential impacts to terrestrial and aquatic resources and threatened and endangered species are described below for both alternatives.

Radiation doses received by terrestrial biota from waste management activities would be expected to be similar to those received by humans. Although guidelines have not been established for acceptance limits for radiation exposure to species other than humans, it is generally agreed that the limits established for humans are also conservative for other species (NRC 1979). Evidence indicates that no other living organisms have been identified that are likely to be substantially more radiosensitive than humans (Casarett 1968; National Academy of Sciences 1972). Additionally, work areas where potential radiation exposure is high and monitored site workers utilize protective equipment, have controlled access measures which limit entry by biota. Thus, so long as exposure limits protective of humans are not exceeded, no substantial radiological impact on populations of biota would be expected as a result of waste management activities at the proposed SNF facility.

5.9.1 Centralization Alternative

Under this alternative, 90 acres (0.36 square kilometer) of the creosote bush plant community would be disturbed during construction. The area disturbed would include construction laydown areas, grading, and new buildings. In addition, disturbance would be expected along access roads and other rights of way which have not been included in the 90 acres. This plant community is common to the southern portion of NTS. To obviate any impacts to this plant community, ground-disturbing activities would be kept to a minimum. This would also serve to reduce the number of non-native species, such as Russian thistle, to the area. However, non-native species would probably become established in some areas, for example, along the access road.

Impacts to wildlife would occur as a direct result of habitat loss and/or an indirect result of increased human presence. There could be a decrease in the number of small mammals and reptiles during the construction period due to ground-disturbing activities. More mobile animal species would be able to move to other areas on the NTS during construction. Depending upon the carrying capacity of these areas, there could be increased competition for food and water resources. After construction activities are complete, it is expected that species which adapt to developed areas would become established.

Impacts to birds protected under the Migratory Bird Treaty Act are expected to be minimal during construction, since there are no water sources at the proposed site. However, surveys prior to construction may be required by the U.S. Fish and Wildlife Service. During operation, there may be an increase in migratory birds utilizing the area due to the increase in water sources.

There would be no impact on wetlands or aquatic habitats due to the construction of the facility because these habitats do not exist in the area. The operation of the proposed SNF facilities would increase water sources for wildlife species due to retention ponds and a sewage lagoon area. This could bring an increase in species, especially migratory birds, seeking aquatic habitats. The addition of new species to the area would impact upon the general ecology by increasing diversity of species. Since these areas would be within fenced enclosures, it is expected that the larger mammals would be unable to directly utilize these water sources.

Noise and activity associated with construction would be expected to have short-term effects on most wildlife. Studies on the effects of noise on wildlife have shown varying responses by different species. Responses include becoming frightened and running away, altering migration or breeding patterns, changing home ranges (often decreasing them), or adapting to the noise and activity (EPA 1980). These effects would continue indefinitely during the operating life of the proposed SNF facilities.

Potential impacts to threatened and endangered species would be the direct result of increased human presence and the loss or alteration of habitat. Any Federal Candidate or state-protected species on the site would result in further consultation with the U.S. Fish and Wildlife Service and the Nevada State Forester. Mitigation plans would be developed in cooperation with the appropriate agencies if any of these species were identified on the project site.

Although positive identification of most of the species listed on Table 4.9-1 has not occurred during prior studies, the addition of water sources to the area could increase the suitability of habitat for some endangered, threatened, or candidate bird species. These might include birds of prey (bald eagle, peregrine falcon, ferruginous hawk, and golden eagle), and species which inhabit water areas such as shorebirds (mountain plover, western least bittern, western snowy plover, and white faced ibis). An increase in loggerhead shrikes may occur due to the fencing that would be erected around the facility and would serve as posts for this bird.

The project area is located within the range of the desert tortoise, a federally listed threatened species. Recent pre-activity surveys for other nearby projects have not identified the desert tortoise in the general area of the project site. However, a pre-activity survey for this project would be needed to determine the presence or absence of the desert tortoise and other species of concern. If present, the desert tortoise could be impacted during construction of the proposed SNF facilities due to increased vehicular traffic, construction of trenches for utilities, and other temporary construction excavations. Prior to and during construction activities, fencing of the areas and removal of tortoises within the fence would decrease the potential to bring harm to the desert tortoise. All activities with this species must be completed by a qualified biologist.

5.9.2 Regionalization Alternative

Impacts under this alternative are expected to be generally the same as under the Centralization Alternative. The major difference between the two is the total area to be disturbed. The Regionalization Alternative is expected to involve construction of fewer buildings and, therefore, to require disturbance of less land.

5.10 Noise

As discussed in Section 4.10, noises generated on the NTS do not propagate offsite at levels that impact the general population. Thus, the NTS noise impacts for both the Centralization and Regionalization Alternatives would be limited to those resulting from the transportation of personnel and materials to and from the site, which affect the nearby communities, and those resulting from onsite sources which may affect some wildlife near these sources. The effect of noise on wildlife near SNF management facilities under the Centralization or Regionalization Alternatives would be addressed in a project-specific environmental assessment.

The transportation noises are a function of the size of the work force (e.g., an increased work force would result in increased employee traffic and corresponding increases in deliveries by truck and rail, and a decreased work force would result in decreased employee traffic and corresponding decreases in deliveries). The analysis of traffic noise took into account noise from the major roadway which provides access to the NTS. Vehicles used to transport employees and personnel on roadways would be the principal sources of community noise impacts near the NTS from the Centralization and Regionalization Alternatives.

This analysis used the day-night average sound level to assess community noise, as suggested by the U.S. Environmental Protection Agency (EPA 1982, 1974) and the Federal Interagency Committee on Noise (FICON 1992). The change in the day-night average sound level from the baseline noise level for each alternative was estimated based on the projected change in employment and traffic levels from the baseline levels. The baseline is comparable to current activity at the NTS for 1993. The combination of construction and operation employment was considered. The traffic noise analysis considered U.S. Route 95, which employees use to access the NTS from Las Vegas. Changes in noise level below 3 decibels would not be expected to result in a change in community reaction (FICON 1992).

5.10.1 Centralization Alternative

Under the Centralization Alternative, the projected NTS work force would increase by about 48 percent of existing onsite employment in the years 2000 to 2002, the peak construction period, and decrease thereafter (Section 5.3). There would be a corresponding increase in truck, private vehicle, and bus trips. The day-night average sound level at 50 feet (15 meters) from U.S. Route 95 would be expected to increase by about 1 decibel. No change is expected in the community reaction to noise along this route. No mitigation efforts are necessary.

5.10.2 Regionalization Alternative

Under the Regionalization Alternative, traffic noise impacts would be the same as for the Centralization Alternative.

5.11 Traffic and Transportation

The proposed SNF management activities would involve a small increase in the number of employees commuting to the NTS and the transportation of SNF and hazardous chemicals on the NTS. This section summarizes potential transportation impacts due to the proposed SNF facilities on the NTS.

5.11.1 Centralization Alternative

5.11.1.1 Levels of Service. Levels of service were calculated for construction and

operation of the SNF facility at the NTS. The maximum reasonably foreseeable scenario for construction and operations occurs when the combined number of employees and population are at their highest. This would occur in 2001, when there would be 3,426 employees and a projected baseline population in the Region of Influence of 1,209,316. The Region of Influence includes Nye and Clark counties. Direct employees associated with the proposed SNF facility generate direct trips in the Region of Influence. These trips are distributed to the Region of Influence road network according to percentages based on a traffic flow between the site and where employees historically have lived. Increases in baseline population and indirect site-related employees generate indirect trips in the Region of Influence. These trips are distributed based on the current average daily traffic per present population in the region of influence for a given segment. Direct and indirect average daily traffic are added and a new level of service is determined. Construction and operation employees contribute little to the future traffic because they represent such a small percentage of the Region of Influence population growth.

None of the future baseline levels of service would change due to SNF-related impacts.

5.11.1.2 Rail Transportation. The generic facility design would require rail access for

Naval fuel delivery. The rail spur would most likely be built from the Union Pacific line, located approximately 50 miles (80 kilometers) east of the NTS. Impacts from construction and operation of the rail spur would be evaluated in detail if the site were selected for the SNF facility.

5.11.1.3 Transportation Impacts of Hazardous Chemicals. It is assumed that the

hazardous chemicals required and hazardous waste generated by the proposed SNF facility operation would be transported by truck. The onsite transportation impacts for these hazardous chemicals and wastes shipments are calculated based on the assumptions that they do not have any incident free impacts, the material would not leak during transport, only risk is due to traffic fatalities, and the material spill of entire contents is bound by the risk evaluated for the Expended Core Facility, considered under facility accidents.

The total distance for onsite shipment of these hazardous chemicals is assumed to be the maximum site boundary distance from the proposed SNF facility to the nearest highway. Based on the unit risk factor (Cashwell et. al. 1986), occupational and non-occupational fatalities considering a rural setting the onsite transportation risks are calculated, assuming 10 annual shipments.

The maximum one-way distance from the site to the NTS gate by which trucks would deliver hazardous wastes is 20 miles (32 kilometers). Based on 1.5 x 10-8 accident occupational fatalities per kilometer per shipment, 4.0 x 10-4 accident occupational fatalities are estimated over a 40-year period. Based on 5.3 x 10-8 accident non-occupational fatalities per kilometer per shipment 1.4 x 10-3 accident non-occupational fatalities are estimated over a 40-year period.

5.11.1.4 Transportation Impacts of Radioactive SNF. The definition of offsite

transportation include transportation of radioactive material from the shipping facility to the storage facility at the receiving site; therefore, local transportation does not separately address the onsite transportation impacts due to radioactive material shipment.

5.11.2 Regionalization Alternative

The impacts due to the Regionalization Alternative would be less than those described for the Centralization Alternative due to the smaller size of the facility and the smaller amount of waste expected.

5.12 Occupational and Public Health and Safety

The Waste Minimization and Pollution Prevention Awareness Plan at the NTS would be implemented within the SNF Management Program. While more chemicals per year would be used, health impacts to the public would continue to be minimal as a result of administrative and design controls to minimize releases of radioactive and chemical pollutants to the environment and to achieve compliance with permit requirements and applicable standards. Workers would continue to be protected from hazards specific to the workplace through appropriate training, protective equipment, monitoring, management controls, and occupational standards that would limit atmospheric and drinking water concentrations of potentially hazardous chemicals as well as limit radiation exposures. This would include protection from wastes generated from the increased use of the chemicals needed to accommodate spent fuel storage and from radioactivity associated with this storage. The NTS Emergency Preparedness Plan would continue to operate as designed to minimize or mitigate the impact of any emergency upon the health and safety of employees and the public.

Health effects from radiation are presented here as the risk of fatal cancer. This risk is in the ratio of their health risk estimator (risk of fatal cancer per rem of exposure). The value of this estimator for exposures to the public is 5.0 x 10-4 for fatal cancers. The corresponding estimator for exposures to workers is 4.0 x 10-4.

5.12.1 Centralization Alternative

This section evaluates the impacts to human health resulting from both contaminated air emissions and direct exposures associated with the proposed SNF facility under the Centralization Alternative. Pathways assessed include inhalation of air, ingestion of food, submersion in plumes, and direct exposure.

5.12.1.1 Radiological Doses. Releases of additional radionuclides to the environment

from operations at the proposed SNF facilities are summarized in Table 5.7-1. The annual committed doses to the public resulting from the proposed SNF facilities plus baseline operations in 1995 are provided in Table 5.7-3. The doses would be approximately 1 percent of the most restrictive health standard, and less than 0.1 percent of the natural background radiation. The dose to the maximally exposed member of the public is assumed to remain constant over the 40-year operational lifetime of the SNF; the population dose would increase slightly (less than 3 percent) due to population growth during this 40-year period.

Doses to SNF facility workers are assumed to be similar to those presently received by major DOE facility Waste Processing/Management personnel. Based on data for the years 1989 through 1991 for the Hanford Site, INEL and the Savannah River Site (SRS) (DOE 1992), it is estimated that the average dose to a worker from annual SNF operations at the NTS would be approximately 40 millirem and the maximum dose would be about 3,000 millirem. Assuming that 800 persons were involved at the peak of these operations, the total worker dose from annual SNF operations would be approximately 32 person-rem. Adding the baseline contribution, the total dose to all workers at the NTS would be about 36 person-rem.

5.12.1.2 Nonradiological Doses. Releases of additional nonradiological airborne

pollutants from operations at the proposed SNF facilities are summarized in Table 5.7-2. The concentrations from these releases have been calculated and are presented in Tables 5.7-4 and 5.7-5.

5.12.1.3 Radiological Health Effects. The fatal cancer risk to the most exposed member

of the public due to operation of the proposed SNF facilities would be 5.9 x 10-8. The fatal cancer risk to the most exposed member of the public due to operation of the proposed SNF facilities plus baseline operations (1995 levels) would be 6.5 x 10, over 40 years (estimated storage duration), the risk to this individual would be approximately 2.6 x 10-6. The estimated number of fatal cancers to the population within 80 kilometers (50 miles) of the proposed facility would be 4.4 x 10-5 for the operation of SNF facilities plus baseline operations and 4.1 x 10-5 for the operation of the SNF facilities without baseline operations. The number of increased fatal cancers from total NTS operations to the public during the estimate storage duration of the SNF would be approximately 1.8 x 10-3. The number of fatal cancers from all causes that would normally be expected to occur during this same time period to the 80-kilometer population is 1,500.

The calculation of the number of health effects to SNF workers from annual operations is based on somewhat lower risk estimators than for the general public. The estimators are lower as the result of different age distributions among workers and members of the public. The risks of fatal cancer to the average worker is estimated to be 1.6 x 10-5. The corresponding risk to the maximally exposed worker is estimated to be 1.2 x 10-3. An excess of 0.013 fatal cancer among all SNF facility workers is projected from peak annual operations. It is projected that exposures to radiation over the lifetime of SNF operations could result in an excess of 0.40 fatal cancer among these workers and an increased risk of 6.4 x 10-4 to an individual worker who is present over this time period. The risks and numbers of excess fatal cancers, both from annual and lifetime operations, would be increased by about 15 percent if the impacts to workers associated with baseline activities (Section 4.12.2.1) were included. The health effects due to radiological doses to a noninvolved worker, i.e., an NTS worker involved in activities other than SNF, would be on the order of 1 percent of the occupational exposure to an SNF worker, based on analyses for the SRS and INEL sites.

5.12.1.4 Nonradiological Health Effects. As indicated in Table 5.7-4, the concentrations

of all measured nonradiological pollutants at the NTS together with the inclusion of the Proposed Action would remain well within the health-based regulatory guidelines. The increases in pollutant concentrations from the Proposed Action would be negligible, compared to the existing baseline concentration; no adverse health effects from these pollutants would be anticipated.

The calculated maximum atmospheric concentrations of hazardous chemicals at the site boundary and onsite for the proposed action are presented in Table 5.7-5. The maximum concentrations at the site boundary are used to evaluate an exposure to a maximally exposed individual, whereas the maximum onsite concentrations could result in an exposure to a worker. Of the potential hazardous chemicals identified for the proposed action, cadmium, nickel and chromium VI (chrome) are carcinogens for which a total cancer risk was calculated. The remaining seven chemicals are noncarcinogens for which a hazard index was calculated. A hazard index value greater than 1 indicates a potential for adverse health effects.

Based on the maximum hazardous chemical concentrations at the site boundary, the lifetime fatal cancer risk and the hazard index to the maximally exposed member of the public would be only 5.4 x 10-13 and 2.5 x 10-3, respectively. Based on the maximum concentrations onsite, the lifetime fatal cancer risk and hazard index to a worker would be only 2.7 x 10-12 and 1.3 x 10-2, respectively. This indicates that there would be virtually no health impacts from nonradiological releases.

5.12.1.5 Industrial Safety. The measures of impacts for workplace hazards used in this

analysis are (1) total reportable injuries and illnesses and (2) non-exposure-related fatalities in the work place.

Based on hazard rates for personnel of DOE and its contractors, it is estimated that 270 injuries and illnesses would be reported and 0.48 fatality would occur from all SNF construction activities. It is further estimated that 807 injuries and illnesses would be reported and 0.81 fatality would occur among SNF workers during lifetime operations.

5.12.2 Regionalization Alternative

Under the Regionalization Alternative, the radiological and nonradiological doses from operation of the proposed SNF facilities at the NTS could generally be lower than those described under the centralization alternative. Any corresponding health effects may also decrease.

5.13 Utilities and Energy

Direct changes in utility demand as a result of the Centralization and Regionalization Alternatives were compared, depending on available data, against either projected 1995 demand or the peak usage for the years 1988 through 1992 for each utility resource. Since utility usage at NTS is projected to decrease, this comparison is conservative. Impacts to provision of a utility are considered to occur if the demand for a utility is equal to or exceeds the available capacity within the designated Region of Influence. For the purpose of analysis, the Region of Influence for each resource is defined as the area served by the utility provider responsible for meeting the service demands of the NTS.

5.13.1 Centralization Alternative

5.13.1.1 Water Consumption. For the Centralization Alternative, approximately

0.43 liter per second (6.85 gallons per minute) of water would be required to operate the modules within the facility (Harr 1994). The 14 active wells had a capacity of 387 liters per second (6,139 gallons per minute) in 1993 (DOE/NV 1993a). The SNF facilities would require 0.1 percent of this amount. NTS wells would operate at 35 percent of total capacity, when the 1989 peak water usage of 134 liters per second (2,125 gallons per minute) was combined with the SNF facility requirements.

The active wells at Area 5 have a capacity of 38 liters per second (595 gallons per minute) (DOE/NV 1994c). The SNF facilities under the Centralization Alternative would require 1 percent of this amount. Water usage in Area 5 would increase to approximately 33 percent of the pump yield if the 1993 water usage of 12 liters per second (191 gallons per minute) for Area 5 is combined with the SNF facility requirements under the Centralization Alternative.

5.13.1.2 Electrical Consumption. Under the Centralization Alternative, the SNF

facilities would require approximately 23,000 megawatt hours of electricity per year, or approximately 2.63 megavolt-amperes average demand (Harr 1994). The annual consumption of electricity of the SNF facilities would be approximately 12 percent of the 1995 annual consumption of electricity at NTS. The average electric demand of the SNF facilities would represent 6 to 7 percent of the projected 1995 peak electrical capacity of NTS. The average electric demand of the SNF facilities, combined with the peak electric demand of 39.5 megavolt-amperes, would utilize 94 to 105 percent of the transmission lines' current capacity.
The 2.63 megavolt-amperes required for the SNF facility represents approximately 61 percent of the operating capacity of the substation at Area 5. The energy requirements of the SNF facility under the Centralization Alternative combined with the 1993 electric demand on the Frenchman Flat substation would utilize 63 percent of the substation capacity. It might be necessary to construct additional transmission lines or another substation to support the SNF facilities.

5.13.1.3 Fuel Consumption. Energy requirements for the SNF facilities under the

Centralization Alternative were calculated assuming electrical power purchased from a utility was the primary source of energy; however, fossil fuels may be used to power backup generators and during construction activities. The amount of fuel that would be required for these operations would have little effect on fossil fuel usage at the NTS site.

5.13.1.4 Wastewater Disposal. Under the Centralization Alternative, approximately

0.43 liter per second (6.85 gallons per minute) of wastewater would be generated (Harr 1994). Currently, Area 5 has no wastewater facilities. A sewage treatment facility would need to be constructed for the SNF facilities under the Centralization Alternative.

5.13.2 Regionalization Alternative

The proposed SNF facilities under the Regionalization Alternative could consume less water, electricity, and fuel than under the Centralization Alternative. Less wastewater may also be generated; however, a sewage treatment facility would still need to be constructed.

5.14 Materials and Waste Management

Operation of the proposed SNF facilities would contribute transuranic, solid low-level, and sanitary waste as a consequence of transport, receipt, unloading, handling, and storage at the NTS. Under the SNF program, sources of potential contaminants would continue to be limited to construction support and site operation activities.

SNF storage activities would require the use of chemicals, and the majority of these would be expected to eventually become waste. Provisions would have to be made for the storage of the chemical raw materials used within the SNF complex as well as the waste material resulting from use. It was conservatively assumed that all chemical raw materials used by SNF would become hazardous wastes. Table 5.14-1 presents the estimated waste generation by waste classification for each of the two alternatives (Centralization and Regionalization) and by each of the two options (wet storage and dry storage).

5.14.1 Centralization Alternative

The Centralization Alternative would generate the greatest amount of waste from the SNF complex, since it is the alternative that contributes the larger amount of spent nuclear fuel to be stored. On an annual basis, the amount of waste generated by the SNF complex for this alternative would generally be greater than under the Regionalization Alternative. The handling capacity of the SNF complex is the factor that determines the amount of waste generation.

Table 5.14-1. Ten-year cumulative estimated waste generation for SNF alternatives at the NTS (m3).

Time Period	1995-2004	2005-2014	2015-2024	2025-2034
Centralization Alternative				
Wet Storage Option				
Transuranic waste	160	160	160	160
Low-level waste	1,950	1,950	1,950	1,950
Hazardous waste	7.4 x 101	7.4 x101	7.4 x 101	7.4 x 101
Sanitary waste	1.2 x 105	1.2 x 105	1.2 x 105	1.2 x 105
Dry Storage Option				
Low-level waste	76	76	76	76
Sanitary waste	1.9 x 104	1.9 x 104	1.9 x 104	1.9 x 104
Regionalization Alternative				
Wet Storage Option				
Transuranic waste	<160	<160	<160	<160
Low-level waste	<1,950	<1,950	<1,950	<1,950
Hazardous	<7.4 x 101	<7.4 x 101	<7.4 x 101	<7.4 x 101
Sanitary waste	<1.2 x 105	<1.2 x 105	<1.2 x 105	<1.2 x 105
Dry Storage Option				
Low-level waste	<76	<76	<76	<76
Sanitary waste	<1.9 x 104	<1.9 x 104	<1.9 x 104	<1.9 x 104

Source: Harr (1994).

5.14.1.1 Wet Storage Option.

5.14.1.1.1 Transuranic Waste-A small quantity (16 cubic meters, or 20.

9 cubic yards) of transuranic waste would be generated per year due to the recovery and purification of transuranic products from the wet storage option (Harr 1994). Placement of this waste into the transuranic waste storage cell would have minimal impact on the current transuranic waste management at the NTS.

5.14.1.1.2 Low-Level Waste-The wet storage option would contribute liquid low-

level waste as a result of its interim storage in water. This underwater storage would require filtered and deionized water to prevent possible corrosion problems with fuel elements and storage hardware; further waste would be generated from deionizer resin regeneration, filter backflushing, and chemical cleaning of the filter. An estimated 195 cubic meters (255 cubic yards) per year of low-level waste would be generated due to operation of the wet storage facility. Placement of this waste into the Radioactive Waste Management Site would be a viable option (see subsection 4.15.3). This quantity of low-level waste represents a minimal impact to the management of low-level waste at the NTS.

5.14.1.1.3 Hazardous Waste-Installation of the SNF complex would require

additional management of hazardous wastes, including the placement of satellite storage areas within the SNF complex and more frequent offsite shipments of hazardous waste. An evaluation of the impact that the additional hazardous wastes generated by the wet storage option would be conducted as part of the required National Environmental Policy Act evaluation.

Additional hazardous waste accumulated would be transferred to the Hazardous Waste Accumulation Site, collected, and removed to an offsite EPA-permitted treatment, storage, and disposal facility. The potential for hazardous waste to adversely affect the environment as a result of an accidental spill would be limited due to the great depth to groundwater and the arid climate, thereby minimizing the likelihood of migration of surface and shallow subsurface contamination. Similarly, any leaks from new underground or aboveground storage tanks would have limited potential to affect the environment (DOE/NV 1992c).

It is estimated that the wet storage option would generate approximately 7.4 cubic meters (9.7 cubic yards) of hazardous waste annually. This quantity of hazardous waste represents a minimal impact to the management of hazardous wastes at the NTS.

5.14.1.1.4 Sanitary Waste-The SNF wet storage option would generate

approximately 1.
2 x 104 cubic meters (15,696 cubic yards) of sanitary waste annually. This quantity of sanitary waste would double the current sanitary waste disposal quantity at the NTS. This would require construction of additional septic/leach field capacity and/or additional sewage lagoon capacity, creating the need for additional land area for sanitary waste disposal.

5.14.1.2 Dry Storage Option. Unless a hazardous material were added to the fuel at the

point of origination, hazardous material or mixed hazardous wastes would not be expected to be produced at a dry storage facility. With administrative controls applied at the storage facility to prevent hazardous material from coming in, the generation of mixed hazardous waste could be reduced or precluded. Any hazardous liquid and solid waste produced at the dry storage facility would be collected in a satellite accumulation area located inside the facility. Mixed waste would be stored onsite unless offsite storage and disposal facilities were licensed to accept radioactive waste.

Nonradioactive hazardous waste, such as oils, solvents, gloves, rags, and other materials associated with plant operation and maintenance, would be stored onsite until there were enough containers for shipment to an approved offsite treatment, storage, and disposal facility (Hale 1994).

5.14.1.2.1 Low-Level Waste-The low-level radioactive contaminated waste stream

would result mainly from wastes generated during the decontamination operations of the cask, crane, and contaminated areas, from disposed personal protective equipment and clothing that would be used and disposed of during decontamination operations, and from the filters and ion exchange resins used to decontaminate the decontamination liquids. This waste would be sent to the waste packaging unit, where it would be compacted into drums for disposal. Old cans and lids removed in the canning process would be collected and placed into solid waste containers (Hale 1994). Approximately 7.6 cubic meters (9.9 cubic yards) of low-level waste would be generated annually from the dry storage facility. This quantity of low-level waste represents a minimal impact to the management of low-level waste at the NTS.

5.14.1.2.2 Sanitary Waste-Sanitary sewage is the only liquid effluent to be

released from the facility.
The SNF dry storage option would generate approximately 1.9 x 103
cubic meters (2.5 x 103 cubic yards) of sanitary waste annually. This quantity of sanitary waste would double the current sanitary waste disposal quantity at the NTS. This would require construction of additional septic/leach field capacity and/or additional sewage lagoon capacity, creating the need for additional land area for sanitary waste disposal.

5.14.2 Regionalization Alternative

The Regionalization Alternative would generate less waste from the SNF facility than would the Centralization Alternative, since it would contribute the smaller amount of SNF to be stored. The handling capacity of the SNF complex determines the amount of waste generation. For either the wet storage option or dry storage option, the wastes generated would be less than those presented for the Centralization Alternative. Therefore, Table 5.14-1 presents the estimated waste generation for SNF for this alternative as less than that generated for the Centralization Alternative. The impacts presented for each of the waste categories for the Centralization Alternative apply to the Regionalization Alternative as well.

5.15 Facility Accidents

A potential exists for accidents at facilities associated with the handling, inspection, and storage of spent nuclear fuel at the NTS. Accidents can be categorized into events that are abnormal (for example, minor spills), events a facility was designed to withstand, and events a facility is not designed to withstand. These categories are termed abnormal, design basis, and beyond design basis accidents, respectively. Summarized here are consequences of possible facility
accidents for a member of the public at the nearest site boundary and at the nearest road, for the collective population within 80 kilometers (50 miles), for workers, and for the environment. See Section 5.11 for a summary of the assessment of transportation accidents.

A review of the historical record of accidents at the NTS is summarized in the following section. Methods used to assess potential future events are summarized in Section 5.15.2. Evaluations of accident impacts by alternative are summarized in Section 5.15.3 through 5.15.7. A summary comparison of accident impacts by alternative is given in Section 3.2. Additional supporting documentation for the accident impacts is given in a separate report (HNUS 1995).

This section examines the various activities that have been performed to assess the potential for accidents and their consequences for workers and the public for each alternative. A set of potential reasonably forseeable accidents over the 40-year period are described which envelop all accidents. Secondary impacts of accidents pertaining to cultural resources, economics, land use, endangered species, water resources, and ecology are also addressed. This section also covers emergency preparedness plans that have been established to mitigate the primary and secondary effects of accidents.

5.15.1 Historical SNF Accidents at NTS

There have been no SNF operations in the past several years at the NTS upon which to base an accident history.

5.15.2 Methodology

There are no facilities currently at the NTS for receiving, handling and storage of SNF that can be used as a basis for accident analysis. In the absence of suitable design details for the proposed SNF facilities during this stage of the SNF Management Program upon which to base
an accident analysis, the approach makes use of accident scenarios and associated data that have been analyzed and documented for similar facilities. They include spent nuclear fuel facilities at
INEL, the Hanford Site, SRS, and Naval sites.

5.15.2.1 Assumptions and Approach. A number of postulated accidents for similar

facilities have been selected to serve as a common basis for estimating accident consequences for workers and the public at the NTS. Although the accident scenarios, source terms, and related assumptions are similar to those for other sites, the estimated consequences are unique to the NTS because of site differences in modeling parameters pertaining to distances to site boundaries and population centers, population distributions, and meteorology. The GENII code (PNL 1988) was used to estimate accident consequences for the general public and for individuals onsite or at the site boundary, based on both 50 percent and 95 percent meteorology. Accident consequences and risk are described in terms of dose, latent cancer fatalities, and total health detriments for workers, for an individual at the site boundary, for a transient individual at the nearest public access, and for the public residing out to 80 kilometers (50 miles) from the proposed SNF facility. The estimated frequency of each selected accident is based on the reference source documentation.

The probability of an airplane crash into the facility is considered very small, because there are no nearby airports with large aircraft activity. For calculational purposes, the probability of such an accident is conservatively estimated at 10-6 per year. Potential accidents initiated by an airplane crash into the SNF facilities and the estimated consequences have been analyzed.

The secondary impacts of accidental releases of radioactive and hazardous materials are also addressed in a qualitative manner. Secondary impacts pertain to effects of accidents on land use, endangered species, water resources, cultural resources, and ecology.

5.15.2.2 Accident Screening. The potential accidents associated with existing SNF

facilities and operations were screened to determine which ones to include in the accident analysis for the NTS. The source documentation for this effort was primarily Appendices A, B, C, and D of Volume 1 that were selected by a screening process for existing SNF facilities. Initiating events were reviewed, including natural phenomena (e.g., earthquakes and tornadoes) and human-initiated events (e.g., human error, equipment failures, fires, explosives, plane crashes, and terrorism). Accidents associated with Expended Core Facility (ECF) operations at the NTS were analyzed separately, and the results are documented in Appendix D. For the NTS the maximum reasonably foreseeable criticality and nonradiological accidents are associated with the ECF. The potential for a criticality exists while the fuel is in dry storage, during handling, and in the wet storage pool. Although the probability of any criticality is very low, a hypothetical criticality of 1 x 1019 fissions was postulated in the ECF wet pool as a basis for estimating the maximum reasonably foreseeable consequences of a criticality.

The selected accidents include beyond-design-basis events in order to reflect the magnitude of accident consequences that envelop all other accidents having a reasonable probability of occurrence. They also include other accidents with lower consequences and typically higher probabilities of occurrence, to show a range of accident types and consequences. The accidents included in this set are reasonably foreseeable, meaning that there are one or more sequences of events that will lead to their occurrence, and the sequence with the highest probability of occurrence is greater than 1 x 10-7 per year. Accidents falling outside of this envelope, such as a meteorite impact, have been judged unreasonable because the probability of occurrence of less than 1 x 10-7 per year.

5.15.2.3 Accident Prevention and Mitigation. Under the Centralization and

Regionalization Alternatives, the proposed SNF facilities at the NTS will be of new design and construction and incorporate the latest technology for safety. The accidents postulated for the SNF facilities are based on operations and safety analyses that have been performed at similar facilities. One of the major design goals for the proposed SNF facilities is to achieve a reduced risk to facility personnel and to public health and safety relative to that associated with similar functions at existing SNF facilities. Significant improvements would exist between the design criteria and safety standards of the new SNF facilities and those for the current facilities, reducing total risk. These would include changes in design to current DOE structural and safety criteria and to planned throughput and storage capacity.

The SNF facilities would be designed to comply with current Federal, state, and local laws, DOE Orders, and industrial codes and standards. This would provide facilities that are highly resistant to the effects of severe natural phenomena, including earthquakes, floods, tornadoes, high winds, as well as credible events as appropriate to the site, such as fires and explosions, and man-made threats to its continuing structural integrity for containing materials.

An emergency preparedness plan will also be prepared to lower the potential consequences of an accident to workers and the public. All workers receive evacuation training to ensure timely and orderly personnel movement away from high-risk areas. Plans and arrangements with local authorities will also be inplace to evacuate the general public that may be at risk of exposure to hazardous materials that are accidently released.

5.15.3 No Action Alternative

There are currently no SNF operations at NTS. The No Action Alternative is not applicable for NTS.

5.15.4 Centralization Alternative

There is a potential for the accidental release of radioactive substances during various stages of SNF handling operations and storage. The operations begin with the receipt of an SNF shipment by truck or rail carrier followed by the unloading of the shipping cask from the transport vehicle. If the SNF requires cooling, the cask is placed into an unloading pool where the SNF is withdrawn from the cask, moved to a temporary wet storage basin, and placed into a fuel rack. Some SNF that does not require cooling will be handled in a special cell, where it will undergo canning and/or characterization. SNF that does not have to be cooled and does not require canning and/or characterization will be loaded into a dry storage canister within a transfer cask and transported to modular above-grade dry storage. Accidents that may occur during these handling operations and storage may involve the release of radioactive material to air or water pathways. The cause of accidents may be due to internal initiators, such as operator error, terrorism, and equipment failure or external initiators, such as an aircraft crash into a facility.

5.15.4.1 Radiological Impacts. The set of accidents described below have been chosen

to envelop the consequences of potential accidents for the proposed SNF facilities at the NTS. Although other accidents may occur, their estimated consequences are bounded by the accidents in the envelop or their probability of occurrence would be less than 1 x 10-6 per year. If such accidents were to occur, the dose and risk would be as shown in Tables 5.15-1 and 5.15-2 for 95 percent and 50 percent meteorology, respectively. Similarly, cancer fatalities are shown in Tables 5.15-3 and 5.15-4, and the health effects are shown in Tables 5.15-5 and 5.15-6.

5.15.4.1.1 Fuel Assembly Breach-Physical damage and breach of a fuel assembly

could accidentally occur from its being dropped, from objects falling on it, or from the fuel part being cut.
The fuel-cutting accident that has been postulated to occur at SRS SNF facilities is

Table 5.15-1. Summary of the Centralization Alternative accident analysis dose and risk estimates for the Nevada Test Site at 95 percent meteorology.

		95 Percent meteorology							
Accident scenario	Frequency (per year)	Dose				Risk			
		MEIa (rem)	NPAIb (rem)	Workerc (rem)	Population (person-rem)	MEI (rem/yr)	NPAI (rem/year)	Worker (rem/yr)	Population (person-rem/yr)
Fuel assembly breach	1.6 x 10-1 d	2.0 x 10-3	1.9 x 10-5	1.5 x 10-3	1.3 x 100	3.2 x 10-4	3.0 x 10-6	2.4 x 10-4	2.1 x 10-1

chosen as representative of the fuel assembly breach accident (E. I. du Pont de Nemours & Co. 1983). During normal SRS operations, the inert, non-uranium-containing extremities of some SNF elements are cut off in the repackaging basin before the elements are bundled. The accident occurs when the actual uranium fuel is inadvertently cut, causing a radioactive release.

The source term for this accident is shown in Table 5.15-7. The estimated frequency of occurrence for this accident is 1.6 x 10-1 per year, based on SRS operating experience with SNF. Because of anticipated differences in operations and facilities at the NTS, however, the actual frequency is expected to be much less than 1.6 x 10-1 per year.

5.15.4.1.2 Dropped Fuel Cask-The dropped fuel cask accident that has been

postulated to occur at the Hanford Site (reference Volume 1, Appendix A) is chosen as representative of the dropped fuel cask/fuel handling accident for the new Centralization Alternative facility at NTS.
This accident is initiated when a fuel cask is dropped and overturned in the fuel transfer area. Broken fuel elements spill out of the cask, within the pool building but away from the pool. It is assumed that the shipping cask ruptures, exposing all of the broken fuel elements in three canisters: 42 fuel elements, each containing 22.5 kilograms (50 pounds) of fuel. The source term for this accident is shown in Table 5.15-8. The probability of this accident is estimated to be less than 1 x 10-4 per year.

5.15.4.1.3 Severe Impact and Fire-The severe impact and fire accident that has

been postulated to occur at the Hanford Site (reference Volume 1, Appendix A) is chosen as representative of the severe impact and fire/onsite transportation accident for the new Centralization Alternative facility at NTS.
This accident assumes an unspecified initiating event that subjects the fuel assemblies to a severe impact, breach of the transport cask, and a fire. During the accident, the fuel pins rupture on impact or upon heating in the fire, which burns for an hour before being extinguished. Volatiles, particulates, and noble gases are released to the atmosphere. The source term for a release of 540 curies is shown in Table 5.15-9. The estimated probability of occurrence for this accident, reflecting the fact that the facilities of this site would be new, is less than 1 x 10-6 per year.

5.15.4.1.4 Wind-driven Missile Impact into Storage Casks-The wind-driven

missile impact into storage casks accident that has been postulated to occur at the Naval Reactors Site (reference Volume 1, Appendix D) is chosen as representative of the wind-driven

missile accident for the new Centralization Alternative facility at NTS. This accident is initiated by natural phenomena, a major wind storm or tornado in excess of facility design basis. In this scenario, a large object is propelled by the wind into a storage container, causing the container seal to be breached. No fuel damage results from the impact because of the strength of the containers used. The source term is based on the spent nuclear fuel corrosion film. One percent of the original corrosion film on the fuel is released from the cask to the atmosphere. The source term is shown in Table 5.15-10. The probability of this event is estimated to be less than 1 x 10-5 per year, based on a design basis tornado probability of 1 x 10-3 per year and a missile impact with damage probability of less than 1 x 10-2.

5.15.4.1.5 Airplane Crash Into Dry Storage-The airplane crash into dry storage

accident that has been postulated to occur at the Naval Reactors Site (reference Volume 1, Appendix D) is chosen as representative of the airplane crash into the dry storage area accident for the new Centralization Alternative facility at NTS. This accident initiated by an airplane crash into the SNF dry storage facility. The accident is postulated to cause damage to a single storage cask. Due to the severity of the impact, the cask seal is assumed to be breached, resulting in damage to the fuel and the release of corrosion products, located on the SNF exterior, to the environment. The impact also causes a fire and a release of fission products. It is assumed that 1 percent of all of the fuel units stored inside the cask are damaged either by the impact or by the fire, and that those fission products are available for release. Of the available fission products, 100 percent of the noble gases, 3 percent of the halogens, 1.1 percent of the cesium, and 0.1 percent of the remaining solids are released to the environment. Also, 10 percent of the original corrosion products from the fuel units are released from the cask to the atmosphere. The source term for this accident is shown in Table 5.15-11. The probability of this accident is small and is assumed to be less than 1 x 10-6 per year.

5.15.4.1.6 Airplane Crash into Dry Cell Facility-The airplane crash into the dry

cell facility accident that has been postulated to occur at the naval Reactors Site (reference Volume 1, Appendix D) is chosen as representative of the airplane crash into the canning and characterization cell accident for the new Centralization Alternative facility at NTS. This accident is initiated by an airplane crash into the dry cell facility. The accident is postulated to cause significant damage to the building, resulting in the loss of containment and filtered exhaust

systems. The fuel units inside the dry cell are damaged by the impacts and fire. The impact also results in the release of corrosion products to the environment. For this accident scenario, 1 percent of the fuel units stored inside the dry cell are assumed to be damaged by either the impact or the resultant fire and those fission products would be available for release. Of the fission products available for release, 100 percent of the noble gases, 3 percent of the halogens, 1.1 percent of the cesium, and 0.1 percent of the remaining solids are released to the environment. Ten percent of the available corrosion products are released to the environment. The source term for this accident is shown in Table 5.15-12. The probability of this accident is estimated to be less than 1 x 10-6 per year.

5.15.4.1.7 Airplane Crash into Water Pool-The airplane crash into the SNF water

pool accident that has been postulated to occur at the Naval Reactors Site (reference Volume 1, Appendix D) is chosen as representative of the airplane crash into the SNF water pool accident for the new Centralization Alternative facility at NTS. This externally initiated accident occurs when an airplane crashes into an SNF water pool and damages the fuel units stored there. Fission products and corrosion products are released from the fuel units into the water pool, but the pool water is not released to the environment. The presence of the pool water results in only a release of gaseous fission products to the atmosphere. In this accident scenario 1 percent of all the fuel units stored inside the pool are postulated to be damaged and those fission products are available for release. Of the available fission products, 100 percent of the noble gases and 25 percent of the halogens are released to the pool water. Due to the presence of pool water, there is a reduction of the halogen release by a factor of 10 prior to release to the atmosphere. The source term for this accident is shown in Table 5.15-13. The probability of this accident is estimated to be less than 1 x 10-6 per year.

5.15.4.2 Nonradiological Hazards. The two bounding accidents involving nonradiological

hazards are a chemical spill and fire and a diesel fuel fire. Both of these accidents are associated with the Expended Core Facility operations and the accident frequencies and impacts are addressed in Volume 1, Appendix D. The analyses of these accidents considered the impacts to workers on the site as well as to the offsite population. The impacts were measured in terms of potential heath effects due to exposure to toxic chemicals released during these accidents. Since the ECF at this site will be a new design and construction, it will incorporate all applicable

Table 5.15-12. Estimated radionuclide releases for an airplane crash into dry facility at the NTS Table 5.15-13. Estimated radionuclide releases for an airplane crach into an SNF water pool at the NTS

standards and regulations and therefore limit the potential exposures to the workers and the public in the event of an accident.

5.15.4.3 Secondary Impacts. In the event of an accidental release of radioactive

substances, there is a potential for secondary impacts to cultural resources, endangered species, water resources, and public and agricultural land use, the ecology in the vicinity of the accident, national defense, and local economics. In order to assess the impacts, a severe accident and the resulting release of radioactive material were evaluated. The accident chosen for evaluation was an airplane crash into the Centralization Alternative canning and characterization (dry) cell. Utilizing the 50 percent meteorology and the typical flat topography of the proposed SNF site, the dispersion of radioactive material and the resulting dose were calculated. Figure 5.15-1 shows the isodose lines ranging from 870 millirem per year down to 87 millirem per year, which is approximately equivalent to cosmic and terrestrial background radiation. The farthest distance between the accident site and the 87 millirem per year line is 8,000 feet (2,400 meters). Therefore, in order to minimize the potential impact of an accident on the non-NTS personnel and the public, the SNF facility should be located at least 8,000 feet (2,400 meters) from the NTS boundary. Given the available space within Area 5 and the large buffer zone surrounding the proposed SNF site and the NTS, the final siting location could easily accommodate this design constraint. This design constraint could be applied to other environmental resources during the final siting process. The secondary impacts in other environmental resources which would not be accommodated as easily are summarized below. Table 5.15-14 presents a summary of the postulated severe accident secondary impacts on the environment, economy, and national defense. The evaluation was performed using 50 percent meteorology.

5.15.5 Decentralization Alternative

The Decentralization Alternative is not applicable for the NTS.

5.15.6 1992/1993 Planning and Basis Alternative

There are currently no SNF operations at NTS. The 1992/1993 Planning Basis Alternative is not applicable for NTS.

Figure 5.15-1. Typical Isodose lines for an airplane crash into a dry cell accident with 50 percent meteorology for northeastern Area 5 of the NTS.

Table 5.15-14. Secondary impacts of the Centralized Alternative accidents at NTS.

Environmental or social factor	Impact
Land Use	Possible minor impact. The dispersion of radioactive material would be limited within the NTS boundaries. The major NTS facilities in the vicinity of the proposed SNF site include the Radioactive Waste Management Site and the Liquified Gaseous Fuels Spill Test Facility.
Cultural Resource	Possible minor impact. Surveys conducted for other Area 5 activities have indicated only scattered artifacts in the vicinity of the proposed SNF site. No major prehistoric/historic sites are anticipated to be located in the vicinity of the proposed SNF site. Access to any random artifacts found during the accident investigation and cleanup would have to be restricted until radioactive decay had occurred.
Aesthetic and Scenic Resources	No impact. The area of contamination does not envelop aesthetic and scenic resources.
Water Resources	No impact. The nuclear testing program has dispersed radioactive material in the vicinity of the proposed SNF site during aboveground nuclear tests. Due to the great depths of the groundwater, the groundwater was not contaminated. It is anticipated that an accident would not alter the pathways to the groundwater.
Ecological Resources	Possible impact. Many threatened or endangered plants and animals, except fish species, are potentially on or near the NTS.
Treaty Rights	No impact. There are no onsite areas subject to Native American Treaty rights.
National Defense	No impact. The area of contamination does not envelop U.S. military or defense industry facilities.
Economic Impacts	Possible minor impact. The dispersion of radioactive material would be limited within the NTS boundaries. The major NTS facilities in the vicinity of the proposed SNF site include the Radioactive Waste Management Site and the Liquified Gaseous Fuels Spill Test Facility.

5.15.7 Regionalization Alternative

Under the Regionalization Alternative, new facilities would be constructed and operated for SNF. Details for the new facilities have not been defined, but it is reasonable to expect that they would be similar to but with less throughput and storage requirements than those needed for the

Centralization Alternative. Due to smaller throughput and storage requirements, the potential for accidents (i.e., probability of occurrence) will be similar to but less than those described for the Centralization Alternative. The accident consequences would be similar for both alternatives.
Consequently, it is reasonable to assume the accident consequences and risks described for the Centralization Alternative envelop the Regionalization Alternative.

5.15.8 Emergency Preparedness and Plans

DOE has issued a series of Orders specifying the requirements for emergency preparedness (DOE Orders 5500.1A, 5500.2A, 5500.3, draft 5500.3A, 5500.4, and 5500.9), and each DOE site has established an emergency management program. These programs are developed and maintained to ensure adequate response for most accident conditions and to provide the framework to readily extend response efforts for accidents not specifically considered. The emergency management program incorporates activities associated with planning, preparedness, and response.

Officials at each DOE site have specified the emergency preparedness requirements for the DOE facilities under their jurisdiction in a manner consistent with the relevant DOE Orders. All existing facilities have emergency plans and procedures that either implement the DOE and site requirements or are integrated with the site planning.

The Nevada Operations Office Emergency Preparedness Plan is designed to minimize or mitigate the impact of any emergency upon the health and safety of employees and the public. The plan integrates all emergency planning into a single entity to minimize overlap and duplication, and to ensure proper responses to emergencies not covered by a plan or directive. The plan is based upon the concept that the Manager, Nevada Operations Office, has the capability to manage, counter, and recover from an emergency occurring within the Nevada Operations Office responsibility.

The Nevada Operations Office plan provides for (1) identification and notification of personnel for any emergency that may develop during operational or nonoperational hours; (2) the receipt of warnings, weather advisories, or any other information that may provide advance warning of a possible emergency; and (3) prearranged actions which may be taken to minimize the effect of the emergency. The plan is based upon current Nevada Operations Office vulnerability assessments, resources, and capabilities regarding emergency preparedness.

5.16 Cumulative Impacts and Impacts from Connected or Similar Actions

The NTS already contains several major DOE and non-DOE facilities, unrelated to SNF, that would continue to operate throughout the operating life of the proposed SNF management facilities. The activities associated with these existing facilities produce environmental consequences that have been included in the baseline environmental conditions (Chapter 4) against which Sections 5.1 through 5.15 have assessed the environmental consequences of the Centralization and Regionalization Alternatives. This section uses the environmental baseline conditions presented in Chapter 4 to assess potential cumulative impacts from the proposed SNF management facilities, if constructed at the NTS, plus other reasonably forseeable activities.

In addition to the proposed SNF management facilities, reasonably foreseeable activities considered in this cumulative impact assessment include the proposed Expended Core Facility (described in Volume 1, Appendix D), activities included in the present Five-Year Plan and Master Plan for the NTS (DOE/NV 1993b), and the potential geologic repository at the Yucca Mountain site. Major programmatic initiatives consist of constructing the following: facilities and site improvements for a new consolidated testing area sponsored by Los Alamos and Lawrence Livermore National Laboratories; a Transuranic Waste Certification Building; refurbishment or expansion of several existing facilities; construction of several small office buildings; several site assessment and remediation projects; several roadway upgrading or improvement projects; several flood control projects; and several utility installation or upgrade projects. In addition, a number of communications, security, an safety improvements identified in the Master Plan are under consideration throughout the NTS.

Specifically with respect to Area 5, a number of projects are proposed (DOE/NV 1993b). Continued use of the Radioactive Waste Management Site and the Spill Test Facility is proposed. Providing storage for transuranic waste and hazardous waste prior to offsite disposal is also proposed. Additional projects have also been proposed to provide utility and infrastructure upgrades and improvements. These projects include replacing the Frenchman Flat power substation and a number of construction projects for water Service Area C including connecting the Yucca Flat and Frenchman Flat water systems, and adding additional tanks and water lines in the area. Nearby proposals identified for Area 6 include following a formal, expansion-oriented land-use plan for the Control Point, Yucca Lake, and the Construction Facilities.

The potential geologic repository at the Yucca Mountain site, which could involve construction and operation of a geologic repository for spent nuclear fuel and high-level waste on NTS land and other federal land on the western boundary of the NTS, is also considered in this cumulative impacts analysis. Considering the relatively isolated location of the NTS, future new offsite activities (other than the potential geologic repository at Yucca Mountain) are assumed to be of limited scope.

The following cumulative impacts analysis considers the potential incremental effects from the proposed SNF management facilities and the proposed Expended Core Facility in detail. The potential incremental impacts from activities proposed in the Five-Year Plan, and Master Plan the potential geologic repository at the Yucca Mountain site, and from future offsite activities are assessed in a more qualitative manner.

5.16.1 Centralization Alternative

Separate analyses of potential cumulative impacts from the Centralization Alternative against the environmental baseline conditions presented in Chapter 4 are provided below.

5.16.1.1 Land Use. Construction of the proposed SNF management facilities would

require the dedication of approximately 90 acres (0.36 square kilometer) of undeveloped land on the NTS. Construction of the proposed Expended Core Facility would require the dedication of an additional 30 acres (0.12 square kilometer) of undeveloped land, increasing the total land requirement to 120 acres (0.48 square kilometer). This represents less than 1 percent of the roughly 450,000 acres (1,800 square kilometers) of undeveloped land remaining on the 864,000 acre (3,500 square kilometers) NTS. Additional unknown areas of undeveloped land, generally parcels of under 100 acres (0.4 square kilometer), might have to be dedicated to some of the activities proposed in the Five-Year Plan and Master Plan. Many of these proposed activities do not require the dedication of undeveloped land. Land on the southwestern part of the NTS has already been allocated for the potential Yucca Mountain repository and current site characterization for a potential geologic repository at the Yucca Mountain site.

Considering the large area of undeveloped land on the NTS, the cumulative dedication of land to all reasonably foreseeable activities on NTS would not likely serve to further limit the availability of land on the NTS for future development. Large areas of undeveloped land are available for development off of the NTS, and any future offsite development coupled with the proposed onsite development discussed above is not likely to create regional land shortages that could severely limit future regional development.

5.16.1.2 Occupational and Public Health. The annual collective effective dose

equivalent from the existing NTS facilities to the population within 50 miles (80 kilometers) of the NTS is 0.0052 person-rem. Added to this baseline, operation of the proposed SNF management facilities might contribute an additional 0.082 person-rem, increasing the cumulative effective dose to 0.087 person-rem.

The annual collective effective dose equivalent from the existing NTS facilities to a potential maximally exposed individual at the site boundary is 0.011 millirem per year. Operation of the proposed SNF management facilities might contribute an additional 0.12 millirem per year, resulting in a cumulative annual dose of 0.13 millirem per year to this maximally exposed individual.

The total annual baseline worker dose seen from normal NTS operations is about 4 person-rem. The total annual SNF management facility worker dose is expected to be roughly 32 person-rem. Hence, the cumulative annual dose might be 36 person-rem.

Over the planned 40-year operational lifetime of the SNF management facility, a total population dose of 3.5 person-rem will be observed from continuous operation of the existing NTS facilities and the SNF management facility. This equates to a risk of fatal cancer of 4.4 x 10-5 over the 40-year span. For the maximally exposed individual, the total dose over the 40-year period equates to a risk of fatal cancer of 2.6 x 10-6. For the SNF management worker, the total dose over the 40-year span corresponds to a risk of fatal cancer of 6.4 x 10-4.

Additional radiological impacts are not expected from operation of the proposed Expended Core Facility. Analysis has shown that the dose to all individuals considered (workers, and offsite individuals) from Expended Core Facility operations might be much less than one millirem per year.

5.16.1.3 Noise. Increases in noise levels from construction and operation of the SNF

management facilities and the Expended Core Facility would be limited to temporary, minor construction noise and small increases in traffic noise occurring along various access routes to the NTS due to increases in employment. Because of the NTS's large size and sparsely inhabited surroundings, any cumulative noise levels generated on the NTS by the proposed SNF management facilities, the proposed Expended Core Facility, the potential geologic repository at the Yucca Mountain site, and activities proposed in the Five-Year Plan and Master Plan would not propagate offsite at levels that would impact the general population. Although the cumulative offsite noise level attributed to future offsite activities can not be estimated, the potential incremental addition attributable to the proposed SNF management facilities would be minimal. Minor increases in traffic noise on U.S. Route 95 could be possible due to increases in activity on and near the NTS.

5.16.1.4 Groundwater and Surface Water Resources. Operation of the proposed SNF

management facilities would require the withdrawal of an estimated 3.6 million gallons per year (13.6 million liters per year) of groundwater from the Ash Meadows Subbasin. Operation of the proposed Expended Core Facility would require the withdrawal of an estimated additional 2.5 million gallons per year (9.5 million liters per year) from that subbasin, resulting in a combined withdrawal of an estimated 6.1 million gallons per year (23.1 million liters per year). The water demands for the potential geologic repository at the Yucca Mountain site would be met by the Alkali Flat Furnace Creek Ranch Subbasin and therefore would not contribute to the cumulative water withdrawals from the Ash Meadows Subbasin. Information concerning the water demands of activities in the Five-Year Plan, Master Plan, or future offsite activities is not available.

Although total withdrawals of groundwater from the Ash Meadows Subbasin have not exceeded the subbasin perennial yield, localized withdrawals of groundwater in the Frenchman Flat hydrographic area of the Ash Meadows Subbasin have exceeded the estimate of precipitation recharge for the area. This recharge estimate was exceeded for more than thirty years with no decline in static water levels. Accurate measurement of static water levels are, however, precluded by numerous conditions on the NTS. Because of hydrogeologic complexities, regional groundwater flow at the NTS is not constrained by the hydrographic basins which are defined by local topography. Therefore any potential groundwater overdraft in the Frenchman Flat hydrographic area indicated by previous yield estimates are likely be made up by untapped groundwater from neighboring hydrographic basins. Localized impacts could occur if the perennial yield of Frenchman Flat hydrographic area is exceeded. Potential impacts include depletion of water stored locally in the regional aquifer, removal of that groundwater from other potential uses, and the potential modification of the rate and direction of contaminant migration resulting from underground nuclear testing. The complex issues of groundwater contamination and use are being addressed in the Resource Management Plan being prepared in conjunction with the NTS site-wide EIS.

5.16.1.5 Biotic Resources. Construction of the proposed SNF management facilities

would require the disturbance of approximately 90 acres (0.36 square kilometer) of desert habitat supporting flora and fauna characteristic of the ecotone between the Mohave Desert and the Great Basin. Construction of the proposed Expended Core Facility would require the disturbance of an additional 30 acres (0.12 square kilometer) of desert habitat, resulting in a combined conversion of 120 acres (0.48 square kilometer) of terrestrial habitat to developed uses.

Additional areas of desert habitat would be lost during construction of activities proposed in the Five-Year Plan and Master Plan, during construction of the potential geologic repository at the Yucca Mountain site, and during future offsite construction activities. Considering the broad extent of desert habitat on and surrounding the NTS, the cumulative loss of desert habitat would be minimal.

The NTS lies within the range of the desert tortoise, a federally listed threatened species. If the desert tortoise occurred in areas subject to development, tortoises could be injured from construction activities. The proposed SNF management facilities (and the proposed Expended Core Facility) would be constructed at the edge of the tortoise's range, however, and few have been found in the affected area. Habitat losses due to construction of the proposed SNF management facilities and other proposed onsite and offsite construction activities could result in a slight cumulative loss of habitat for the desert tortoise. The U.S. Fish and Wildlife Service would be consulted in accordance with Section 7 of the Endangered Species Act prior to construction of the potential SNF management facilities to ensure that any potential cumulative effect on desert tortoise populations would be minimal. The U.S. Fish and Wildlife Service would also have to be similarly notified and given an opportunity to comment prior to construction of the potential geologic repository at the Yucca Mountain site and prior to any other major construction activities.

5.16.1.6 Air Quality. The potential cumulative air emissions from the proposed SNF

management facilities and the proposed Expended Core Facility would not result in an exceedance of the National Ambient Air Quality Standards or Nevada state criteria. Also, there would be no exceedance of Federal National Emissions Standards for Hazardous Air Pollutants or DOE radiological standards. Air emissions from the other planned activities have not yet been defined.

5.16.1.7 Socioeconomics. Operation of the proposed SNF management facilities might

generate up to 800 new jobs during the year 2005 and beyond. Operation of the proposed Expended Core Facility might generate up to 562 additional jobs during that year, resulting in a combined increase of up to 1,362 new jobs. The 7,091 jobs presently forecasted for the NTS in the year 2005 might be increased by 19 percent, to as much as 8,453 jobs. The 752,356 jobs presently forecasted for the surrounding area in the year 2005 might be increased by less than 1 percent, to as much as 753,718 jobs. Additional employment increases could also result from the potential geologic repository at the Yucca Mountain site, activities proposed in the Five-Year Plan and Master Plan, and new offsite activities, but specific estimates are not available.

The cumulative effect of the employment increases discussed above would depend on future actions at the NTS and throughout the regional economy. These employment increases could cause minor fluctuations in employment and housing demands. However, activities at the NTS generally have a relatively modest effect on long-term regional economic growth and productivity in Clark County because of the implicit growth projections in the services and retail trade sectors driving long-term growth in the Las Vegas Metropolitan Statistical Area. Additionally, in recent years the shutdown of nuclear testing activities at the NTS has caused employment levels to fall. These losses have not been considered in long-term employment forecasts. If nuclear testing activities do not resume at the NTS, the projected employment increases noted above could be offset by employment losses.

5.16.1.8 Transportation. An estimated 4.0 x 10-4 and 1.4 x 10-3 accident occupational

fatalities and accident nonoccupational fatalities might occur over the 40-year life of the proposed SNF management facilities due to the transportation of hazardous material to the facilities. This does not include fatalities due to leakage of hazardous waste. Similar data are not available for the other planned activities.

5.16.1.9 Waste Management. Operation of the proposed SNF management facilities

would generate an estimated 203 cubic meters (266 cubic yards) per year of low level waste and an estimated 16 cubic meters (21 cubic yards) per year of transuranic waste. Operation of the proposed Expended Core Facility would generate an additional 425 cubic meters (556 cubic yards) of low level waste (for a combined total by both facilities of 628 cubic meters (821 cubic yards)) but would not generate any additional transuranic waste. No other radioactive waste, including high level waste or mixed waste, would be generated by either facility. Comparable data for the potential geologic repository at the Yucca Mountain site or for offsite activities or activities proposed in the Five-Year Plan and Master Plan is not available. All wastes generated by the proposed SNF management facilities and other planned activities on the NTS would be treated and disposed of in accordance with all applicable Federal and state regulations.

5.16.1.10 Other Resources. The absence of impacts, or very minimal impacts, from the

proposed SNF management facilities to cultural resources, aesthetic and scenic resources, utilities, and geologic resources ensures that their potential contribution to cumulative impacts affecting these resources would be negligible.

5.16.2 Regionalization Alternative

Because impacts from the proposed SNF management facilities under the Regionalization Alternative would be equal to or less than those under the Centralization Alternative, the potential cumulative impacts would also be equal or less. Generally, the Regionalization Alternative requires less construction and smaller scale operations, and the potential for cumulative impacts is therefore less.

5.17 Adverse Environmental Effects That Cannot Be Avoided

5.17.1 Overview

This chapter discusses potentially unavoidable adverse impacts to the environment resulting from construction and operation of the proposed SNF facilities at the NTS under the Centralization and Regionalization Alternatives. Unavoidable adverse impacts are impacts which cannot be mitigated by changes in project design, operation, or construction, or by other measures.

5.17.2 Centralization Alternative

Operation of the proposed SNF facilities at the NTS under the Centralization Alternative would increase the radiation dose rate to the maximally exposed individual by 0.12 millirem/year, resulting in only a minimal increase in cancer risk. The number of fatal cancers per year of operations on the NTS from existing sources and the SNF facilities would be 4.4 x 10-5.

Construction of the proposed SNF facilities would require the disturbance of approximately 90 acres (0.36 square kilometer) of undeveloped land. Although this represents less than 1 percent of the undeveloped land on NTS, it would eliminate potential terrestrial wildlife habitat, including habitat potentially suitable for the federally listed desert tortoise. It would also require the dedication of a small land parcel potentially suitable for other construction projects, but similar land parcels are abundant on the NTS.

Operation of the proposed SNF facilities would require the withdrawal of an estimated 3.6 million gallons (13.6 million liters) per year of groundwater from the Ash Meadows Subbasin. Existing localized withdrawals of groundwater from Frenchman Flat hydrographic area of this subbasin already exceed the estimate of precipitation rechange for the area. However, the total withdrawal from the Ash Meadows Subbasin does not exceed its total perennial yield. Any water withdrawn would therefore not be discharged at Ash Meadows and the other discharge points in the deserts southwest of NTS.

The potential impacts from the Centralization Alternative to the other environmental resources discussed in Chapter 5 are not unavoidable adverse impacts.

5.17.3 Regionalization Alternative

Potential unavoidable adverse impacts associated with the Regionalization Alternative would resemble those discussed above for the Centralization Alternative. The extent of the impacts could be less due to the reduced land requirements, reduced extent of construction disturbance, and reduced scale of operations.

5.18 Relationship Between Short-Term Use of the Environment

and the Maintenance and Enhancement of Long-Term Productivity

Implementation of any of the SNF management alternatives would cause some adverse impacts to the environment and permanently commit certain resources. These resources include use of the environment and those associated with construction and operation of the SNF management facilities.

The proposed alternatives for SNF management would require the short-term use of resources including energy, construction materials, and labor in order to achieve the objective of safety managing SNF to minimize the risk to workers, the public, and the environment.

Development of new SNF interim management facilities would commit lands to those uses from the time of construction through the cessation of operations, at which time the facilities could be converted to other uses or decontaminated, decommissioned, and the site restored to its original land use.

5.19 Irreversible and Irretrievable Commitments of Resources

5.19.1 Overview

This chapter discusses the irreversible and irretrievable commitments of resources resulting from the use of materials that can not be recovered or recycled, or that must be consumed or reduced to irrecoverable forms.

5.19.2 Centralization Alternative

Construction and operation of SNF facilities under the Centralization Alternative would require commitments of electrical energy, fuel, concrete, steel, sand, gravel and miscellaneous chemicals. Groundwater to operate the SNF facilities would not be discharged in the deserts to the southwest of NTS. More detailed analyses would be required to determine irreversible effects on localized groundwater availability. The land dedicated to the SNF facilities would become available for other rural uses following closure and decommissioning.

5.19.3 Regionalization Alternative

Irreversible and irretrievable commitments of resources associated with the Regionalization Alternative would resemble those discussed above for the Centralization Alternative. However, the extent of these resource commitments could be less, due to the reduced land requirements and reduced scale of operations.

5.20 Potential Mitigation Measures

5.20.1 Pollution Prevention

The DOE Nevada Field Office (DOE/NV) published a Waste Minimization and Pollution Prevention Awareness Plan in June 1991 to reduce the quantity and toxicity of hazardous, mixed, and radioactive wastes generated at DOE/NV facilities. The plan is designed to reduce the possible pollutant releases to the environment and thus increase the protection of employees and the public. All DOE/NV contractors and NTS users that exceed the EPA criteria for small-quantity generators are establishing their own waste minimization and pollution prevention awareness programs that are implemented by the DOE/NV plan. Contractor programs ensure that waste minimization activities are in accordance with Federal, state, and local environmental laws and regulations, and DOE Orders (DOE/NV 1993c).

Additional goals include the promotion and use of nonhazardous materials, establishment of a baseline of waste generation data, calculations of annual reductions of wastes generated, and implementation of recycling programs. Goals also include incorporation of waste minimization concepts and technologies in planning and design of new processes and facilities, and in upgrades of existing facilities. A waste minimization task force composed of representatives from each contractor and NTS user has been established to coordinate DOE/NV waste minimization and pollution awareness activities (DOE/NV 1993c).

5.20.2 Potential Mitigation Measures

Potential impact avoidance and mitigation measures are addressed in Chapter 5, Sections 1 through 15 as appropriate.

OAK RIDGE RESERVATION

FIGURES

TABLES

#1. INTRODUCTION

This part assesses the impacts of contruction and operation of proposed spent nuclear fuel (SNF) facilities at the Oak Ridge Resevation (ORR). The ORR is being evaluated for these facilities because of the area available, the appparently suitable site environmental parameters, previous U.S. Department of Energy activities involving radioactive materials at the site, and the planned long-term government control of the site.

This appendix is organized as follows. Chapter 1 is the introduction, Chapter 2 sets the stage for the area under analysis by providing an overview of the ORR and a discussion of the Regulatory Framework and the SNF Management Program, and Chapter 3 explains the SNF alternatives being considered at the site.

Chapter 4 describes the human and natural environment that could be affected as a result of the introduction of an SNF facility at the ORR. Environmental parameters such as water resources, socioeconomics, biological resources, and air quality are examples of those characterized.

Chapter 5 enumerates the environmental consequences that might be anticipated, summarizes the cumulative impacts, describes unavoidable adverse impacts, and describes the irreversible and irretrievable committment of resources that might be anticipated if an SNF facility were built at the ORR. Chapter 6 contains the references used to develop this part of the environmental impact statement. Chapter 7 contains a list of abbreviations and acronyms used in this part of the environmental impact statement.

2. OAK RIDGE RESERVATION SITE BACKGROUND

2.1 Overview

2.1.1 Site Description

The Oak Ridge Reservation (ORR) is located on approximately 34,667 acres (140 square kilometers) of federally owned land within the incorporated city limits of Oak Ridge, Tennessee (see Figure 2.1-1). The City of Oak Ridge and the ORR lie between the Cumberland and Southern Appalachian mountain ranges. Knoxville is located approximately 25 miles (40 kilometers) southeast of the ORR and is the largest city in the area. The population varies within the five counties surrounding the ORR. The area around Knoxville is a heavily populated and highly developed urban area, whereas the area surrounding the ORR is sparsely populated, with the exception of the city of Oak Ridge, which is considered to have medium density population. The two main land uses in the five counties surrounding the ORR are forestry and agriculture.

Within the ORR there are three primary complexes: the Y-12 Plant, the K-25 Site (formerly the Oak Ridge Gaseous Diffusion Plant), and the Oak Ridge National Laboratory (ORNL) (see Figure 2.1-2). Currently these facilities are being used for research, development, and production.

The Y-12 Plant is located on the eastern portion of the ORR known as Bear Creek Valley. The Y-12 Plant serves as a key manufacturing technology center for the development and demonstration of unique materials, components, and services of importance to DOE and the nation. This mission is accomplished through the reclamation and storage of nuclear materials, the manufacture of components to the nation's defense capabilities, support to national security programs, and services provided to other customers as approved by DOE (MMES 1994a).

The K-25 Site is located on the northwestern portion of the ORR. Its mission is to provide a base of operation for the Energy Systems Environmental Restoration and Waste Management programs, thus serving as the "platform" for the restoration of the environment and management of DOE wastes through leadership and central management of the Environmental Restoration and Waste Management and Technology Development Programs in support of DOE, sites managed for DOE by Energy Systems, other elements of the Federal Government, and the public. The Toxic Substances Control Act incinerator is managed by and located on the K-25 Site (MMES 1994a).

Figure 2.1-1. Oak Ridge Reservation regional map. Figure 2.1-2. Oak Ridge Reservation site and transportation.

The ORNL is located in the southern portion of the ORR. The primary mission of ORNL is to perform leading edge research and development in support of nonweapons roles of DOE (MMES 1994a). The ORNL uses test and experimental reactors to perform research and for small-scale radioisotope production activities. The amount of spent nuclear fuel (SNF) generated by these facilities, the amount expected to be generated through the year 2035, and accommodations being undertaken at the present time to store the fuel currently being generated are discussed in the following sections.

The buildings located off the ORR but owned and/or operated by the U.S. Department of Energy (DOE) are 1) the Scarboro Facility, 2) the Central Training Facility, 3) the Transportation Safeguards Division Maintenance Facility, and 4) some ancillary and administrative facilities and structures. The majority of the facilities used by various plant protection and security groups are located within the plant's boundary. Other offsite facilities include the DOE Oak Ridge Operations Office, the DOE Office of Scientific and Technical Information, the Oak Ridge Associated Universities facilities, the American Museum of Science and Energy, the prime contractor's "Townsite" facilities, the National Oceanic and Atmospheric Administration's Atmospheric Turbulence and Diffusion Laboratory, and others. With the exception of the Federal Office Building and space leased from the private sector, all facilities are located on DOE-owned land.

The proposed site of the SNF management facility is located on 100 acres (0.40 square kilometer) of land designated as the West Bear Creek Valley site (see Figure 2.1-2) (La Grone 1994; MMES 1994b). The proposed SNF storage facility will require 90 of the 100 acres (0.36 of the 0.40 square kilometer) set aside for the facility (Johnson, V. 1994).

The proposed SNF management facility is on Bear Creek Road adjacent to the Clinch River on the west end of the ORR. The westernmost boundary of the proposed SNF facility is less than 1 mile (1.6 kilometers) from the ORR boundary. Across Bear Creek Road from the proposed SNF management facility there is a privately owned industrial park (MMES 1994b).

2.1.2 Site History

The ORR was originally purchased in the early 1940s to house the large-scale production of fissionable material for the first nuclear weapon in the world. The original tract of land purchased was 56,833 acres (230 square kilometers). Portions of the original tract were used to build the City of Oak Ridge for the people who constructed and operated the ORR. Residential and business areas of the city were sold, and the ORR has been reduced to its present size.

ORNL began in 1943 as the Clinton Laboratories, a pilot plant for testing and development of the plutonium-239 production and chemical separations processes. Major facilities at the ORNL included the X-10 Graphite Reactor, a chemical pilot plant, and numerous support laboratories and shops. The ORNL's initial mission was fulfilled by 1945, but because of its unique capabilities, new research and development programs were initiated in energy, materials, and environmental technology (DOE 1988).

Since 1945 emphasis at ORNL has been on exploration of the use of nuclear science and technology, which continues as a major component of research and development of the laboratory. A number of additional nuclear reactors and supporting facilities have been built and operated at ORNL since the original mission associated with the Manhattan Project. Research and development in nuclear science and technology is supported currently by one operating research reactor, the High Flux Isotope Reactor. ORNL has proposed the Advanced Neutron Source, which would take over many of the tasks now carried out by the High Flux Isotope Reactor (Brown 1994a; Hoel 1994).

In 1943 the Y-12 Plant was constructed as part of the Manhattan Project. The Y-12 Plant separated fissionable isotopes of uranium-235 by the electromagnetic process, which was used in the world's first atomic bomb, detonated on August 5, 1945 (MMES 1990; DOE 1987). Since that time Y-12 has developed into a highly sophisticated nuclear weapons component manufacturing and development engineering organization and currently is used for weapons disassembly.

The Oak Ridge Gaseous Diffusion Plant, now the K-25 Site, was used to produce enriched uranium for U.S. nuclear weapons. It also provided an industrial toll enrichment service, in which uranium was enriched for use in nuclear-powered reactors around the world. In 1987, the Oak Ridge Gaseous Diffusion Plant was permanently shut down.

2.1.3 Mission

The missions of the primary plant complexes within ORR are:

- Energy Research and Development at ORNL.
- Reclamation and Storage of Nuclear Material, Manufacturing of Defense Hardware, and National Security, Technology Transfer, and Work for Others Programs at Y-12.
- Environmental Restoration and Waste Management at the K-25 Site (MMES 1994a).

The mission of ORNL includes services that only research reactors provide, including, 1) the production of transuranium isotopes used in basic research, medical, defense, and industrial applications, 2) neutron scattering research to determine fundamental structure and properties of materials, 3) production of unique isotopes for medical treatment and research, 4) production of special commercial isotopes, and 5) irradiation of structural and fuel materials for fusion energy reactors and advanced nuclear reactors (Brown 1994a; Hoel 1994).

2.1.4 Oak Ridge Reservation Operations Management

Martin Marietta Energy Systems, Inc., operates the major facilities at the ORR (Y-12 Plant, K-25 Site, and ORNL). They are under contract to and administered by the DOE Oak Ridge Operations Office. Current missions and functions can be grouped into the following four categories: defense production activities; environmental management activities; other DOE activities; and work for others.

2.2 Regulatory Framework

The National Environmental Policy Act (NEPA) of 1969 (42 USC 4321-4347, as amended) provides Federal agency decision makers with a process to systematically consider the potential environmental consequences of agency decisions. The DOE has prepared this environmental impact statement (EIS) in conformance with the requirements of NEPA to evaluate the potential impacts of programmatic decisions on the management of SNF. This EIS provides the necessary background, data, and analyses to help decision makers understand the potential environmental consequences of each alternative.

On October 22, 1990, the DOE published a Notice of Intent in the Federal Register (FR 1990) announcing its intent to prepare a programmatic EIS addressing environmental restoration and waste management (including SNF management) activities across the entire DOE complex. On October 5, 1992, the DOE published a Notice of Intent in the Federal Register (FR 1992) announcing its intent to prepare an EIS addressing environmental restoration and waste management and SNF activities at the Idaho National Engineering Laboratory. For further programmatic discussion of this topic, see Volume 1.

Significant state environmental and nuclear materials management laws applicable to the

ORR include the following (listed alphabetically):

- Air Pollution Control Regulations (Chapter 1200-3)
- Air Quality Act (Title 68 Chapter 201-101)
- Emergency Rules--Hazardous Substance Remedial Action (Chapter 1200-1-13)
- Emission Standards and Monitoring Requirements for Additional Control Areas (Chapter 1200-3-19)
- Hazardous Substance Site Remedial Action (Chapter 1200-1-13)
- Hazardous Waste Management (Chapter 1200-1-11)
- Licensing Requirements for Land Disposal of Radioactive Waste (Chapter 1200-2-11)
- New Source Performance Standards (Chapter 1200-3-16)
- Prevention of Hazards and Pollution (Chapter 1200-1-6)
- Rules and Regulations Applied to Tennessee Codes Annotated -69-1-1 (Chapter 1200-4-8)
- Solid Waste Processing and Disposal (Chapter 1200-1-7)
- Underground Storage Tank Program (Chapter 1200-1-15)
- Visible Emission Regulations (Chapter 1200-3-5)
- Volatile Organic Compound (Chapter 1200-3-18)

2.3 Spent Nuclear Fuel Management Program

In the past, reactor-irradiated nuclear materials, which include SNF and reactor-irradiated target material, have been stored prior to reprocessing activities to recover plutonium, tritium, and other isotopes. In the past several years, however, the DOE has either phased out or stopped its reprocessing of these materials. With this change, reactor-irradiated nuclear materials were being stored for longer periods of time than originally planned. The amount of reactor-irradiated nuclear materials and the conditions of storage for the materials were in question throughout DOE facilities.

In an effort to assess whether extended storage conditions for reactor-irradiated nuclear materials are safe (i.e., whether protection exists for workers, the public, and the environment), the DOE commissioned a study. This assessment also grouped any vulnerabilities of the storage conditions into three categories where management attention could be directed: less than 1 year, 1 to 5 years, and greater than 5 years. In November 1993, the DOE published the Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and other Reactor Irradiated Nuclear Materials and Their Environmental, Safety and Health Vulnerabilities, hereafter referred to as the Spent Fuel Working Group Report, as a result of the assessment efforts (DOE 1993b; 1994b).

As a result of the Spent Fuel Working Group Report, a Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities was also commissioned to address what was discovered in the original Working Group Report. Phase I of the Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities was published in February 1994. Phase II and Phase III were issued April 1994 and October 1994, respectively. To address the vulnerabilities identified in the Spent Fuel Working Group Report, individual action plans were developed to reflect the DOE's sense of urgency, concern for worker protection, commitment to minimize environmental impacts, and need for compatible long-term solutions.

The ORR was assessed as part of the Spent Fuel Working Group Report. SNF located on the ORR is currently stored in facilities at the ORNL. The SNF at ORR is primarily spent fuel from research or experimental reactors that are operating or have operated at ORNL. Samples of SNF left over from research on fuel elements removed from commercial or demonstration reactors utilized by DOE predecessor agencies for advancement of nuclear science are also present. In the past, most of the SNF from the Oak Ridge research and experimental reactors was chemically processed to recover fissile materials at Savannah River Site (Brown, 1994a; Hoel 1994).

This section describes the status of the SNF at the ORR using the information presented in the Spent Fuel Working Group Report, the Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities, the Spent Fuel Inventory Data developed for the SNF EIS, and through discussions with ORR. If fuel can be contact handled, it has not been listed in the Spent Fuel Inventory as SNF. The SNF management program at ORR utilizes 10 facilities for storage. These facilities and their SNF contents are summarized on Table 2.3-1.

2.3.1 Building 3525 - Irradiated Fuels Examination Laboratory

This two-story brick structure was built in 1963 and contains hot cells. The facility mission continues to be disassembly and examination of irradiated fuel and components. Building 3525 contains 1 unit of research reactor fuel in the form of fuel samples and targets (DOE 1993b; Wichmann 1995a, b).

2.3.2 Building 4501 - High-Level Radiochemical Laboratory

Constructed in 1951, this facility contains centrally located hot cells supported by various laboratories capable of handling radioactive materials. SNF is in dry storage at this facility. Building 4501 contains 0.006 metric tons of heavy metal (MTHM) of DOE-owned commercial fuel (DOE 1993b; Wichmann 1995a, b).

2.3.3 Building 7920 - Radiochemical Engineering Development Center

The Radiochemical Engineering Development Center is a multipurpose hot cell facility with equipment, shielding, and containment provisions to safely process and store significant quantities of highly radioactive targets. This facility was specifically built to prepare and process targets from the High Flux Isotope Reactor. Building 7920 contains 0.024 MTHM of research reactor fuel in the form of fuel samples in dry storage (DOE 1993b; Wichmann 1995a, b).

2.3.4 Dry Storage Facilities 7823A, 7827, and 7829

Now closed to further storage, these shielded, retrievable storage facilities are stainless-steel dry wells placed in the ground in Solid Waste Storage Area 5 North. They vary from 8 to 30 inches (20 to 76 centimeters) in diameter and from 10 to 15 feet (3 to 4.6 meters) in depth. The wells are placed on a concrete pad and are held in place by concrete collars or slabs and are surrounded by dirt. Spent fuel and other materials were placed in the wells beginning in 1972. Facility 7823A contain 0.0008 MTHM; facility 7827 contains 0.0837 MTHM; and facility 7829 contains 0.0137 MTHM. Activities to address the vulnerabilities in these facilities include 1) transferring the fuel, 2) adding a new inner liner and relocating fuel in modified units, and 3) overpacking any fuel in suspect condition. These activities are expected to be completed in fiscal year 1996 (DOE 1994b; 1993b; Wichmann 1995a, b).

Table 2.3-1. Oak Ridge Reservation SNF Storage Facilities.

Facility name	Material stored at facility	Heavy metal mass (MTHM)
High Flux Isotope Reactor (HFIR) Pool	HFIR fuel	0.45
Bulk Shielding Reactor (BSR) Pool	BSR & ORR fuel	0.01
Molten Salt Reactor Experiment (MSRE)	MSRE fuel	0.037
Bldg. 4501	Misc. LWR fuels	0.006
Tower Shielding Reactor (TSR)	TSR fuel	0.0092
Facility 7823A	Misc. fuel	0.0008
Facility 7827	Misc. fuel	0.0837
Facility 7829	Peach Bottom	0.0137
Bldg. 7920	Dresden-1 fuels	0.024
Bldg. 3525	Misc. fuels	
Solid Waste Storage Area 6	KEMA Suspension Test Reactor fuela	0.037

a. See Section 2.3.5.6.

2.3.5 Research Reactors

Six existing reactors and one planned reactor are expected to be generating and storing SNF at the ORNL. They are the High Flux Isotope Reactor (currently operating), the Tower Shielding Reactor No. II (shut down in 1992), the Bulk Shielding Reactor (shut down in 1991), the Oak Ridge Research Reactor (shut down in 1987), the Molten Salt Reactor Experiment (shut down in 1969), the KEMA Suspension Test Reactor, and the Advanced Neutron Source Reactor (planned to start up in 2002 or 2003) (ANS 1988).

2.3.5.1 High Flux Isotope Reactor. The High Flux Isotope Reactor is a beryllium-reflected, light water cooled and moderated, flux-trap-type reactor. The reactor uses aluminum-clad fuel plates containing highly enriched uranium-235. The reactor became operational in 1965 and its current power level is 85 megawatts. Reactor missions include production of isotopes for medical and industrial applications, neutron-scattering experiments, and various material irradiation experiments (ANS 1988; DOE 1993b).

The High Flux Isotope Reactor is operating. At the present time there are 62 fuel assemblies amounting to 0.45 MTHM from the research reactor fuel in onsite wet storage. The High Flux Isotope Reactor currently does not use onsite dry storage. If the reactor continues operation through the year 2035, the predicted SNF production will be an additional 110 fuel assemblies totalling 1.58 MTHM. (Holt 1993; ORNL 1992a; Wichmann 1995a, b).

Onsite storage at the reactor facility would have to be expanded to accommodate this projected SNF generation rate. At the present time, reracking the existing storage facility and installing modular dry-storage units at the High Flux Isotope Reactor are being considered. With the installation of the dry-storage units, the potential for future expansion of storage facilities is expected to continue indefinitely (ORNL 1992a).

In the past, SNF assemblies were shipped in casks via truck to the Savannah River Site, and the baseline plan is to continue shipments there. However, the Savannah River Site has limited space and plans to accept only 20 fuel assembly shipments from the High Flux Isotope Reactor. If shipment of SNF to another DOE storage facility is precluded or the commencement of reracking at the High Flux Isotope Reactor is not approved by the DOE, the reactor will be required to shut down because the present pool storage racks cannot accommodate additional fuel after early 1995 (Clark 1994).

2.3.5.2 Tower Shielding Reactor No. II and Tower Shielding Facility Building 7708.

The 1 megawatt Tower Shielding Reactor No. II is a light water moderated, movable tank, research reactor which was shut down in 1992. There are no plans for resuming operations at this time. Tower Shielding Reactor No. II has no containment and was used at ground level or suspended from towers. The research included testing shielding designs and obtaining associated data (ANS 1988; DOE 1993b).

The Tower Shielding Reactor No. II was placed in standby in September 1992 pending DOE direction to prepare the facility for shutdown. At that time, the only existing Tower Shielding Reactor No. II fuel assembly was being stored in the reactor core. For handling and storage purposes, an element is an integral core assembly composed of 4 upper central plates, 4 lower central plates, 12 annular plates, a central plug, and 4 fuel plates. One element, 0.0092 MTHM, is being stored in the reactor core. The corrective actions associated with the vulnerabilities identified in the Spent Fuel Working Group Report for the Tower Shielding Reactor No. II and Tower Shielding Facility Building 7708 are: 1) implement access control to the Tower Shielding Reactor No. II area; 2) implement emergency operating procedures for the Tower Shielding Reactor, i.e., those applicable to a seismic event requiring the experimental area to be checked for hazards by knowledgeable staff before personnel enter the area; 3) implement radiation protection controls requiring that a survey be completed by Radiation Protection personnel to verify acceptable radiation levels prior to granting access to a radiological area; and 4) remove the fork-lift from Building 7708 to eliminate a potential fire hazard and transfer the fuel pins to the Y-12 area for long-term storage to eliminate the potential of an activity release in the same building (completed January 1994). All of these corrective actions plans have been completed and are being implemented (Holt 1993; ORNL 1994; DOE 1994b; Wichmann 1995a, b).

Present options being discussed for storage of this fuel include shipment to the Savannah River Site or onsite dry storage at ORNL. Because this reactor is shut down, no additional elements are expected to accumulate through the year 2035 (Holt 1993; ORNL 1994).

2.3.5.3 Bulk Shielding Reactor. The 2 megawatt Bulk Shielding Reactor is an open pool,

light water moderated and reflected, training and research reactor. This reactor was built in 1951 and shut down in 1991; there are no plans for resumption of operations at this time (ANS 1988; DOE/OSTI 1993; DOE 1993b).

The Bulk Shielding Reactor is shut down and currently has no elements in the reactor or in on-site dry storage. Seventy-three of 90 storage locations are occupied in the onsite wet storage. There are 41 elements from the Bulk Shielding Reactor and 32 elements from the Oak Ridge Research Reactor for a total of 0.010 MTHM in the storage area. As the reactor is shut down, no additional fuel is expected to be added to the inventory through the year 2035; therefore, no expansion of storage facilities onsite is expected (DOE 1993b; Wichmann 1995a, b).

2.3.5.4 Oak Ridge Research Reactor. The Oak Ridge Research Reactor was shut down

permanently in 1987 and has been defueled. Most of the fuel was transported to the Savannah River Site, but some of the fuel was transferred to the Bulk Shielding Reactor pool. Refer to the discussion of the spent fuel inventory in subsection 2.3.5.3 (Holt 1993; ANS 1988; ORNL 1992b).

2.3.5.5 Molten Salt Reactor Experiment. The Molten Salt Reactor Experiment

operated from June 1965 to December 1969 at a nominal power level of 8 megawatts. The purpose of the reactor was to test the practicality of a molten-salt reactor concept for central power station applications. The circulating fuel solution was a mixture of fluoride salts containing uranium fluoride as the fuel. The initial charge was uranium-235, but this was later replaced with a charge of uranium-233. Processing capabilities were included as part of the facility for on-line fuel additions, removal of impurities, and uranium recovery. Following reactor shutdown, the fuel and flush salts were drained to critically safe storage tanks and isolated (Hargrove 1993).

The inventory at the Molten Salt Reactor Experiment consists of approximately 4,650 kilograms (9,514 pounds) of fuels salt mixture. The uranium salt is predominantly uranium-233 (31 kilograms [68 pounds]) with lesser amounts of uranium-234, uranium-235, and uranium-238. The balance of the fuel salt is composed of lithium fluoride (LiF, 64.5 percent), beryllium fluoride (BeF_2, 30.3 percent), and zirconium fluoride (ZrF_4, 5.0 percent). The Molten Salt Experiment contains 0.037 MTHM as the reactor is shutdown, no additional SNF is expected to be generated through the year 2035 (DOE 1993b; Hargrove 1993; Wichmann 1995a, b).

Radioactive material migration has been detected from the storage tanks. This vulnerability could result in unnecessary personnel exposure. If left unabated, radiation levels could increase to a point where access would be difficult. ORNL is determining appropriate corrective actions and expects to implement its corrective action plan during fiscal year 1995 (DOE 1994b; 1993b).

2.3.5.6 KEMA Suspension Test Reactor. The KEMA Suspension Test Reactor was an

experimental fluidized bed test reactor. The fuel, consisting of one core, was placed in Solid Waste Storage Area 6 and totals 0.037 MTHM. The area of Solid Waste Storage Area 6 where the fuel was placed is being managed by DOE as part of waste area grouping 6, an environmental restoration program activity, under the Comprehensive Environmental Response, Compensation, and Liability Act. As the reactor is shutdown, no additional SNF is expected to be generated through the year 2035 (Wichmann 1995a, b).

2.3.5.7 Advanced Neutron Source Reactor. The Advanced Neutron Source Reactor is

currently in the conceptual design stage and has been proposed to be operational in the year 2002 or 2003. Its principal purpose will be for neutron beam experiments, but it will also be used for some isotope production (Holt 1993; DOE/OSTI 1993).

Since the current schedule projects initial operation of the Advanced Neutron Source Reactor in the year 2002 or 2003, spent fuel is not expected to be generated until 2004. Estimates are that 18 elements per year will be discharged. (For handling and storage purposes, an element is an integral core assembly composed of two concentric fuel plates.) A total of 576 SNF elements are predicted to be produced if the reactor is in operation from the years 2002 through 2035 (Holt 1993). As this reactor is in the conceptual design stage, the SNF expected to be generated is not included in the SNF Inventory Data.

3. SPENT NUCLEAR FUEL ALTERNATIVES

This chapter describes the spent nuclear fuel (SNF) management alternatives evaluated by the U.S. Department of Energy (DOE) for this Programmatic Environmental Impact Statement (EIS) that are applicable to the Oak Ridge Reservation (ORR). The ORR generates and stores SNF as a result of reactor research activities. Unlike the Hanford Site, the Idaho National Engineering Laboratory (INEL), and the Savannah River Site (SRS), SNF management is only a minor part of the ORR mission. Therefore, the No Action, Decentralization, and 1992/1993 Planning Basis alternatives could have minimal to no impact on ORR operations. However, the Regionalization and Centralization Alternatives would produce major impacts on ORR operations.

3.1 Description of Management Alternatives

3.1.1 Alternative 1 - No Action

The No-Action Alternative is restricted to the minimum actions necessary for the continued safe and secure management of SNF. As defined, this alternative stipulates no SNF shipments to or from DOE facilities. While the ORR generates and stores SNF as a result of reactor research activities, it does not receive SNF from offsite generators except occasionally in small quantities for specific research assignments. No offsite SNF would be shipped to the ORR under this alternative, nor would SNF be shipped offsite, which could affect the planned shipment of High Flux Isotope Reactor assemblies to the SRS. SNF storage capacity at the ORR for the existing High Flux Isotope Reactor would be adequate only through the year 2002. This could result in the shutdown of this reactor after this date. The proposed Advanced Neutron Source Reactor would need to consider this situation in the design and operation activities.

The environmental effects of the No-Action Alternative are essentially the same as those of current onsite SNF storage and are included in the affected environment discussions covering current site operations.

Implementation of the No-Action Alternative at ORR could lead to the shutdown of the High Flux Isotope Reactor as a result of filling the SNF storage capacity. If the High Flux Isotope Reactor were shutdown, it would eliminate the national capacity to provide transuranic isotopes, eliminate the only western-world source of some medical isotopes, and eliminate the nationally and internationally important capability for research and development in the structure of materials and irradiation effects on materials (Brown 1994a; Hoel 1994).

This alternative for the ORR is not analyzed or discussed further in this or subsequent chapters except in the Facility Accidents section, 5.15.

3.1.2 Alternative 2 - Decentralization

Decentralization involves storage of SNF at or close to generation sites. Under this alternative no offsite SNF would be shipped to the ORR nor would SNF be shipped offsite. The environmental effects of this alternative are the same as those of the No-Action Alternative. The environmental effects of current onsite SNF storage are included in the affected environment discussions covering current site operations. Consequently, this alternative is not analyzed or discussed further in this or subsequent chapters for the ORR. Construction of new SNF storage facilities could be initiated under this option.

The Decentralization Alternative would allow DOE to upgrade and/or replace facilities for the management of the SNF currently located on site. This alternative would allow for continued operation of the High Flux Isotope Reactor by allowing new dry-storage facilities for newly generated and existing SNF in the High Flux Isotope Reactor pool. To allow the High Flux Isotope Reactor to continue operations until a dry storage facility is available, a dry-storage cask may be acquired. DOE could propose an interim, retrievable, aboveground, dry-storage facility for consolidating the SNF at ORR. DOE could also prepare facilities as necessary for the characterization and packaging of SNF for interim storage. The fuel in the Molten Salt Reactor Experiment reactor would need conditioning and stabilization before being relocated to the new facility, or the Molten Salt Reactor Experiment fuel would need special storage facilities (Brown 1994a; Hoel 1994).

3.1.3 Alternative 3 - 1992/1993 Planning Basis

The 1992/1993 Planning Basis Alternative is DOE's documented 1992/1993 plan for the management of DOE and Naval SNF. This plan would include the shipment of SNF from the ORR to other DOE sites as necessary to permit continued operation of ORR research reactors. The environmental effects of current onsite SNF storage are included in the affected environment discussions covering current site operations. Under this alternative, the amount of SNF storage at ORR would not increase. Therefore, this alternative would not have a measurable impact on the environment since there would be no changes to current ORR operations. Consequently, this alternative is not analyzed or discussed further in this or subsequent chapters for the ORR.

At ORR, this alternative would be very similar to the Decentralization alternative except that some SNF would be shipped to SRS. The SNF currently stored at the High Flux Isotope Reactor and Bulk Shielding Reactor pools, and at the Tower Shielding Reactor would be shipped to SRS. Only 20 elements from the High Flux Isotope Reactor can be shipped to SRS unless other arrangements can be made. If the quantity of High Flux Isotope Reactor fuel that can be shipped to SRS is limited to 20 elements, then the High Flux Isotope Reactor will require dry-storage facilities to continue operation. DOE could prepare an interim, retrievable, aboveground, dry-storage facility for consolidating the SNF remaining at ORR. This facility would be similar to the one built under Alternative 2 except it would probably be smaller

(Brown 1994a; Hoel 1994).

3.1.4 Alternative 4 - Regionalization

3.1.4.1 Overview. The Regionalization Alternative consists of two subalternatives.

Subalternative A would distribute existing and new SNF between the Hanford Site, INEL, and SRS by SNF type. Under Subalternative B, SNF would be distributed to either an eastern or western regional site based on geographical location. SNF east of the Mississippi River would be shipped to the eastern regional site (i.e., SRS or ORR). SNF west of the Mississippi River would be shipped to the western regional site (i.e., Hanford Site, INEL, or Nevada Test Site [NTS]). Additionally all Naval SNF would be shipped to only one of the regional sites, but not both. A regional site will only receive all the Naval fuel if also selected as the Naval site. The ORR would be the alternative to the SRS as the eastern regional site, and the NTS would be the alternative to both the Hanford Site and INEL as the western regional site.

3.1.4.2 Regionalization Subalternative B. The following fuels would be transported to

the ORR for storage under the Regionalization Subalternative B:

- Naval-type SNF (if selected)
    - All, including from the INEL, shipyards, and prototypes
- Hanford Production SNF
    - From eastern sites
- Graphite SNF
    - From eastern sites
- DOE-owned commercial SNF
    - From eastern sites, including the West Valley Demonstration Project and B&W Lynchburg
- Experimental - Stainless Steel SNF
    - From eastern sites, including the Foreign Research Reactors, and non-DOE domestic research reactors
- Experimental - Zirconium SNF
    - From eastern sites, including the SRS
- Experimental - Other
    - From eastern sites
- SRS Production and Aluminum SNF
    - From eastern sites, including SRS, Brookhaven National Laboratory, Foreign Research Reactors, and non-DOE domestic research reactors.

All SNF presently in storage at DOE facilities would arrive at the ORR stabilized and canned to the extent necessary for safe transportation. However, this SNF may need to be uncanned, stabilized, prepared, and recanned at the ORR to ensure safe interim storage. New non-DOE domestic and Foreign Research Reactor SNF would arrive in a state necessary for safe transportation but uncanned. This fuel would be stabilized, prepared, and canned at the ORR to ensure safe interim storage. All fuel would be cooled for a minimum of 120 days prior to shipping and 5 years before being placed in dry storage.

The ORR currently has only limited-capacity facilities suitable for receiving, canning, storing, or supporting the research activities necessary for the safe management of SNF. As a result, a new SNF management complex would be built at the ORR under the Regionalization Subalternative B. The SNF management complex would include the following:

- SNF receiving and canning facility
- Technology development facility
- Interim dry storage area
- Expended Core Facility similar to the one currently at the INEL (if selected for Naval fuel receipt).

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before it is placed into dry storage, as necessary. The technology development facility would investigate the applicability of dry storage technologies and pilot-scale technology development for disposal of the various types of SNF. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. If ORR is selected for Naval fuel receipt, Naval SNF would be examined at the Expended Core Facility prior to being turned over for interim storage management.

The SNF management complex which would be built at the ORR under the Regionalization Alternative would have the same components as that built under the Centralization Alternative. The dry storage component would be smaller, however, due to the smaller SNF inventory that would be transported to the ORR under the Regionalization Alternative. The other components of the SNF management complex would be the same general size as those built under the Centralization Alternative. This is because the inventories of new uncanned fuel which would be sent to the ORR under the Regionalization and Centralization Alternatives would be very similar. Additionally, since the major portion of the potential radiological and chemical releases and waste generation rates are associated with these components, the Regionalization Alternative is not analyzed separately but is compared to the Centralization Alternative in a semiquantitative manner.

If the ORR was not chosen as the eastern regional site, all SNF at the ORR would be shipped to the SRS. An exception would be those fuels for which there is no available technology for stabilization to permit safe transport. There is a small quantity of SNF from the Molten Salt Reactor Experiment that is stored in tanks at the ORR. Currently, technology to stabilize this SNF for transport does not exist. Under this alternative, if ORR were to ship SNF to the SRS, this Molten Salt Reactor Experiment SNF would continue to be stored at the ORR until it could be stabilized for safe shipment.

Based on the projected schedule for operation of additional regional SNF storage facilities, the option for acquiring dry storage facilities at the ORR would be maintained to ensure continued High Flux Isotope Reactor operation (Brown 1994a; Hoel 1994).

3.1.5 Alternative 5 - Centralization

3.1.5.1 Overview. Under the Centralization Alternative, all existing and new SNF would

be shipped to one DOE site. There are five Centralization options considered in this EIS: the Hanford Site, the INEL, the SRS, the NTS, and the ORR. If the ORR was chosen as the centralization site, all SNF stored at the Hanford Site, INEL, SRS, and other sites currently storing DOE fuel would be transferred to the ORR.

3.1.5.2 Centralization Alternative Option D. The following fuels would be transported

to the ORR for storage under Centralization Alternative Option D:

- Naval-type SNF
    - From the INEL, shipyards, and prototypes
- Hanford Production SNF
    - From the Hanford Site
- Graphite SNF
    - From the INEL and the Public Service of Colorado
- DOE-owned commercial SNF
    - From the Hanford Site, INEL, West Valley Demonstration Project, and B&W Lynchburg
- Experimental - Stainless Steel SNF
    - From the Hanford Site, INEL, SRS, Foreign Research Reactors, and non-DOE domestic research reactors
- Experimental - Zirconium Clad SNF
    - From the INEL and SRS
- Experimental - Other
    - From the ORNL
- SRS Production and Aluminum Clad SNF
    - From the INEL, SRS, ORNL, Los Alamos National Laboratory, Brookhaven National Laboratory, Foreign Research Reactors, and non-DOE domestic research reactors.

All SNF presently in storage at DOE facilities would arrive at the ORR stabilized and canned to the extent necessary for safe transportation. However, this SNF may need to be uncanned, stabilized, prepared, and recanned at the ORR to ensure safe interim storage. New non-DOE domestic, Foreign Research Reactor, and Naval SNF would arrive in a state necessary for safe transportation but uncanned. This fuel would be stabilized, prepared, and canned at the ORR to ensure safe interim storage. All fuel would be cooled a minimum of 120 days prior to shipping and 5 years before being placed into dry storage. Additionally, Naval SNF would be examined at the ORR before it was turned over for interim storage management.

Although the ORR has a number of experimental and pilot facilities, probably none of them is suitable for receiving, canning, storing, or supporting research activities necessary for the safe management of SNF, unless they are extensively upgraded and expanded. As a result, a new SNF management complex would be built at the ORR under the Centralization Alternative Option D. The SNF management complex would include the following:

- SNF receiving and canning facility
- Technology development facility
- Interim dry storage area
- Expended Core Facility for Naval-type fuel similar to the one currently at the INEL.

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before it is placed into dry storage, as necessary. The technology development facility would investigate the applicability of dry storage technologies and pilot-scale technology development for disposal of the various types of SNF. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. Naval SNF would be examined at a new Expended Core Facility constructed at the ORR prior to being turned over for interim storage management.

The SNF management complex which would be built at the ORR under the Centralization Alternative would have the same components as that built under the Regionalization Alternative. However, the dry storage component would be about 10 times larger, due to the larger SNF inventory that would be transported to the ORR under the Centralization Alternative. The other components of the SNF management complex would be the same general size as those built under the Regionalization Alternative. This is because the inventories of new uncanned fuel which would be sent to the ORR under the Centralization and Regionalization Alternatives would be very similar. Additionally, the major portion of the potential radiological and chemical releases and waste generation rates are associated with these components and would not be significantly different for the Regionalization Alternative. Therefore, this alternative is used as the basis for a semiquantitative comparison with the Regionalization Alternative.

If the ORR is not chosen as the centralization site, all SNF at the ORR would be shipped to the selected centralization site. An exception would be those fuels for which there is no available technology for stabilization to permit safe transport. There is a small quantity of SNF from the Molten Salt Reactor Experiment that is stored in tanks at the ORR. Currently, technology to stabilize this SNF for transport does not exist. Under this alternative, if ORR were to ship SNF to the SRS, this Molten Salt Reactor Experiment SNF would continue to be stored at the ORR until it could be stabilized for safe shipment.

Based on the projected schedule for operation of additional centralized SNF storage facilities, the option for acquiring dry storage facilities at the ORR would be maintained to ensure storage facilities at the ORR would be maintained to ensure continued High Flux Isotope Reactor operation (Brown 1994a; Hoel 1994).

3.2 Comparison of Alternatives

Table 3.2-1 shows a comparison of the alternatives. The Regionalization Alternative column does not include the requirements of the Naval Expended Core Facility, although this facility may be constructed at the site under this alternative. The Centralization Alternative column does include the requirements of the Naval Expended Core Facility, which are presented in Volume 1, Appendix D, since this facility will be built at the site under this alternative.

Table 3.2-1. Comparison of alternatives at the Oak Ridge Reservation.

Parameter	Regionalization Subalternative B at ORR	Centralization Option D[a]
Land for new facilities (acres)	90	120
Site area (acres)	34,667	34,667
Percent of site area	0.26	0.35
SNF-related employment[b]	556	1,118
Baseline site employment	17,082	17,082
Percent of baseline site employment	3.3	6.5
Estimated maximum latent cancer fatalities in 80-km population per year, SNF management operations[c]	2.5 x 10-3	2.5 x 10-3
Estimated cancer fatalities in 80-km population per year, other site operations	2.7 x 10-2	2.7 x 10-2
Estimated probability of cancer fatalities in MEI per year, SNF management operations[c]	3.1 x 10-6	3.1 x 10-6
Estimated probability of cancer fatalities in MEI per year, other site operations	9.2 x 10-6	9.2 x 10-6
Estimated probability of cancer fatality in average worker per year, SNF management operations[c]	1.6 x 10-5	1.6 x 10-5
Estimated probability of cancer fatality in average worker per year, other site operations	1.1x 10-6	1.1x 10-6
Water use (million gallons) per year, SNF management	3.6	6.1
Baseline water use (million gallons) per year, site operations	6,680	6,680
Percent of baseline site water use	0.05	0.09

Electricity use (megawatt-hours) per year, SNF management	23,000	33,000

Table 3.2-1. (continued).

Parameter	Regionalization Subalternative B at ORR	Centralization Option D[a]
Baseline electricity use (megawatt-hours) per year, site operations	1,000,000	1,000,000
Percent of baseline site electricity use	2.30	3.30
Sewage discharge (million gallons) per year, SNF management	3.6	6.1
Baseline sewage discharge (million gallons) per year, site operations	200	200
Percent of baseline site sewage discharge	1.8	3.1
High-level waste (cubic meters) per year, SNF management	0	0
Transuranic waste (cubic meters), SNF management	16	16

a. Centralization Option includes the Naval Expended Core Facility (ECF) results from Volume 1, Appendix D. Centralization without ECF would be the same as for Regionalization.
b. Annual average SNF direct construction and operation jobs over the 10-year period 1995 to 2005.
c. Excludes baseline site operations.
d. Centralization Option is the same as the Regionalization Option for the SNF Management Facility and does not include the Naval Expended Core Facility accident analyses results from Volume 1, Appendix D.

4.0 AFFECTED ENVIRONMENT

4.1 Overview

This chapter describes the existing environmental conditions in areas potentially affected by a programmatic decision to site spent nuclear fuel (SNF) facilities at the Oak Ridge Reservation (ORR) under the Centralization and Regionalization alternatives. Topics were selected for analysis based upon their potential to be affected by these alternatives. Each topic is addressed in the detail necessary to serve as a baseline for assessment of potential environmental consequences in Chapter 5.

4.2 Land Use

The ORR occupies an area of approximately 34,667 acres (140 square kilometers) in eastern Tennessee, in a predominantly rural area about 25 miles (40 kilometers) west of Knoxville. The ORR, which is bordered on the southeast and southwest by the Clinch River, is within the jurisdictional boundaries of the City of Oak Ridge, and also lies within Roane and Anderson Counties (MMES 1989).

The ORR consists of three plants located on three separate sites: the Y-12 Plant (1.3 square miles or 3.4 square kilometers); the Oak Ridge National Laboratory (ORNL) (1.8 square miles or 4.7 square kilometers); and the K-25 Site (1.1 square miles or 2.8 square kilometers) (MMES 1989).

Land use activities at the ORR have historically occurred within the boundaries of the three main plant sites. However, more recently, other ORR lands have also begun to be used. ORR land was first utilized for waste storage in the mid-1940s and for environmental research in the 1950s. A forestry management program was initiated in 1964, and the first comprehensive forest management program was released in 1965. The ORR has been used by research institutions, universities, and government agencies as a site for the study of terrestrial ecology, aquatic ecology, forestry, and agriculture. In 1980, Department of Energy (DOE) designated approximately 21 square miles (54 square kilometers) of undeveloped ORR land as a National Environmental Research Park, which today provides protected land areas for research and education in the environmental sciences (MMES 1989).

Land use outside the three main plant sites falls into seven general categories: multi-purpose research and development; support services; waste management; environmental restoration; natural areas; public recreational park; and national environmental research park (Figure 4.2-1). Approximately 58 percent of the land on the ORR (20,051 acres or 31 square miles) can be classified as undeveloped due to its current land use designation (MMES 1994a).

Land uses bordering the ORR are primarily forest and agricultural. Residential and commercial are the only other significant uses of land in the vicinity, and occur along the northeast and northwest boundary of the ORR in the City of Oak Ridge. The land areas bordering the ORR comprise woodlands (mostly hardwood forests), small farms, and rural residences. Commercial forestry and agriculture account for approximately 76 percent of the total land use in this region (MMES 1994a).

The entire ORR has been placed under the forestry, agriculture, industry, and research zoning classification by the City of Oak Ridge, although this designation does not bind DOE land use decisions on the site. DOE land use plans applicable to the ORR include the Oak Ridge Reservation Site Development and Facilities Utilization Plan, issued in 1989 and updated in 1990; the City of Oak Ridge Comprehensive Plan and Zoning Ordinance, issued in 1985 and updated in 1988; and the Resource Management Plan for the U.S. DOE Oak Ridge Reservation, first issued in 1984.

The region surrounding the ORR has numerous local, state, and national public recreation areas (Figure 4.2-2). Federal outdoor recreation facilities include the Great Smoky Mountains National Park; the Cherokee National Forest; the Cumberland Gap National Historic Park; the Big South Fork National River and Recreation Area; and the Obed Wild and Scenic River (MMES 1994a). State parks near the ORR site include the Frozen Head State Natural Area; the Big Ridge State Park; the Cove Lake State Park; the Fall Creek Falls State Park; the Pickett State Rustic Park; the Panther Creek State Park; and the Hiwassee State Scenic River (MMES 1994a).

Figure 4.2-1. Generalized land use at the Oak Ridge Reservation. Figure 4.2-2. Recreation areas in the vicinity of the Oak Ridge Reservation.

Several lakes exist within the ORR surrounding region, offering year-round recreational activities such as fishing and boating. Wildlife management areas that allow in-season hunting include the Big South Fork National River and Recreation Area, Catoosa Wildlife Management Area, Chuck Swan Wildlife Management Area, and the ORR (MMES 1994a).

Numerous locally funded recreational areas exist near the ORR, the closest being in the City of Oak Ridge. The City of Oak Ridge has 2 golf courses, 11 athletic fields, 36 tennis courts, 12 playground areas, and a public outdoor swimming pool (MMES 1994a).

Clark Center Recreational Park, located on the ORR, is a 90-acre (0.36-square-kilometer) recreational area that is open to the public. The park consists of three shelters, a boat ramp, two softball fields, a swimming area, and a paved access road. It is located approximately 2 miles (3.2 kilometers) south of the Y-12 Plant (MMES 1994a).

The ORR is a controlled area with public access limited to through traffic on Tennessee State Routes 95, 58, 62, 162, and 170 (MMES 1991b).

The site proposed for SNF activities is located within the West Bear Creek Valley Area, located in the western portion of the ORR site near the site boundary. This area of the ORR is currently in the Natural Areas land use category and is designated for future Waste Management land use (MMES 1994a). The area is designated as a Potential Site for a Future Programmatic Initiative in the most recent ORR Master Plan (MMES 1994a). With the exception of an industrial park, land uses bordering the ORR in the area of West Bear Creek Valley are primarily agricultural farmland and commercial forest, with sparsely located residences (MMES 1994a).

The industrial park located just to the south of the proposed SNF management facility on Bear Creek Road houses two organizations. The Scientific Ecology Group, Inc., employs about 700 to

800 people and is a low-level radioactive waste incinerator who's commercial operation began in 1989. International Technology, Inc., operates a hazardous and radioactive waste geotechnical laboratory and a pilot lab, also on Bear Creek Road. This International Technology, Inc., operates a hazardous and radioactive waste geotechnical laboratory and a pilot lab, also on Bear Creek Road. This International Technology, Inc., facility is an extension of the Knoxville office and employs about 10 people at the facility (IT undated a, undated b; SEG undated).

There are no onsite areas that are subject to Native American Treaty rights or contain any prime or unique farmland.

4.3 Socioeconomics

4.3.1 Region of Influence

The socioeconomic information presented in this Programmatic Environmental Impact Statement covers the baseline conditions in the Region of Influence. The Region of Influence is defined as the region in which the principal direct and indirect socioeconomic effects of actions at the ORR are likely to occur and are expected to be of consequence for local jurisdictions. The Region of Influence includes the current residential distribution of the DOE and contractor personnel employed by the ORR, the probable location of offsite contractor operations, and the probable location of labor and capital supporting indirect economic activity linked to the ORR. The Region of Influence includes the counties where 92 percent of DOE and contractor personnel employed by ORR reside. The Region of Influence includes the counties of Anderson, where 34 percent of ORR personnel reside, Knox (36 percent), Roane (16 percent), and Loudon (6 percent) (Truex 1991 [Table J]).

4.3.2 Regional Economic Activity and Population

Regional economic linkage supporting production activity at the ORR occurs primarily with Anderson, Knox, and Roane counties, where most of the supporting contractors offsite and labor and capital supporting indirect economic activity linked to the ORR are located.

4.3.2.1 Anderson County. Most of the industrial and commercial development, dominated by

energy-related companies specializing in manufacturing and research and development in support of the ORR, has occurred in the City of Oak Ridge in Anderson County and Roane County.

The major employment sectors in Anderson County in 1990 were services, manufacturing, government, and retail trade. As a percentage of Anderson County wage and salary employment, the service and manufacturing sector each accounted for 30 percent, the government sector 13 percent, and retail trade 11 percent. The number of employed persons in Anderson County in 1990 was 39,596. Jobs in Anderson County have increased 3 percent annually between 1980 and 1990, and are projected to continue to increase at an average rate of less than 1 percent annually for the next several years (U.S. Department of Commerce 1993). Since 1988, the unemployment level for Anderson County has remained below the national unemployment rate. The unemployment rate reached a low of 4.4 percent in 1990 and has slowly increased to 5.6 percent in 1992 (Anderson County 1993; Department of Economic and Community Development Industrial Development Division 1993).

Approximately 40 percent of the Anderson County population resides in the City of Oak Ridge, with an additional 42 percent in rural areas, and the remaining 18 percent in other municipalities in Anderson County (Anderson County 1993). Between 1980 and 1990, the population in Anderson County increased by over 1 percent from 67,500 to 68,250 persons (0.10 percent annually). The population in Anderson County is projected to continue to grow at an average rate of less than 1 percent annually over the next several years, reaching 76,100 persons by 2004 (U.S. Department of Commerce 1993).

4.3.2.2 Knox County. In Knox County, the major employment sectors in 1990 were service,

manufacturing, retail trade, and government. As a percentage of Knox County wage and salary employment, the service sector accounted for approximately 27 percent, retail trade 20 percent, manufacturing 12 percent, and government 17 percent. The total number of persons employed in Knox County in 1990 was 215,948. Jobs have increased 2 percent annually between 1980 and 1990, and are projected to continue to grow at an average rate of less than 1 percent annually for the next several years (U.S. Department of Commerce 1993). The unemployment rate for Knox County was 4.6 percent in 1992 (Department of Economic and Community Development Industrial Development Division 1992).

Between 1980 and 1990, the population in Knox County increased 5 percent from 319,700 to 335,750. The population in Knox County is projected to continue to increase at an average rate of less than 1 percent annually for the next several years, reaching 377,130 persons by 2004 (U.S. Department of Commerce 1993).

4.3.2.3 Roane County. Development that has occurred in Roane County has been

predominantly residential. In Roane County, the major employment sectors in 1990 were retail trade, manufacturing, services, and government. As a percentage of wage and salary employment in Roane County, retail trade accounted for approximately 26 percent, manufacturing 24 percent, services 22 percent, and government 15 percent. The total number of persons employed in Roane County in 1990 was 24,640. Jobs have increased less than 1 percent annually between 1980 and 1990, and are projected to continue to increase at an average rate of less than 1 percent annually for the next several years (U.S. Department of Commerce 1993). The unemployment rate for Roane County was 6.8 percent in 1992 (East Tennessee Development District 1993).

Between 1980 and 1990, the population in Roane County decreased 2.5 percent, from 48,430 to 47,230. The population in Roane County is projected to increase at an average rate of less than 1 percent annually for the next several years, reaching 52,670 persons by 2004.

4.3.2.4 Loudon County. Total employment in Loudon County in 1990 was 12,560 persons. In

1990, the farming sector accounted for a considerably larger percentage, while the services and government sector accounted for a smaller percentage of total jobs than in Anderson, Knox, and Roane counties (U.S. Department of Commerce 1993). The unemployment rate for Loudon County was 6.7 percent in 1992, dropping from 7.2 percent in 1991 due to increase in construction and mining jobs (East Tennessee Development District 1993).

The population of Loudon County increased by 1 percent annually, from 28,700 in 1980 to 31,300 in 1990. The population of Loudon County is projected to increase at an average rate of less than 1 percent annually for the next several years, reaching 32,900 persons by 2004 (U.S. Department of Commerce 1993).

4.3.2.5 Oak Ridge Reservation. The employment level at the ORR in 1994 was 18,200

persons (Truex 1995). In 1993, there were approximately three full-time-equivalent employment positions involved in SNF operations on the ORR (Brown 1994b). Employment levels are expected to decrease to 16,980 by the year 1999 and are projected to remain constant through the year 2004 (Fritts 1994).

4.3.2.6 Aggregate Regional Economic and Demographic Baseline. For the purposes of establishing a regional baseline to compare potential impacts for the programmatic analyses in Section 5.3, regional economic and demographic data for the four-county Region of Influence were aggregated to form one region (Table 4.3-1).

The total population of the Region of Influence, shown in Table 4.3-1, is projected to be 489,230 persons in 1995, and is projected to grow at an annual average rate of less than 1 percent, reaching 538,820 persons in 2004. The labor force of the Region of Influence is also projected to grow at an annual average rate of less than 1 percent, growing to 360,000 persons in 2004. The total employment in the Region of Influence is projected to grow at an annual average rate of approximately 1 percent, growing from 292,700 jobs in 1995 to 338,070 jobs in 2004.

4.3.3 Public Service, Education and Training, and Housing Infrastructure

4.3.3.1 Police and Fire. ORR fire protection services are provided by the fire departments on the reservation. The ORR fire departments have mutual aid agreements among themselves and with the City of Oak Ridge (MMES 1989).

Twelve city, county, and state law enforcement agencies provide police protection in the Region of Influence. In 1990, the largest law enforcement agency in the four-county Region of Influence was in Knoxville, with 296 sworn officers (FBI 1991). Law enforcement on the ORR is provided by the City of Oak Ridge Police Department. Security enforcement, established to meet the Atomic Energy Act and mission requirements, is provided by the prime management and operations contractor (MMES 1989).

Table 4.3-1. Aggregate regional economic and demographic indicators for ORR. a

Years	Regional employment	Regional labor force	Regional population
1995	311,700	332,000	506,600
1996	315,100	335,700	510,300
1997	318,600	339,400	51,400
1998	322,100	343,100	517,900
1999	325,700	346,900	521,700
2000	329,300	350,700	525,500
2001	331,500	353,000	528,800
2002	333,700	355,400	532,100
2003	335,900	357,700	535,500
2004	338,000	360,000	538,800
2005	340,300	362,400	542,200
Average Annual Growth Rate	0.9%	0.9%	0.7%

a. Sources: U.S. Department of Commerce 1993; East Tennessee Development District 1993.

Note: Aggregate region includes the Roane, Anderson, Loudon and Knox Counties. Labor force projection developed for this study.

4.3.3.2 Education and Training. Four school districts, Anderson, Knox, Loudon, and Roane, provide public education services in the Region of Influence. In 1990, the four school districts had an average daily membership of 66,510 students. Knox County had the highest average daily membership of 50,324 students (Tennessee Department of Education 1992).

4.3.3.3 Housing. Between 1980 and 1990, the number of housing units in the Region of

Influence increased 14 percent from 181,299 to 206,234. In 1980 and 1990, the homeowner vacancy rates in the Region of Influence averaged 1.4 and 1.5 percent, respectively (Census 1982, 1991).

Housing additions in the Region of Influence peaked at 3,882 units in 1990, but declined to 3,662 in 1991. In 1992, however, housing additions increased to a total of 3,880 units (East Tennessee Development District 1993).

4.4 Cultural and Paleontological Resources

4.4.1 Archeological Sites and Historic Structures

For approximately 10,000 years, people have inhabited the ORR site. A cultural resources survey conducted in 1975 did not identify any cultural resources on the proposed site for the SNF management facilities. Therefore, no prehistoric or historic resources are expected to be located on the proposed site for the SNF management facilities (Fielder 1975).

4.4.2 Native American Resources

In the early 1700s, the Overhill Cherokee lived in the area that is now the ORR. The tribe remained in the area until 1838, when it was moved forcibly to Oklahoma under Federal orders (Oakes et al. 1984a). While the Cherokee may retain cultural affiliation with their ancestral home, there are no known Native American resources on the proposed site for the SNF facilities.

4.4.3 Paleontological Resources

The ORR is underlain by nine geologic formations or groups ranging in age from Early Cambrian to Early Mississippian. On the ORR, the only formations known to contain fossils are the Knox Group (which does not usually contain fossils but does contain small coiled gastropods in a limestone bed); the Chickamauga Limestone (which contain many fossils including brachiopods, bryozoans, gastropods, cephalopods, crinoid stems, corals, and trilobites); the Sequatchie Formation (which does not have an abundant supply of fossils in the formation, but does contain large brachiopods, colonial corals, and bryozoans within several thin beds of gray limestone); the Rockwood Formation (which contains crinoid stem fossils in the upper half of the formation); and the Fort Payne Chert, which contains many casts of crinoid stems (McMaster 1988). No unusual paleontological remains from the ORR were identified.

4.5 Aesthetics and Scenic Resources

Visual or scenic resources comprise the natural and man-made features that give a particular environment its aesthetic qualities. These features form the overall impression that a viewer receives of an area or its landscape character. Visual sensitivity is assessed by considering the activities, awareness, and expectations of the public within a given area. High visual sensitivity exists when a view is rare, unique, or in other ways special to viewers. Medium visual sensitivity exists when a view is similar to others in the area or is of secondary importance relative to other significant aspects of the area. Low visual sensitivity exists when a view has little value to viewers and an intrusion or alteration of that view would have no impact on viewers.

Scenic resources at the ORR and the surrounding area are set in a landscape of heavily forested,

predominantly parallel ridges with steep slopes interspersed with relatively flat valleys, known physiographically as the Ridge and Valley Province. Due to the rolling topography at the ORR, approximately 62 percent of the reservation is located on slopes of less than 14 percent (MMES 1994a).
The reservation is framed by the Clinch River at the west, south, and eastern boundary, and by Poplar Creek to the north. The vegetation present at the reservation is primarily a mixture of deciduous and coniferous forest covering approximately 80 percent of the site (MMES 1989). Roads providing public access to the interior of the site include State Routes 95 and 58, along with Bethel Valley Road (Figure 4.2-1).

The location of the proposed SNF management facilities, under the Centralization Alternative, is set along the north side of Bear Creek Road west of State Route 95, between the extension of Blair Road and State Route 95, at the western end of the reservation. The public has access to Bear Creek Road west of State Route 95. As a result, the entrance to the site will be visible to traffic on Bear Creek Road (MMES 1994a). The proposed facilities would consist of 90 acres (0.36 square kilometer), 85 of which would be located within security fencing. The facility would have the appearance of industrial buildings ranging in height from one to three stories. The site would receive and unload up to one truck shipment per day, or a total of 5,500 truck shipments over the 40-year operation period. The site would be set on the south side of Pine Ridge midway between the top of the ridge, with elevations ranging between 900 and 1,100 feet (274 and 335 meters), and Bear Creek Valley, with an elevation of approximately 700 feet (213 meters) (TVA 1987). Chestnut Ridge, located south of Pine Ridge on the reservation, faces the site.

Under the Regionalization Alternative, the location of the proposed SNF facility would remain the same but would be reduced in area and extent. Operation of the facilities would also be reduced, resulting in the receipt of fewer truck shipments over the 40-year operation period.

The viewshed surrounding the ORR consists mainly of sparsely populated rural land. The City of Oak Ridge, along the northeast portion of the site, is the only adjacent urban area. Views of DOE facilities from areas surrounding the reservation include those from public roadways such as Interstates 40 and 75, U.S. Route 70, and State Routes 62, 162, and 95. The reservation can also be viewed from the south bluffs along the Clinch River. The Great Smoky Mountains National Park and the Blue Ridge Mountains are approximately 70 miles southeast of the ORR and are generally not visible from the reservation (MMES 1989). In general, views are limited by the rolling terrain, heavily forested vegetation, and hazy atmospheric conditions.

The developed areas of the ORR could generally be classified as having low visual sensitivity. The remainder of the site ranges from low to moderate visual sensitivity. Of the jurisdictions that may be affected by the construction and operation of the proposed SNF facilities, only the City of Oak Ridge in its Comprehensive Plan has provided policies that promote elements of scenic resource enhancement and preservation through streetscape design, landscaping, lighting, and signage improvements at entrances to the urban area and the city center. One entrance to the urban area that promotes scenic resource enhancement and preservation is Illinois Avenue, crossing the northeast portion of the ORR (City of Oak Ridge 1989).

4.6 Geologic Resources

This section provides a general description of the geology, soils, geologic resources, and seismic, volcanic, and other geologic hazards at the ORR and surrounding area. This section also describes any existing impacts to the geology and geologic resources resulting from past and present human activities at the ORR.

4.6.1 General Geology

As shown in Figure 4.6-1, the ORR lies entirely within the western portion of the Valley and Ridge Province, near the boundary with the Cumberland Plateau. The Valley and Ridge Province, a zone of folded and faulted sedimentary rocks in the Appalachian mountain belt, is characterized by numerous linear ridges and valleys that trend approximately southwest-northeast as shown on Figure 4.6-2. The rocks of the Valley and Ridge Province in eastern Tennessee are Early Cambrian to Early Mississippian in age. A stratigraphic column for the ORR southeast of East Fork Ridge (south of Interstate 95) is shown on Figure 4.6-3. A generalized geologic map of the ORR is shown on Figure 4.6-2. Most of the ORR is underlain by the Rome Formation and Conasauga, Knox, and Chickamauga Groups, sedimentary rocks of Cambrian and Ordovician age (Hatcher et al. 1992). A geologic cross-section of the ORR is shown on Figure 4.6-4.

The Rome Formation consists of interbedded sandstone, siltstone, and shale. The base of the Rome is not exposed in the Oak Ridge area, but consideration of regional structural trends suggests that the Rome Formation is in fault contact with younger rocks. On the Copper Creek and Whiteoak Mountain thrust sheets the Rome is 120-180 meters (390-590 feet) thick, and on the Kingston thrust sheet it is over 450 meters (1,500 feet) thick (Hatcher et al. 1992). Thrust sheets carry the name of the fault at their front, or northwest edge. Faults are shown on Figure 4.6-4. The transition between the sandstones of the Rome Formation and the overlying Pumpkin Valley Shale of the Conasauga Group occurs rather abruptly, as the more resistant sandstones grade into the less resistant shales.

Figure 4.6-1. Generalized map of the southern Appalachian geologic provinces showing the location of the Oak Ridge Reservation.
Figure 4.6-2. Geologic map of the Oak Ridge Reservation. Figure 4.6-3. Stratigraphy of the ORR on the Whiteoak Mountain and Copper Creek Thrust Sheets. Figure 4.6-4. Generalized geologic profile beneath the Oak Ridge Reservation.

The formations of the Middle to Upper Cambrian Conasauga Group are primarily limy shales interlayered with shales, limestones, and siltstones. At the ORR, the Conasauga Group is divided into six units (see Figure 4.6-3). Approximately 450 meters (1,500 feet) of the Conasauga Group is exposed at the ORR. The transition from the Conasauga Group to the overlying Knox Group is gradational, with the dominant rock type shifting from shale and dolomitic limestones in the Conasauga Group to dolomites with occasional limestones in the Knox Group.

At the ORR, as in the rest of eastern Tennessee, the Upper Cambrian to Lower Ordovician Knox Group is divided into five formations, which are shown on Figure 4.6-3. The Knox Group is approximately 914 meters (3,000 feet) thick on the ORR and consists primarily of thick beds of silty dolomite (Hatcher et al. 1992). Above the Knox Group is the Middle to Upper Ordovician Chickamauga Group. See Figure 4.6-3 for the units that comprise the Chickamauga on the Whiteoak Mountain thrust sheet.

Surface relief at the ORR typically ranges from a ridge crest to valley floor relief of 30 to 69 meters (100 to 225 feet) (Lee and Ketelle 1987). Surface elevations on the ORR range from a maximum of 413 meters (1,356 feet) National Geodetic Vertical Datum at the crest of Melton Hill (see Figure 2.1-2) to a minimum of 226 meters (740 feet) National Geodetic Vertical Datum near Mile 10 on the Clinch River (Boyle et al. 1982). A series of crests and ridges that trend northeast and southwest make up the ORR (Figure 4.6-2). In general, the crests or ridges are composed of resistant sandstone or dolomite beds. Limestone and shale generally form the ridge flanks and valley bottoms.

Sinkholes, large springs, caves, and other karst features are common in the Knox Group, and those parts of the ORR underlain by limestones and dolomites (certain units in the Conasauga, Knox, and Chickamauga Groups) are for the most part classified as karst terranes. In a karst terrane there is very little surface drainage because of the diversion of surface waters to subterranean (underground) flow routes. These subterranean routes are caves and other enlarged openings that have formed through dissolution of the carbonate rock. Four major karst zones exist at the ORR that appear to be related to distinct stratigraphic horizons (Ketelle 1982). These four karst zones all occur in the Knox Group, specifically in the Copper Ridge Dolomite, near the base of the Chepultepec Dolomite, near the top of the Chepultepec Dolomite, and in the Kingsport Formation (Ketelle 1982). Karst development is also present to varying degrees in the carbonate rocks of the Conasauga Group, most notably in the Maynardville Limestone. In Bear Creek Valley, karst development in the Maynardville Limestone causes variations in discharge along Bear Creek as the surface water and groundwater components vary in dominance (Lee et al. 1988). Bear Creek Valley is underlain by calcareous shale and limestone of the Conasauga Group (Bailey and Lee 1991). Although no site-specific geologic characterization has been conducted at the West Bear Creek Valley site, it appears the proposed SNF management facility is located over the lower Conasauga Group strata not normally characterized by karst development.

The soils occurring in the ORR are predominantly clay, although chert and quartz are also present. Soils developed in the Conasauga are clay. Hatcher et al. (1992) provides detailed information on soils. Many of the soils belong to the broad group of Ultisols, which are reddish or yellowish, moderately acidic soils. Entisols, which are thin surface soils over bedrock that show little development of soil horizons, are found locally in steeply sloping areas. In addition, small areas of inceptisols are found in alluvial areas adjacent to streams (Boyle et al. 1982). These are young soils, also with minimal horizon development. Soils on the ORR tend to retain moisture and are typically 90 percent saturated below a depth of 3 meters (10 feet) (Ketelle and Huff 1984). Depths of soil profiles on the ORR vary from 15 centimeters (6 inches) on slopes to 18 meters (60 feet) over dolomites in the Knox Group (Boyle et al. 1982).

4.6.2 Geologic Resources

The known resources of the geologic units exposed on the ORR are limited to industrial minerals, including quarry rock and clay. These industrial minerals are of low unit value and can be found elsewhere. Quarry rock has been mined at several major locations throughout ORR, but no quarries are currently in operation (Oakes et al. 1984b).

There has been extensive seismic testing by private companies along roads traversing the ORR to explore for deep accumulations of oil and gas. Land has been leased by major oil companies west and northwest of K-25 off the ORR; no exploratory wells have been drilled and the status of oil and gas resources underlying the ORR is unknown at this time (Oakes et al. 1984b).

4.6.3 Seismic and Volcanic Hazards

There is no evidence that there has been volcanic activity in the vicinity of the ORR for more than 1 million years.

4.6.3.1 Historical Seismic Activities. From 1811 to 1975, only five major earthquakes or

earthquake series have affected the ORR area. These are the New Madrid, Missouri, earthquake series, and the Charleston, South Carolina; Knoxville, Tennessee; Strawberry Plains, Tennessee; and Kingston, Tennessee earthquakes. The New Madrid earthquake series of December 1811 to February 1812 produced maximum Modified Mercalli Intensity disturbances of V to VI in the ORR area. A Modified Mercalli Intensity V earthquake is felt by everyone. Typical damage includes some dishes, windows, etc. being broken, a few instances of cracked plaster, and unstable objects being overturned. A Modified Mercalli Intensity VI earthquake is also felt by all, and many become frightened and run outdoors. Typical damage includes some heavy furniture moved and a few instances of fallen plaster or damaged chimneys. A Modified Mercalli Intensity of VI is approximately equal to a Richter Magnitude 4.7 (Griggs and Gilchrist 1977).

The 1844 Knoxville earthquake, which occurred approximately 40 kilometers (25 miles) from the ORR, had an epicenter shaking of Modified Mercalli Intensity VI. The Charleston earthquake of 1886 had a Modified Mercalli Intensity of V to VI at the ORR, as did the 1913 Strawberry Plains earthquake. The 1930 Kingston earthquake, 8 kilometers (5 miles) northwest of the ORR, had an epicenter shaking of Modified Mercalli Intensity V (Boyle et al. 1982). When intensities are reported at epicenters, they would have been less at the ORR, as intensities diminish with distance.

A Modified Mercalli Intensity VII earthquake does not typically cause severe damage, but rather causes breaking of weak chimneys at the roof line, cracks in masonry, and the falling of plaster, loose bricks, and stones. No Modified Mercalli Intensity VII earthquakes have been recorded at the ORR during the 165-year period from 1811 to 1975. Earthquakes with a Modified Mercalli Intensity of VII generally occur one order of magnitude less frequently than earthquakes with a Modified Mercalli Intensity of V to VI. Seismic records indicate that the ORR is located in a region of moderate seismic activity having an average of one to two earthquakes per year, with seismic activity occurring in bursts followed by long periods of no activity. No deformation of recent surface deposits has been detected, and seismic shocks from the surrounding, more seismically active areas are dissipated by distance from the epicenters (Boyle et al. 1982).

The underlying structure of the ORR is complex due to the extensive faulting and deformation characteristic of the region. There are three regional thrust faults in the ORR area, the Kingston, Whiteoak Mountain, and Copper Creek Faults (see Figure 4.6-4). All three strike to the northeast and dip to the southeast. Latest movement on the faults was Late Pennsylvanian/Early Permian (280 to 290 million years ago); consequently, they are not considered to be capable faults at present (Oakes et al. 1984b). According to 10 CFR Part 100, Appendix A, capable faults include those faults that have exhibited movement at or near the ground surface at least once during the past 35,000 years or movement of a recurring nature within the past 500,000 years.

4.6.3.2 Seismicity Studies. Four seismic studies have been specifically conducted for the

ORR for which the results have been published. Three of these studies have been summarized by Beavers et al. (1982), and were performed by Blume in 1973, Dames and Moore in 1973, and TERA in 1981. The first two studies were directed toward the seismic hazards at the K-25 Site (formerly the Oak Ridge Gaseous Diffusion Plant), and the latter focused on ORNL (Beavers et al. 1982).

These three early studies presented preliminary analysis and conclusions. The fourth study (McGuire et. al. 1992), is a more recent seismic analysis for the entire ORR. DOE Standards 1020 (DOE 1994a) and 1024 (DOE 1992b) summarize the results of recent seismic analyses at DOE sites and show that the peak ground accelerations for the ORR for 500-year, 1,000-year, 2,000-year and 5,000-year seismic events are 0.08g, 0.13g, 0.19g and 0.29g, respectively.

Figure 4.6-5 presents the site specific uniform hazard response spectra for horizontal rock motion which were approved by DOE Headquarter's Office of Nuclear Energy on August 25, 1993 (Benedict 1993). The response spectra noted on Figure 4.6-5 are for top of rock sites.

4.6.3.3 DOE Seismic Design Criteria. DOE Order 5480.28 requires that the Design and

Evaluation Guidelines for Department of Energy Facilities Subjected to Natural Phenomena Hazards, UCRL-15910 (Kennedy et al. 1990), be used for natural phenomena hazards design and evaluation criteria until a DOE standard is issued. In April 1994, DOE-STD-1020 was issued to replace UCRL-15910.

At the SNF management facility site the categorization of each structure, system and component would be determined in accordance with DOE Standard DOE-STD-1021, Performance Categorization Criteria for Structures, Systems and Components at DOE facilities Subjected to Natural Phenomena Hazards.

A maximum horizontal ground surface acceleration of 0.19g at ORR is estimated to result from an earthquake that could occur once every 2,000 years (DOE, 1994a). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. DOE orders, standards and site specific procedures require that potential seismic hazards for existing and new facilities be evaluated on a facility specific basis.

Figure 4.6-5. Oak Ridge- Site Specific Uniform Hazard Response Spectra for Horizontal Rock Motion 4.7 Air Resources

4.7.1 Climatology

Except where indicated, the information presented in this section is derived from Fitzpatrick 1982 and NOAA 1991.

The ORR site is located within the Great Valley of Tennessee in which the Cumberland Plateau borders to the northwest and the Great Smoky Mountains lie to the southeast. Climate at the ORR is influenced by these terrain features.

The climate and meteorology in the lowlands are generally unlike those that occur in the more mountainous regions of the southeastern United States. Daytime winds are usually southwesterly, while night-time winds are northeasterly, at least during periods of light wind. The elevated ridges of the Cumberland Plateau and Great Smoky Mountains encompassing the valley impede wind speeds to a moderate degree. The Cumberland Plateau retards the drainage of cold air from the northwest into the valley during winter, thus reducing the probability of extremely cold temperatures.
The average daily temperature at the Oak Ridge National Weather Service Station, considered representative of the ORR, was 14.2oC (57.5oF) for the period of record 1961-1990. The average daily temperatures varied from a low of 2.6oC (36.7oF) in January to a high of 24.8oC (76.6oF) in July.

Humidity data are maintained at the Knoxville National Weather Service with a period of record from 1961-1990. Records are reported for humidity readings during the hours 0100, 0700, 1300, and 1900 (local time). The 0700 and 1900 values will be reported here. The mean 0700 relative humidity was 86 percent with the mean monthly maximum of 92 percent occurring in July and August, and the mean monthly minimum of 80 percent occurring during February and March. The mean 1900 relative humidity is 63 percent with the mean monthly maximum of 68 percent occurring in September and December, and the mean monthly minimum of 52 percent occurring in April.

The mean wind speed measured at the Oak Ridge National Weather Service over the period 1969 to 1984 was 2.0 meters per second (4.4 miles per hour) at an average height above ground of about 13 meters (41 feet). At a meteorological tower at the ORR the mean wind speed was 2.1 meters per second (4.7 miles per hour) at about 10 meters (33 feet) above ground level. Wind speeds in the ORR area are influenced by local topographic conditions and are generally higher on top of the ridges than in the valleys.

The wind direction above the ridgetops and within the valleys tends to follow the orientation of the valleys. The prevailing wind direction is from the southwest, with a secondary maximum from the northeast during the winter, spring, and summer months. The situation is reversed in the fall.

Figure 4.7-1 shows 1992 wind roses for the 10- and 60-meter levels of the Y-12 west meteorological tower. The annual 10-meter level on the Y-12 west meteorological tower shows peak wind direction frequencies from the west-southwest, with the secondary peak from the northeast. The annual 60-meter level shows wind direction frequencies from the northeast and a secondary peak from the southwest. Since the valley floor is inclined, cold air will drain down the valley during stable periods. Both wind rose levels show the influence of the topography on the wind direction.

Damaging winds are uncommon in the region. Peak gusts recorded in the Great Valley are generally in the 27- to 31-meter-per-second (60- to 70-mile-per-hour) range for the months of January through July; in the 22- to 27-meter-per-second (50- to 60-mile-per-hour) range for August, September, and December; and in the 16- to 20-meter-per-second (35- to 45-mile-per-hour) range in October and

November. The maximum gust reported in the region was about 37 meters per second (82 miles per hour); it occurred during the month of March at Chattanooga. Knoxville has reported a peak gust of about 33 meters per second (73 miles per hour) and Oak Ridge a gust of about 26 meters per second (59 miles per hour).

Winter is the wettest of the seasons in the ORR area; March and December are the wettest months and October the driest. The annual average precipitation measured at the ORR in Bethel Valley from 1944 through 1964 was 130.9 centimeters (51.5 inches), while the annual average precipitation for the National Weather Service in Oak Ridge from 1961 through 1990 was 137.2 centimeters (54.0 inches). The maximum monthly precipitation was 48.9 centimeters (19.3 inches) in July 1967, while the maximum rainfall in a 24-hour period observed at the Oak Ridge National Weather Service was recorded in August 1960 at 19.0 centimeters (7.5 inches).

Figure 4.7-1. Wind Roses for Y-12 west tower (@ 10 and 60m) for 1992 at ORR.

On average there are about 51 thunderstorm days per year at the Oak Ridge National Weather Service station. The summer thunderstorms, which may be accompanied by strong winds, heavy precipitation, or, less frequently, hail, occur primarily during the late afternoon and evening hours. Summer thunderstorms are attributable primarily to convective activity resulting from solar heating of the ground and generally moist atmospheric conditions. Thunderstorm activity in the winter months is attributable mainly to frontal activity.

The Great Valley of Tennessee is infrequently subject to tornadoes. The western half of the state has experienced three times as many tornadoes as the eastern half, where the ORR is located. The ORR did experience a tornado from a severe thunderstorm on February 21, 1993 (MMES 1993b). The tornado path passed the Y-12 Plant in an east-northeast direction for approximately 21 kilometers (13 miles), ending just north of Knoxville. The wind speeds associated with this tornado ranged from 18 meters per second (40 miles per hour) to nearly 58 meters per second (130 miles per hour), depending on the location along the path (MMES 1993b).

Hurricanes are rarely sustained once they reach as far inland as the Great Valley due to the rapid loss of energy when they are cut off from their source of moisture. The remnants of nine hurricanes that were classified as devastating after crossing the coastline of the United States have traversed the borders of Tennessee in the last 70 years.

Atmospheric dispersion improves as wind speed increases, conditions become more unstable, and the depth of the mixing height increases. The transport and dispersion of airborne material are direct functions of air movement. Transport directions and speeds are governed by the general patterns of air flow (and by the nature of the terrain), whereas the diffusion of airborne material is governed by small-scale, random eddying of the atmosphere (i.e., turbulence). Turbulence is indicated by atmospheric stability classification. Data collected at Y-12 for calendar year 1992 were classified using the vertical temperature difference (i.e., between 60- and 10-meter levels) in accordance with Nuclear Regulatory Commission Regulatory Guide 1.23 (NRC 1986). The atmospheric conditions are unstable (i.e., Stability Classes A through C) approximately 5 percent of the time, neutral (Class D) approximately 43 percent of the time, and stable (Classes E through G) approximately 52 percent of the time at the 10-meter level.

4.7.2 Air Monitoring Networks

This section discusses the air monitoring networks of the ORR. Atmospheric emissions from the ORR facilities are monitored by stack monitors and by a network of ambient air monitoring stations on the perimeter of each major ORR operations area (ORNL, the Y-12 Plant, and K-25 Site), as well as on the ORR perimeter and throughout the surrounding communities.

4.7.2.1 Radiological Monitoring Network. Twelve of the ambient air monitoring stations on the perimeter of the Y-12 Plant routinely monitor total suspended uranium particulates. The ORNL perimeter monitoring network consists of four stations that monitor radiation parameters (i.e., gross alpha, gross beta, iodine, and gamma-emitting radionuclides). Samples of atmospheric tritium are also collected monthly at selected perimeter stations.

4.7.2.2 Nonradiological Monitoring Network. The perimeter ambient air monitoring network for K-25, which was upgraded in 1986, consists of five stations that monitor airborne particulate contaminants such as nickel, lead, and chromium. In 1988, two additional ambient air monitoring stations were installed at the K-25 Site. These stations measure polychlorinated biphenyls, furans, dioxins, and hexachlorobenzene that may accidentally be released due to the Toxic Substance Control Act incinerator (located in the K-25 area).

4.7.3 Air Releases

4.7.3.1 Radiological Emissions. Table 4.7-1 presents the radioactive emissions to the atmosphere from each of the three ORR areas (ORNL, K-25, and Y-12) during 1992.

Table 4.7-1. Radioactive atmospheric emissions (curies/yr) from the ORR during 1992.

Isotope	ORNL	K-25	Y-12
Hydrogen-3 (Tritium	2.14 x 103	0.0 x 100	0.0 x 100

4.7.3.2 Nonradiological Emissions. Table 4.7-2 presents the nonradiological emissions to the atmosphere from each of the three ORR areas during 1992.

4.7.4 Air Quality

4.7.4.1 Radiological. A summary of ORR airborne radionuclide emissions for 1992 is presented in Table 4.7-1. The GENII environmental transport and dose assessment model was used to calculate the effective dose equivalent resulting from these radionuclide emissions. These results are summarized in Table 4.7-3. The maximum effective dose equivalent at the ORR boundary is 3.3 millirem. This is 33 percent of the corresponding National Emissions Standard for Hazardous Air Pollutants. The collective effective dose equivalents to the estimated population of 910,000 persons within 80 kilometers (50 miles) of the proposed SNF facility is 52 person-rem. This dose is 0.019 percent of the natural background radiation affecting this population. Background radiation doses are presented in Figure 4.7-2.

4.7.4.2 Nonradiological. The ORR is located in Anderson and Roane Counties, in the Eastern Tennessee-Southwestern Virginia Interstate Air Quality Control Region 207. As of 1993, the areas within this Air Quality Control Region were designated as attainment with respect to all National Ambient Air Quality Standards (CFR 1993a).

One Prevention of Significant Deterioration ambient air quality Class I area can be found in the vicinity of ORR. That is the Great Smoky Mountains National Park, located approximately 48 kilometers (30 miles) southeast of ORR. Since the promulgation of the Prevention of Significant Deterioration regulations, no such permits have been required for any emissions source at the ORR.

Ambient air quality within and near the ORR is monitored for total suspended particulates, particulate matter less than 10 microns in diameter (PM10), fluorides, lead, and sulfur dioxide, which was monitored until August 1990 (MMES 1993a). Ambient air quality monitoring data collected at the ORR are summarized in Table 4.7-4.

Table 4.7-2. Nonradiological emissions at ORR (kg/yr).

Pollutant	Y-12	ORNL	K-25
Carbon monoxide	36,807	45,872	12,119

Chrome	8-hour	5	b	c	c

a. Ambient air quality data (MMES 1992a, 1991a).

b. Not monitored.

c. Not estimated because the potential release is negligible.

d. It is conservatively assumed that data for particulate matter less than 10 microns in diameter (PM10) are total suspended particulates data.

e. State standard.

f. State guideline.

Table 4.7-4 presents the effects of site emissions on local ambient air quality. Concentrations of pollutants obtained from ambient air quality monitoring data are added to pollutant concentrations determined from air dispersion modeling using site-specific emission rates. The resulting sum is used to compare total concentrations to applicable Federal and state criteria pollutant and hazardous/toxic air pollutant guidelines and regulations. All pollutant concentrations of existing emissions at the ORR are below applicable regulations.

4.8 Water Resources

4.8.1 Surface Water

The hydrologic system on the ORR is controlled by the Clinch River (MMES 1994a). The Clinch River flows about 350 miles (560 kilometers) from its headwaters in southwest Virginia, near Tazewell, to its confluence with the Tennessee River at Kingston, Tennessee. Its drainage area is about 4,410 square miles (11,340 square kilometers) (Boyle et al. 1982). All water that drains from the ORR enters the Clinch River and subsequently the Tennessee River.

Flow in the Clinch-Tennessee River system is regulated by multipurpose dams of the Tennessee Valley Authority (TVA). Three dams operated by the TVA control the flow of the Clinch River. Norris Dam, approximately 31 miles (50 kilometers) upstream of the ORR, was constructed to provide flood control and low-flow regulation. Melton Hill Dam, south of the ORNL site, controls the flow of the Clinch River near the ORR. Its primary function is power generation. Flood control is a secondary function. Watts Bar Dam, also used for power generation, is located on the Tennessee River and influences the lower reaches of the Clinch River by creating backwaters that can extend as far upstream as Melton Hill Dam (Oakes et al. 1987).

Heavy precipitation in the area causes localized flooding, primarily in the City of Oak Ridge (MMES 1994a) and along the Clinch River. A flood analysis was prepared by the TVA for the ORR (TVA 1991). This analysis provides flood elevations for flooding events in the Clinch River and major tributaries on the ORR. Flooding events analyzed ranged from the 25-year flood (a flood with a 1 in 25 chance of being equaled or exceeded in any given year) to probable maximum flooding events. Approximate 500-year floodplains (1 in 500 chance in any given year) are shown on Figure 4.8-1. Site-specific surveys should be performed to more accurately determine locations of flooding elevations.

The average discharge from Melton Hill Dam between 1963 and 1979 was 5,300 cubic feet (150 cubic meters) per second (Boyle et al. 1982). The average summer (June-September) discharge for the same period was 4,730 cubic feet (134 cubic meters) per second. However, power is generated at Melton Hill Dam to help meet peak loads and, as a result, flow in the Clinch River is pulsed. Periods of no flow at the dam can be followed by periods of flow of up to 20,000 cubic feet (560 cubic meters) per second. Variations in the flow of the Clinch River affect the flow of the tributaries on the ORR. For example, during peak periods of power generation at Melton Hill Dam, flow from White Oak Creek can be blocked or even reversed. The 1992 minimum monthly release at the Melton Hill Dam occurred in May and was 3.5 billion cubic feet (100 million cubic meters) (MMES 1994a).

The ORR is drained by a network of tributaries of the Clinch River (Figure 4.8-1). A statewide stream classification system based on water quality, water use, and resident aquatic biota designates most streams on the ORR for fish and aquatic life, irrigation, and livestock watering (MMES 1992a). For each designated classification, specific water quality criteria are applied, forming the basis for facility-specific National Pollutant Discharge Elimination System permits. No rivers designated as wild and scenic occur on the ORR.

Stream flow on the ORR varies primarily with seasonal precipitation (MMES 1994a). Precipitation varies throughout the year, with the winter months and July experiencing the highest rainfall. Five-year cycles of wet and dry seasons are also evident. Precipitation is lost through evaporation, vegetation uptake, runoff to streams, and to groundwater recharge through the soil.

The drainage pattern on the ORR is a weakly developed "trellis" pattern (Lee and Ketelle 1987). The majority of the small streams are located in the northeast-southwest-trending valleys. Some streams flow across the ridges through water gaps that may have formed due to the presence of structural features (Golder Associates 1988). Karst topography also affects the appearance of surface drainage patterns, primarily because of the presence of sinkholes in areas underlain by the Knox Group.

Figure 4.8-1. Locations of the Clinch River and tributaries on the Oak Ridge Reservation.

A number of wetlands occur on the ORR (MMES 1994a). Wetlands are surface features periodically saturated with or covered by water, and have hydric soils and hydrophytic plants. With regards to water resources issues, wetlands absorb flood waters and improve groundwater quality. Characteristic wetlands of the ORR region include forested wetlands along creeks, wet meadows and marshes associated with streams and seeps, and emergent communities in shallow embayments and ponds.

The abundance of limestone and dolomite is reflected by the presence of calcium bicarbonate in the surface waters at the ORR. Water hardness is typically moderate, and the concentrations of total dissolved solids normally range between 100 and 250 milligrams per liter (Rogers et al. 1988).

Measurements of surface water quality and flow are made at a number of sampling stations on and around the ORR. Reference surface waters, ORR surface waters receiving effluents, off-reservation surface waters, and effluents are all sampled and analyzed as part of the surface water monitoring program. Water samples are collected and analyzed for radiological and nonradiological content, and the results are reported yearly in publicly available environmental reports (e.g., MMES 1993a; 1992a; 1991a).

Although bedrock characteristics differ somewhat among the watersheds of these streams, most of the observed differences in water quality are attributed to different contaminant loadings (Rogers et al. 1988). Both wastewater discharges and the groundwater transport of contaminants from waste disposal sites affect water quality in ORR streams. Consequently, a number of surface streams have been contaminated by activities at the ORR (DOE 1992c). In the past, contaminants have been directly released to surface waters on the ORR. Indirect releases via shallow groundwater discharge to surface water streams have occurred in the past and continue to date. For example, activities at the ORNL have contaminated reaches of the White Oak Creek system and Melton Branch with radionuclides, metals, and other hazardous chemicals. The stream channel of Upper East Fork Poplar Creek in the Y-12 Plant area has been contaminated from past activities at the Y-12 Plant. Activities at the Y-12 Plant have also contaminated surface water and groundwater in the Bear Creek Valley with nitrates, volatile organics, radionuclides, and metals beyond the ORR boundary. Operations at the Y-12 Plant have also contaminated Lower East Fork Poplar Creek beyond the ORR boundary with mercury, other metals, organics, and radionuclides. Ultimately, contaminants from all these streams have been discharged to the Clinch River, where sediment contamination is a primary concern.

All effluent discharges to streams are required to meet specified National Pollution Discharge Elimination System permit limits (MMES 1994a). For example, the quality of water in East Fork Poplar Creek partially reflects the influence of the Y-12 Plant and the City of Oak Ridge municipal wastewater treatment facility. Each of the ORR installations has a National Pollution Discharge Elimination System permit. In 1992, more than 400 National Pollution Discharge Elimination System stations were sampled, requiring more than 65,000 water analyses. Significant reductions in the number of noncompliances for the ORR between 1991 to 1992 were engineered especially with respect to the Y-12 Plant. The K-25 Site was in 99.9 percent compliance with discharge limits. The Y-12 Plant was in 99.5 percent compliance with discharge limits. The ORNL was in 99 percent compliance with discharge limits. Table 4.8-1 lists the National Pollution Discharge Elimination System noncompliances by installation **and discharge point.** At the Y-12 Plant, ORNL, and the K-25 Site, radiological effluents were well within limits at all effluent monitoring locations (MMES 1993a).

Water quality in the Clinch River is affected by ORR activities, by contaminants introduced upstream from the ORR, and by flow regulation at the Tennessee Valley Authority dams. Stream impoundment has resulted in a rise in water temperatures, sediment retention, and contaminant adsorption. Several institutions routinely monitor water quality in the Clinch River. Both the Tennessee Valley Authority and the U.S. Geological Survey monitor just below Melton Hill Dam. The Tennessee Department of Environment and Conservation maintains a monitoring station on the Clinch River about 2 miles (3.2 kilometers) below the mouth of Poplar Creek and the K-25 Site (Rogers et al. 1988).

The Clinch River supplies most of the water to the ORR, the City of Oak Ridge, and other cities along the river (MMES 1994a). Major surface water uses in the Oak Ridge area include withdrawals for

Table 4.8-1. 1992 National Pollutant Discharge Elimination System noncompliance at the ORR.

industrial and public water supplies, commercial and recreational navigation, and other recreational activities such as fishing, boating, and swimming. Five public water supplies are located downstream of the ORR (MMES 1994a). The two nearest are the K-25 Site water treatment plant and the Kingston water treatment plant. These are located 2.5 miles (4 kilometers) above and 21 miles (34 kilometers) below the mouth of Poplar Creek, respectively.

4.8.2 Groundwater

Groundwater beneath the ORR is heavily influenced by the site geologic structure (Solomon et al. 1992). Geologic units of the ORR are assigned to two broad hydrologic groups: (1) the Knox aquifer, formed by the Knox Group and the Maynardville Limestone (carbonate rocks), in which flow is dominated by solution conduits and which stores and transmits relatively large volumes of water; and (2) the ORR aquitards, made up of all other geologic units of the ORR (sandstones, siltstones, and shales), in which flow is controlled by fractures. These aquitards may store fairly large volumes of water, but they transmit only limited amounts.

The hydrologic groups are divided into the near-surface stormflow zone, the vadose zone, the groundwater zone, and the aquiclude (Solomon et al. 1992). Flow in the 3- to 7-foot-deep (1- to 2-meter) deep stormflow zone accounts for approximately 90 percent of the water moving laterally through the subsurface. The stormflow zone can transmit some water laterally to surface streams at approximately 39 feet (12 meters) per hour through large pores; however, less than 1 percent of the total void volume of the zone is large pores. Most water mass resides and migrates through smaller pores in the stormwater zone at rates 10 to 100 times slower. Advective-diffusive exchange between pores substantially reduces contaminant migration rates. A vadose zone between the stormflow and groundwater zones exists at the ORR except where the water table is at the land surface, such as along perennial stream channels. The vadose zone is thickest beneath ridges and thinnest or non-existent in valleys. Most groundwater movement through the vadose zone occurs vertically during precipitation events and occurs along discrete features such as fractures in the bedrock. Measurements of permeability, recharge, and conductivity vary considerably by locality in the vadose zone. Generally, conductivity is less than an inch (on the order of millimeters to centimeters) per day. The groundwater zone is the continuously saturated area in which the remaining 10 percent of lateral sub-surface water movement occurs. Very little water movement occurs in the deep aquiclude layer.

The Knox aquifer is the only true aquifer of the ORR and is the primary source of sustained natural flow in perennial streams such as Upper White Oak Creek, East Fork Poplar Creek, and Bear Creek (Solomon et al. 1992). In some places the Knox aquifer can supply large quantities of water to wells. Flow volumes are significantly larger than in the aquitards, and flow paths are deeper. The potential groundwater flow path length in the Knox aquifer is also substantially greater than in the aquitards--on the order of a few miles or kilometers. The one strongly suspected instance of groundwater flow across the ORR boundary occurs along the northeastern portion of Chestnut Ridge, where water in the Knox aquifer travels along a geological strike northeastward from the Y-12 Plant accross the ORR boundary. In March 1994, DOE announced that elevated levels of four industrial solvents (carbon tetrachloride, chloroform, tetrachloroethylene, and trichloroethylene) had been found in groundwater wells in the Knox aquifer, 2,500 feet east of the Y-12 Plant in the Union Vally Industrial Park (Bowdle 1994). The same solvents are found in groundwater monitoring wells at the Y-12 Plant. DOE is currently investigating the size and direction of the solvent plume. No proposed SNF management facilities would be sited in areas overlying the Knox aquifer.

Virtually all mobile water in the aquitards is discharged to local streams within the ORR. Flow in the ORR aquitards is shallow; about 98 percent occurs at depths of less than 100 feet (30 meters) (Solomon et al. 1992). Water in the aquitards travels through the uppermost part of the groundwater zone along flow paths of up to 1,000 feet (300 meters) in length before being discharged to local surface waters. Groundwater flow volume decreases and solute residence times increase sharply with depth. Mean solute transport rate in the stormflow zone is on the order of meters per hour, but in the intermediate and deep intervals of the groundwater zone, representative transport rates are as low as a few centimeters per year. Additionally, the mobility of most contaminants on the ORR is greatly reduced by sorption onto subsurface solids. Residence times of solutes near the water table in the aquitards range from a few days to a few years. In the intermediate and deep intervals, estimates of residence times range from hundreds to tens of thousands of years. Most groundwater flow in the aquitards occurs through a few widely spaced (23-164 feet [7-50 meters]) permeable regions.

Water in the aquitards is at best a marginal resource (Solomon et al. 1992). A typical well yields under 0.25 gallon per minute (0.02 liter per second). In many places, wells are incapable of producing enough water to support a typical household.

Background groundwater quality at the ORR is generally good in the surficial aquifer zones and poor (because of high total dissolved solids) in the bedrock aquifer at depths greater than 1,000 feet (300 meters) (DOE 1993a). Water in the surficial aquifer is typically a nearly neutral to moderately alkaline calcium bicarbonate type. Transport processes in the subsurface (including diffusion from fractures to the rock matrix, sorption, and exchange) have resulted in an accumulation of contaminants downgradient of the sources (Solomon et al. 1992).

Contaminated sites in need of environmental restoration include past-practice waste disposal sites, waste storage tanks, spill sites, and contaminated inactive facilities (DOE 1993a). Principal groundwater contaminants that exceed applicable standards at the Y-12 Plant include volatile organics, nitrates, heavy metals, and radioactivity (MMES 1993a). Exact rates and extent of the contamination have not been quantified. However, data indicate that most contamination remains relatively close to the source. As an example of the maximum extent of groundwater contamination, nitrate has been detected in wells 3,000 feet (920 meters) southwest of the source. Nitrate is relatively mobile in groundwater and may therefore define the maximum horizontal migration of contamination. At the ORNL, 20 waste area groupings have been identified and are being monitored for groundwater contamination. Monitoring data from each waste area group will direct further groundwater studies. At the K-25 Site, organics are the most commonly detected groundwater contaminants. Elevated levels of gross alpha and gross beta have also been detected in a number of wells. Uranium and technetium-99, respectively, appear to be primarily responsible for the elevated gross alpha and gross beta levels. The metals chromium, lead, arsenic, and barium have been detected in a number of wells at concentrations exceeding drinking water standards. Elevated levels of fluoride and polychlorinated biphenyls have also been detected in some wells.

In 1989, the Oak Ridge National Laboratory implemented an off-site residential drinking water quality monitoring program (MMES 1993a). The program objective is to document groundwater quality near the ORR and to monitor the potential impact of ORR operations on groundwater quality.

Parameters monitored under the program include volatile organics, metals, anions, and various radioactive parameters. Radionuclides and organics have been detected in some of the off-site monitoring wells, however, concentrations have been below drinking water standards. Fluoride has been detected at concentrations exceeding drinking water standards in one of the off-site wells. The high fluoride concentrations and accompanying high pH are most likely attributed to natural chemical reactions in the substrate. No sources or flow paths have been identified for the other constituents detected.

Although surface water sources provide the main portion of potable water supplies in the area, groundwater does provide for some domestic, municipal, farm, irrigation, and industrial use (MMES 1993a). Single-family wells are common in areas not served by public water supplies (MMES 1992a). However, because of the abundance of surface water and its proximity to the points of use, almost no groundwater is used at the ORR (DOE 1993a). Only one supply well exists on the reservation; it provides a supplemental supply to an aquatics laboratory.

All aquifers at the ORR are classified as Class II (DOE 1993a). Class II groundwaters are current and potential sources of drinking water and those waters having other beneficial uses. There are no sole-source aquifers beneath the ORR (DOE 1993a). Water rights are not an issue in the region.

4.9 Ecological Resources

Land for the ORR was primarily in agricultural use at the time of acquisition by the DOE's predecessor agencies. Clearings for orchards and pastures were on some of the upper slopes, rocky areas, and ridgetops; tillage crops were raised on the lower slopes and bottomland. Severe soil erosion also occurred in some areas. Except on very steep slopes, most of the forests had been cut for timber, though not necessarily cleared for agricultural uses. Natural plant communities have since reestablished themselves on most of the ORR, although many areas are maintained as pine plantations or nonforested areas (ORNL 1988). Plant communities at the ORR are characteristic of the intermountain regions of central and southern Appalachia. Approximately 10 percent of the ORR has been developed since it was withdrawn from public access; the remainder of the site has reverted to or been planted with natural vegetation (MMES 1989).

Biotic media, such as fish and deer, that may be affected by the releases or that might provide pathways of exposure to people are included in the environmental surveillance programs at the ORR. Bluegill (Lepomis macrochirus) and whitetail deer (Odocoileus virginianus) are routinely analyzed for radionuclide contamination. In 1992, the maximum doses to man projected from actual measurements were within the applicable regulatory requirements (see Section 4.12.4 and 4.12.5) (MMES 1993a).

The following describes biotic resources at the ORR, including terrestrial resources, wetlands, aquatic resources, and threatened and endangered species. Within each biotic resource area, the discussion focuses first on the ORR as a whole and then on the proposed site.

4.9.1 Terrestrial Resources

The vegetation of the ORR has been categorized into seven plant communities (Figure 4.9-1) (Parr and Pounds 1987). The pine and pine-hardwood forest is one of the most extensive plant communities on the ORR. Important species of this community type include loblolly pine (Pinus taeda), shortleaf pine (Pinus echinata), and Virginia pine (Pinus virginiana) (Parr and Pounds 1987). Another abundant plant community is the oak-hickory forest, which is commonly found on ridges throughout the ORR. Northern hardwood forest and hemlock-white pine-hardwood forest are the rarest plant community types on the ORR. Currently, timber on the ORR is managed by thinning young stands and harvesting mature stands. Timber is also sold when an area is to be cleared for development (Bradburn 1994). A total of 899 species, subspecies, and varieties of plants have been identified on the ORR (Mann et al. 1985; Cunningham and Pounds 1991).

Thirty areas on the ORR that are representative of the vegetational communities of the southern Appalachian region or that possess unique biotic features have been designated by DOE as National Environmental Research Park Reference Areas (Pounds et al. 1993). Several of these areas are wetlands.

Figure 4.9-1. Oak Ridge Reservation plant communities. The ORR provides habitat for a large number of animal species. Twenty-six species of amphibians, 33 species of reptiles, 169 species of birds, and 39 species of mammals have been recorded (Parr and Evans 1992). Habitats dominated by hardwood trees support the greatest number of wildlife species, followed in order by wetlands, old fields, and pine plantations (ORNL 1988).

Game animals present on the ORR include the whitetail deer, which has been hunted on the reservation since 1985 (MMES 1992b). Animals commonly found on the ORR include the American toad (Bufo americanus), eastern garter snake (Thamnophis sirtalis), Carolina chickadee (Parus carolinensis), northern cardinal (Cardinalis cardinalis), white-footed mouse (Peromyscus leucopus), and raccoon (Procyon lotor). Raptors, such as the red-shouldered hawk (Buteo lineatus) and great horned owl (Bubo virginianus), and carnivores, such as the gray fox (Urocyon cinereoargenteus) and mink (Mustela vison), are ecologically important groups on the ORR (Loar et al. 1981).

The surrounding countryside has much greater proportions of cultivated fields, pastures, and residential areas than the ORR, and much more fragmented forest cover. Because of the greater continuity of forests and a lack of human disturbance over much of the ORR, wildlife species that are affected by forest fragmentation offsite may find an abundance of suitable habitat on the ORR. Thus, the ORR may serve as a refuge for wildlife and as a source of wildlife migration (ORNL 1988).

Vegetative communities of the West Bear Creek site are typical of the ORR as a whole, composed of second-growth oak-hickory forest and mixed pine-hardwood forest. There are some loblolly pine plantations adjacent to the northern edge of the powerline right-of-way and between the right-of-way and Bear Creek Road (Rosensteel 1994). There are no National Environmental Research Park Reference Areas on the SNF site. Fauna of the site would also be similar to those expected throughout the ORR.

4.9.2 Wetlands

Wetlands on ORR have recently been evaluated based on National Wetland Inventory maps and field surveys of vegetation (Cunningham and Pounds 1991). Soils and hydrology were not specifically considered in this survey. Wetlands on the ORR include emergent, scrub/shrub, and forested wetland located in embayments of the Melton Hill and Watts Bar Reservoirs that border ORR; along all the major streams, including East Fork Poplar Creek, Poplar Creek, Bear Creek, and their tributaries; in old farm ponds; and around groundwater seeps.

Several well-developed emergent communities greater than 1 acre (0.004 square-kilometers) occur in shallow embayments of the reservoirs. The emergent communities typically grade into marshy areas adjoining forested wetlands. Most forested wetland sites are typically less than 1 acre, although forested wetlands greater than 1 acre are found along the East Fork Poplar Creek and the Clinch River near Gallahar Bridge. Ponds on the ORR vary in size and support diverse flora and fauna. Other wetland areas exist along utility rights-of-way, especially in Bear Creek and Melton Valleys (Cunningham and Pounds 1991).

Originating on the lower slopes of Pine Ridge are several headwater tributary systems of Grassy Creek that flow from north to south across the West Bear Creek site. The stream valleys contain forested wetlands. A powerline right-of-way crosses the stream bottoms, where the vegetation is dominated by wetland scrubs and herbaceous species, of which a portion adjacent to the west boundary has been designated a National Environmental Research Park Natural Area for the protection of state-listed rare plant species.

4.9.3 Aquatic Ecology

Aquatic habitats on or adjacent to the ORR range from small, free-flowing streams in undisturbed watersheds to larger streams with altered flow patterns because of dam construction. These aquatic habitats include tailwaters, impoundments, reservoir embayments, and large and small perennial streams.

Sixty-four fish species have been collected on or adjacent to the ORR. The minnow family has the largest number of species and is numerically dominant in most streams (ORNL 1988). Representative fish species of the Clinch River in the vicinity of the ORR are shad (Dorosoma sp.), herring (Alosa sp.), common carp (Cyprinus carpio), catfish (Ictalurus sp.), bluegill, crappie (Pomoxis sp.), and drum (Aplodinotus sp.) (Loar et al. 1981). Important fish species taken commercially in the ORR area are common carp and catfish. Recreational species include crappie, bass (Micropterus sp.), sauger (Stizostedion canadense), sunfish (Lepomis sp.), and catfish (Rector 1994).

Results from the ORNL monitoring program indicate varying degrees of impact on the benthic communities of the small perennial streams resulting from past waste disposal practices. Portions of these streams are dominated by pollutant-tolerant insect species (Loar 1992).

Portions of certain streams on the ORR have been designated by DOE as National Environmental Research Park Aquatic Natural or Reference Areas. These areas generally represent nonimpacted streams or reaches of streams and are used primarily for reference areas as part of the biological monitoring and abatement programs or environmental remediation efforts at ORR facilities. There are presently eight Aquatic Natural Areas and nine Aquatic Reference Areas (Pounds et al. 1993). Many of the Aquatic Natural Area streams contain the Tennessee dace, a species listed as in need of management by the State of Tennessee.

The aquatic resources occurring in the area of the West Bear Creek site are limited to several headwater tributary systems of Grassy Creek originating on the lower slopes of Pine Ridge and flowing from north to south across or adjacent to the site. Fifteen fish species have been recorded in Grassy Creek.

A National Environmental Research Park Aquatic Reference Area is located along Grassy Creek and its tributaries, one of which runs through the eastern portion of the proposed site. Grassy Creek has a diverse assemblage of invertebrates and fish species for a stream its size. The ORR uses Grassy Creek as a reference area for studies of other streams affected by site development (Pounds et al. 1993).

4.9.4 Threatened and Endangered Species

Federally and state-listed threatened, endangered, or other special-status species designated by the Endangered Species Act and/or the state's Nongame and Endangered Species and the Rare Plant Protection and Conservation Laws that have a reasonable potential for occurrence on the ORR are listed in Table 4.9-1. The table indicates that 25 of these species have recent records of occurrence on the ORR. The potential occurrence of the other 22 species listed is due to historical record, proximity to geographic ranges, and migratory nature of species. No critical habitat for threatened and endangered species, as defined in the Endangered Species Act (U.S. DOI 1992), exists on the ORR.

Although not all of the ORR has been surveyed for rare species, 33 different areas harboring rare plant species (federally or state-listed) have been designated as National Environmental Research Park Natural Areas by DOE (Pounds et al. 1993). The plant species listed in Table 4.9-1 are scattered among these Natural Areas but are not excluded from other areas on ORR. These Natural Areas are designated to provide protection for rare plant and animal species. The designated areas include river and creek bluffs, calcareous barrens, mesic forests, flood plains, and wetland cover classes.

No animal species listed by the Federal Government as threatened or endangered are known to reside on the ORR (Kroodsma 1987). The bald eagle (Federal, endangered) is a winter visitor to Watts Bar Lake and Melton Hill Lake. None of the species listed in Table 4.9-1 have been recorded on the proposed West Bear Creek Valley site. The purple fringeless orchid occurs in a Natural Area adjacent to the western border of the site (Pounds et al. 1993). Pink lady's-slippers are expected to occur throughout the Pine Ridge area (MMES 1992a). Preferred habitat within the site indicates a greater potential for occurrence of the barn owl, black vulture, Cooper's hawk, red-shouldered hawk, and sharp-shinned hawk. Surveys of the proposed site will be required to verify the presence of these and other plant and animal species.

Table 4.9-1. Federally and state-listed threatened, endangered, and other special-status species that potentially occur on or in the vicinity of the Oak Ridge Reservation.

Common name	Scientific name	Status[b]

e. Observed near ORR on Melton Hill and Watts Bar Lakes.

4.10 Noise

The major noise sources within the ORR occur primarily in developed operational areas and include various facilities, equipment, and machines (e.g., cooling towers, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles). Major noise sources outside the operational areas consist primarily of vehicles and railroad operations. At the site boundary, away from most of these activities, noise from these sources would be barely distinguishable from background noise levels. Some disturbance of wildlife activities might occur on the ORR as a result of operational activities and construction activities.

Sound-level measurements have been made around the ORR in the process of testing sirens and preparing support documentation for the Atomic Vapor Laser Isotope Separation site (Cleaves 1991). The acoustic environment along the ORR site boundary in rural areas and at nearby residences away from traffic noise is typical of a rural location, with the average day-night sound level in the range of 35 to 50 decibels, A-weighted. Areas near the site within Oak Ridge are typical of a suburban area with the average day-night sound level in the range of 53 to 62 decibels, A-weighted (EPA 1974). The primary source of ORR noise at the site boundary and at residences near the site boundary is traffic, including trucks, private vehicles, and freight trains. During peak hours, plant vehicular traffic is a major contributor to traffic noise levels in the area. In addition, some noise due to air cargo and business travel via commercial air transport through the airport at Knoxville can be attributed to ORR operations. Section 4.11 (Traffic and Transportation) discusses vehicular, air, and rail transportation.

The State of Tennessee has not established specific numerical environmental noise standards applicable to the ORR. The City of Oak Ridge has specified allowable noise levels at property lines as shown in Table 4.10-1.

During a normal week, about 17,000 employees travel to the ORR each day in private vehicles from surrounding communities. In addition, both government-owned and private trucks pick up and deliver materials at the site. Based on the number of employees, it was estimated that about 33,000 vehicle trips are generated to and from the site each day; mostly on Tennessee State Routes 58, 62, 95,

Table 4.10-1. City of Oak Ridge maximum allowable noise limits applicable to the ORR.

Adjacent uses	Where measured	Maximum sound level (dBA)b
All residential districts	Common lot line	50
Neighborhood business district	Common lot line	55
General business district	Common lot line	60
Industrial district	Common lot line	65
Major streets	Street lot line	75
Secondary residential streets	Street lot line	60

a. Source: City of Oak Ridge (1984).

b. Decibels, A-weighted.

and 162, which pass through the ORR and are open to the general public. Both government-owned and private trucks pick up and deliver materials at the site. The contribution of ORR operations to traffic volumes along these routes, especially during peak traffic periods, affects noise levels in the immediate vicinity of the ORR and through the City of Oak Ridge.

Use of the railroad branches from the CSX and the Norfolk Southern Corporation lines to deliver and pick up shipments at the ORR may cause some noise impacts along these routes. Twice a week service is scheduled to Y-12 from the CSX line. However, only 60 cars were delivered in 1993. Service to K-25 is provided as needed. Only three or four trains serviced K-25 in 1993. However, two or three trains per week may be required beginning in 1994 (Pearman 1994). Noise sources from rail transport include diesel engines, wheel-track contact, and whistle warnings at rail crossings.

4.11 Traffic and Transportation

Traffic congestion is measured by level of service. Level of service A represents free flow of traffic. Level of service B is in the range of stable flow, but the presence of other users in the traffic stream begins to be noticeable. Level of service C is in the range of stable flow, but marks the beginning of the range of flow in which the operation of individual users becomes significantly affected by interactions with others in the traffic stream. Level of service D represents high-density, but stable, flow. Level of service E represents operating conditions at or near the capacity level. Level of service F is used to define forced or breakdown flow. The calculated level of service are for discrete locations along a segment. Level of service will most likely be worse in urban areas and better in rural areas along the segment.

The Region of Influence for the ORR includes site roads and regional roads in Anderson, Blount, Knox, Loudon, and Roane counties. Regional and local transportation routes are presented in Figure 4.11-1 and Figure 2.1-2.

Primary roads on the ORR include Tennessee State Routes 95, 62, 162, and 170 (Bethel Valley Road), and Bear Creek Road. Except for Bear Creek Road, all are public roads. The remaining roads on the ORR are private. Interstate 75 and Tennessee State Routes 162, 62, and 61 form a loop around ORR.

Figure 4.11-1. Oak Ridge Reservation regional transportation map. Bear Creek Road, Bethel Valley Road, Tennessee State Routes 62 and 95 experience high average traffic and peak hour volume. Other areas on the site that have traffic problems include Scarboro Road, security entrances, and intersections.

Current baseline traffic (i.e., 1995) along segments providing access to the ORR is projected to contribute to differing service level conditions (TDOT 1993). Tennessee State Route 61 would operate at level of service D between Interstate 75 at Norris and U.S. Route 25W at Clinton, and at level of service C between U.S. Route 25W at Clinton to Tennessee State Route 62 east of Oliver Springs. Tennessee State Routes 58 and 170 (providing access from the east), as well as Bear Creek Valley Road, would operate between level of service D and B. Tennessee State Routes 62 and 95 would operate at widely varying levels of service in the vicinity of ORR. Tennessee State Route 62 would operate at a level of service E between Tennessee State Route 95 at Oak Ridge and Tennessee State Route 170. Tennessee State Route 95 would operate at a level of service E between Tennessee State Route 61 and Tennessee State Route 62 at Oak Ridge.

Road reconstruction, widening, modification of interchanges, and new interchange construction projects are planned for segments of Bear Creek Valley Road, Scarboro Road, and Tennessee State Routes 58, 62, and 95 (Johnson, C. 1994; MMES 1991b).

Current baseline traffic along segments providing regional access to the ORR is projected to contribute to differing service level conditions. Interstate 40 passes within 5 miles (8 kilometers) to the south of the ORR. It has a level of service of A to B between U.S. Route 27 at Harriman to Interstate 75, which passes northeast about 11 miles (18 kilometers) and south about 3 miles (5 kilometers) of the ORR. U.S. Route 25W passes the ORR about 10 miles (16 kilometers) to the east and northeast. It has a level of service of D to E between Interstate 75 at Lake City to Tennessee State Route 131.

In 2001, when site-related impacts are at their highest along segments providing access to the ORR, background traffic is projected to contribute to differing service level conditions for local roads. Tennessee State Route 61 would operate at level of service D between Interstate 75 at Norris and U.S. Route 25W at Clinton and level of service C between U.S. Route 25W at Clinton to Tennessee State Route 62 east of Oliver Springs. Tennessee State Routes 58 and 170 as well as Bear Creek Valley Road would operate between level of service D and B. Tennessee State Routes 62 and 95 would operate at widely varying levels of service in the vicinity of the ORR, with a level of service F between Tennessee State Route 95 at Oak Ridge and Tennessee State Route 162. U.S. Routes 11/70 would operate at level of service F between Tennessee State Route 131 and U.S. Routes 11E/11W Split. All other local roads operate at level of service E or better (University of Tennessee 1993). Interstate 40 has a level of service B to D between U.S. Route 27 at Harriman to Tennessee State Route 162.

The level of service was calculated using average daily traffic counts (TDOT 1990) and standard parameters (ITE 1991; TRB 1985; Rand McNally 1993).

No public transportation service exists in the City of Oak Ridge. Other modes of transportation within the Region of Influence include railways and waterways. Railroad service in the Region of Influence is provided by CSX Transportation and the Norfolk Southern Corporation. Two main lines serve the ORR. A CSX Transportation spur line serves the ORR site as well as the City of Oak Ridge. Waterborne transport in the Region of Influence is via the Clinch River, which provides an alternative mode of transportation to the Oak Ridge area. The Clinch River waterway has rarely been used for DOE business, and no designated port facilities exist for such purposes (Corps 1991).

McGhee Tyson Airport in Knoxville, 40 miles (64 kilometers) from the ORR, receives jet air passenger and cargo services from both national and international carriers. The closest air transportation facility to ORR is Atomic Airport in Oliver Springs. Numerous other private airports are located throughout the Region of Influence (DOT 1991).

4.12 Occupational and Public Health and Safety

The Department of Energy's Oak Ridge Reservation released chemicals and small quantities of radionuclides to the environment from operations at all facilities during 1992. These releases are quantified and characterized in detail in the Oak Ridge Environmental Report for 1992. This release information, along with estimates of the potential consequences resulting from these releases, is summarized in greater detail within sections 4.7, 5.7, 4.8, and 5.8 for the purpose of characterizing the existing radiation and chemical environment. The ORR baseline data presented within this section are expected to remain essentially constant between 1992 and 1995 (the year in which SNF operations are expected to commence).

Health effects from radiation are presented here as the risk of fatal cancer. This risk is in the ratio of the health risk estimator (risk of fatal cancer per rem of exposure). The value of this estimator for exposures to the public is 5 x 10-4 for fatal cancers. The corresponding estimator for exposures to workers is 4 x 10-4.

4.12.1 Atmospheric Emissions and Doses

Table 4.7-1 in Section 4.7 illustrates the breakdown of radioactive emissions to the atmosphere from each of the three ORR operations areas (ORNL, K-25, and Y-12), during 1992. The calculated total dose of 3.3 millirem/year due to 1992 operations, to the maximally exposed individual at the site boundary, is well within the 10 millirem/year limit given in 40 CFR Part 61 (the U.S. Environmental Protection Agency's National Emission Standards for Hazardous Air Pollutants) (MMES 1993a).

The concentrations at the ORR boundary of all radionuclides released to the atmosphere from the three operations areas in 1992 were less than 1 percent of the DOE Derived Concentration Guide, which is based upon an exposure of 100 millirem; this equates to a dose of less than 1 millirem (MMES 1993a).

The associated isotopic gaseous release cancer risks are presented within Section 4.12.4.

Table 4.7-2 in Section 4.7 presents the chemical releases for 1992 in a fashion analogous to Table 4.7-1. All of these releases are within permitted levels. The associated chemical release cancer risks are presented within Section 4.12.6.

4.12.2 Groundwater/Surface Water Contamination and Doses

Referring to the various water contamination data presented in Section 4.8, it was found that a plausible 0.62 mrem/year of site operation could be incurred by a potential maximally exposed individual at the site boundary due to water ingestion, fish ingestion, and other associated factors (see **Table 4.12-1) (MMES 1993a).**

Additionally, a dose of 17 mrem/year of site operation could be incurred by this potential maximally exposed individual, due to external exposure from contaminated liquid effluents (see Table 4.12-1). Fifteen mrem/year of this dose would result from a hypothetical individual fishing for 250 hours/year along Poplar Creek near the K-25 storage areas (MMES 1993a).

Table 4.12-1. Summary of estimated radiation dose to public from 1992 operations at ORR.

Pathway	Location of maximally exposed individual	Committed effective dose equivalent to maximally exposed individual (mrem)	Collective committed effective dose equivalent (person-rem)a
Gaseous effluents	Nearest resident to		
Inhalation plus direct radiation from air, ground, and food chains	Y-12 Plant	2.7	29
	ORNL	0.06	2
	K-25 Site	0.53	21
	ORR	3.3	52
Liquid effluents			
Drinking water	Gallaher	0.2	0.85
Eating fish	Poplar Creek	0.4	1.0b
Other activities	Poplar Creek	0.02	
Direct radiationb	Clinch River shoreline	2	
	Poplar Creek (K-25 Site)	15	

a. Within 80 kilometers (50 miles) of the ORR.

b. Includes doses from all liquid pathways (MMES 1993a).

The associated cancer risks related to these doses are presented in Section 4.12.4.

4.12.3 External Gamma Radiation

External gamma radiation measurements were made with thermoluminescent dosimeters at locations coinciding with the ambient air locations. The average external gamma radiation level at the ORR perimeter for 1992 was 7.6 microroentgens per hour. All of the measurements were well within the range of typical values for cities in the United States (MMES 1993a).

4.12.4 Radiation Dose and Health Effects Summary (Public and ORR Workers)

A summary of the effective dose equivalents to the hypothetical maximally exposed individual from the important pathways of exposure during 1992 is presented in Table 4.12-1. If the resident who receives the highest effective dose equivalent (3.3 millirem) from gaseous effluents also drank water from the Gallaher area (0.2 millirem), and went fishing at Poplar Creek (for 250 hours/year) near the K-25 site (15 millirem), that individual would receive a total effective dose equivalent of approximately 18.5 millirem, which is roughly 6.3 percent of the annual dose (295 millirem) from natural background radiation (see Figure 4.7-2). All of these doses are within the applicable regulatory requirements, (i.e., 4 millirem/year from the drinking water pathway, 10 millirem/year from the airborne release pathways, and 100 millirem/year total for all pathways) (MMES 1993a).

The risk of fatal cancer to the maximally exposed individual at the site boundary (due to atmospheric emissions only) is 1.7 x 10-6 per year of operation, and the corresponding (ingestion) risk to this maximally exposed individual from drinking water is 1.0 x 10-7 per year of operation. The risk of fatal cancer from direct radiation due to an individual's spending 250 hours/year fishing at Poplar Creek (K-25 Site) is 7.5 x 10-6 per year of exposure. A more realistic maximally exposed individual scenario from direct radiation, an individual spending 250 hours/year along the Clinch River shoreline near a field on which cesium-137 experiments were performed, yields an associated risk of 1 x 10-6. The resulting risk to the maximally exposed individual is 9.2 x 10-6 per year of operation; over the 40-year SNF management facility lifetime this risk would be 3.7 x 10-4. Table 4.12-1 also includes the collective doses to the general population within 50 miles (80 kilometers) of the ORR. It was found that approximately 54 person-rem (which translates to an expected 0.027 fatal cancer) were received (from liquid and gaseous effluents) by this population from 1992 ORR operations. Thus, over a 40-year period, there would be approximately 1.1 fatal cancers expected.

Doses to onsite workers at the ORR have been reported by DOE for 1991 operations. Of the approximately 17,000 workers monitored, the maximally exposed individual was reported to receive 1 to 2 rem (assumed as 2 rem), which is well below the DOE guidelines of 5 rem (DOE 1992a). The average dose to workers at the site was 2.8 mrem/yr. The risk of fatal cancer to the average worker is 1.1 x 10-6 per year of operation; the risk to a worker who spent 40 years at ORR is approximately 4.5 x 10-5. Additionally, the total collective (population) dose received by these workers was 48 person-rem, which corresponds to 0.019 fatal cancers per year of exposure. Over a 40-year period, there would be an expected 0.76 fatal cancer to this worker population.

4.12.5 Health Effects Studies

Two epidemiologic studies were conducted to determine whether the ORNL facility contributed to any excess cancers in the communities surrounding the facility. One study found no excess cancer mortality in the population living in counties surrounding ORNL when compared to the control populations located in other nearby counties and elsewhere in the United States (Jablon et al. 1991). The other found slight excess cancer incidences of several types in the counties near ORNL, but none of the excess risks were statistically significant (Sharpe 1992).

An Oak Ridge health assessment study is ongoing. This study will include a reconstruction of doses received by the public from historical releases of radioactivity from the reservation. To date, a Phase I report has been issued (Tennessee Department of Health and the Oak Ridge Health Agreement Steering Panel 1993).

Studies of workers at Oak Ridge National Laboratory (Jablon et al 1991; Wing et al. 1993) showed an excess of leukemia deaths among maintenance workers and engineers who had worked for more than 10 years, suggesting a possible excess attributed to exposures other than radiation. An increase of 2.68 percent in deaths from all causes and 4.94 percent for all cancers with every rem of cumulative dose exposure with a 20-year exposure lag was also reported. Excess cancer deaths were associated with working in radioisotope production and chemical operations but not with work in physics, engineering, or unknown job categories. Cancer mortality was also associated with exposure to beryllium, lead, and mercury.

In March 1990, the Secretary of Energy announced that DOE would turn over responsibility for analytical epidemiologic research on long-term health effects on workers at DOE facilities and surrounding communities to the Department of Health and Human Services, and directed that worker health and exposure data be released. A Memorandum of Agreement with the Department of Health and Human Services was signed in January 1991. The Department of Health and Human Services is now conducting the ongoing health effects research program. To develop a database on workers, DOE has initiated an Epidemiologic Surveillance Program and Health-Related Records Inventory.

4.12.6 Chemical Dose and Health Effects Summary

Table 4.7-2 in Section 4.7 presents the ORR chemical releases for 1992. Exposure to chemicals released from the ORR was compared with acceptable levels of exposure (no adverse effect from noncarcinogens) for the ingestion exposure pathway via drinking water and consumption of fish. Aluminum, nitrate, and polychlorinated biphenyls were measured above acceptable levels in upper Bear Creek; the ratios of their doses to acceptable doses were 3.4, 2.2, and 11.1, respectively. The only other chemical exposure attributable to ORR operations that was found to exceed acceptable levels was mercury. This noncarcinogen was found in fish caught from the Clinch River. The ratio of the mercury dose to acceptable dose levels was found to be 1.1 (MMES 1993a).

Because of concerns for possible contamination of the population by mercury, the Tennessee Department of Health and Environment conducted a pilot study in 1984. The study showed no difference in urine or hair mercury levels between individuals with potentially high mercury exposures (residence or activity in contaminated areas based on soil measurements or consumption of fish caught in the contaminated areas) and those with little potential exposure. Mercury levels in some soils measured as high as 2,000 parts per million. Analysis of a few soil samples showed that most of the mercury in the soil was inorganic, however, thereby lowering the probability of bioaccumulation and health effects.

Planned occupational studies at the ORR include a 24-month clinical follow-up of 111 heavily exposed mercury workers (Wing et al. 1991).

4.13 Utilities and Energy

4.13.1 Water Consumption

Both the Clinch River and the Melton Hill Reservoir supply water to the ORR. Because they are a part of the TVA flood control system, they are capable of maintaining a constant volume of water well in excess of the demands of the ORR (MMES 1993a).

In 1995, water supply facilities at the ORR will have a capacity of approximately 1,761 liters per second (27,916 gallons per minute). In 1993, the average demand for water on the ORR water supply facilities was approximately 801 liters per second (12,708 gallons per minute) (Fritts 1994).

A pumping station near Y-12 on the Melton Hill Reservoir supplies untreated water to the DOE water treatment plant. After treatment, the water is stored in two reservoirs with a combined capacity of 26 million liters (7 million gallons). From the reservoirs, water is supplied by gravity flow to the Y-12 operations site, ORNL, the Scarboro Facility (which houses the Oak Ridge Institute of Science and Education's Energy/Environmental Systems Division), and the City of Oak Ridge (MMES 1994a).

A pumping station on the Clinch River provides water to the K-25 water system. After treatment, the water is stored in two water storage tanks on Pine Ridge. This system provides water to the K-25 Site, the Transportation Safeguards Facility, and the city's Clinch River Industrial Park (MMES 1994a).

The SNF facilities will be supplied with water from the K-25 water system. In 1995, the K-25 water system will have a capacity of approximately 184 liters per second (2,917 gallons per minute). In the years 1988 to 1994, K-25 water usage varied from a high of 97 liters per second (1,533 gallons per minute) in 1990 to a low of 78 liters per second (1,235 gallons per minute) in 1988. In 1994, the average demand was 84 liters per second (1,324 gallons per minute). Significant growth in water capacity or demand is not expected (Fritts 1994).

4.13.2 Electrical Consumption

The ORR electrical system is supplied power from four major power sources in the TVA system: Kingston Steam Plant, Bull Run Steam Plant, Wolf Creek Hydroelectric Plant, and Fort Loudon Hydroelectric Plant. The K-25 Power Operations Department manages and operates the electrical transmission and substation system of the ORR (MMES 1994a).

Three substations located at the K-25, Y-12, and ORNL sites comprise the ORR power system. The substations are tied together onsite by five DOE 161-kilovolt transmission lines. Power is supplied to ORR substations by six TVA electrical lines at 161 kilovolts, which is reduced to 13.8 kilovolts for distribution (MMES 1994a).

In 1995, the connected capacity of ORR facilities would be approximately 920 megavolt-amperes. From 1989 through 1993, the peak demand of electricity varied from a high of 116 megavolt-amperes in 1989 to a low of 98 megavolt-amperes in 1993 (Fritts 1994).

4.13.3 Fuel Consumption

The East Tennessee Natural Gas Company supplies natural gas to the ORR, transporting the gas from the supply areas through upstream pipelines and then through its own pipeline system for ultimate delivery to the ORR (MMES 1994a). By contract, ORR natural gas capacity is 7,600 decatherms. This amount can be increased if necessary. In 1994, the average daily usage of natural gas was 3,600 decatherms (Fritts 1994).

Coal is used to produce steam at ORNL and as a backup fuel at the Y-12 steam plant. Y-12 plans to use more coal in the future as a replacement for natural gas (Fritts 1994).

4.13.4 Wastewater Disposal

The ORR does not have a centralized sewage system for all facilities. The K-25 Site and ORNL have their own sewage systems, while Y-12 shares sewage lines with the City of Oak Ridge (MMES 1994a).

The sanitary sewage effluent from the Y-12 operations area flows to the Oak Ridge West End Treatment Plant. DOE maintains the sewage lines extending from Y-12 to the east end of the security road (Bear Creek Road). The City of Oak Ridge maintains the sewage lines from the end of the security road to the treatment plant on West Oak Ridge Turnpike (MMES 1994a).

The sewage treatment plant for ORNL discharges treated effluent into White Oak Creek in full compliance with all permit requirements (MMES 1994a). There are no anticipated capacity problems with the K-25 sanitary sewage system, which is permitted by the National Pollution Discharge Elimination system (MMES 1994a).

The SNF management facility could use the K-25 sanitary sewer treatment system, located directly north of the proposed SNF site. The K-25 system has a capacity of 26 liters per second (417 gallons per minute). From 1988 to 1994, wastewater production peaked at 24 liters per second (378 gallons per minute) during wet conditions in 1994 (Fritts 1994). As an alternative, a new onsite sanitary sewage system and wastewater treatment plant might be required for the proposed SNF management facility.

4.14 Materials and Waste Management

This section describes the hazardous materials management (chemical raw materials), the waste categories, and the ongoing waste management activities, including onsite treatment, onsite storage, onsite waste disposal, and preparation for appropriate offsite disposal, for the three primary complexes within the ORR: the Y-12 Plant, the K-25 Site, and the ORNL (see Figure 2.1-2). Ongoing nuclear-related activities at the ORR have resulted in the generation of low-level, mixed low-level, hazardous, transuranic, spent nuclear fuel (see Chapter 2 for discussion), and industrial solid waste categories, which are discussed in this section. Section 4.8 discusses nonhazardous liquid waste treatment. A description of the Y-12 Plant, the K-25 Site, and ORNL waste categories and the waste management process unique to each of these complexes follows.

Facilities at the Y-12 Plant are being used to manage low-level radioactive, hazardous (Resource Conservation and Recovery Act hazardous/mixed polychlorinated biphenyl and polychlorinated biphenyl/uranium), and nonhazardous solid wastes. Figure 4.14-1 shows the waste management process at the Y-12 Plant.

Figure 4.14-1. Flow diagram of Y-12 Plant storage and disposal units at ORR (Page 1 and 2). Figure 4.14-1. Flow diagram of Y-12 Plant storage and disposal units at ORR (page 2 of 2).

Facilities at the K-25 Site are being used to manage low-level radioactive, hazardous, and mixed wastes. Nonhazardous solid wastes are disposed at the Y-12 Plant Sanitary Landfill. Figure 4.14-2 shows the waste management process at the K-25 Site.

Facilities at the ORNL are being used to manage transuranic, low-level radioactive, hazardous, and mixed waste. Nonhazardous solid wastes are disposed at the Y-12 Plant Sanitary Landfill. Figure 4.14-3 shows the waste management process at the ORNL.

The overall ORR waste management activities, as well as details on the facilities used to manage wastes, are presented by waste category (transuranic, mixed low-level, low-level, hazardous, and industrial solid) in Sections 4.14.1 through 4.14.5 respectively. Note that the 1995 waste generation rates presented in tables associated with these sections are a representation of the annual generation rates for operations until the year 2035. Section 4.14.6 describes the management of the chemical raw materials used for ORR activities.

4.14.1 Transuranic Waste

The ORNL is the only complex at the ORR that generates and manages transuranic waste. Table 4.14-1 presents a summary of transuranic waste management activities projected for 1995, and details on the facilities used to manage transuranic wastes are presented in Table 4.14-2.

4.14.2 Mixed Low-Level Waste

All three complexes at the ORR generate and manage mixed low-level wastes. The Y-12 Plant, K-25 Site, and the ORNL manage non-Resource Conservation and Recovery Act wastes (polychlorinated biphenyls, beryllium, and asbestos) contaminated by low-level radioactive materials as dangerous substances and include them with the Resource Conservation and Recovery Act-regulated radionuclide-contaminated materials as mixed wastes. Table 4.14-3 presents a summary of mixed low-level waste management activities projected for 1995, and details on the facilities used to manage mixed low-level waste are presented in Table 4.14-4.

Figure 4.14-2. Flow diagram of K-25 waste storage units at ORR (Page 1 of 2). Figure 4.14-2. Flow diagram of K-25 waste storage units at ORR (page 2 of 2). Figure 4.14-3. Flow diagram of ORNL waste treatment units and storage and disposal units at ORR (Page 1 of 2).

Figure 4.14-3. Flow diagrams of ORNL waste treatment units and storage and disposal units at ORR (Page 2 of 2).

4.14.3 Low-Level Waste

The Y-12 Plant, K-25 Site, and the ORNL generate and manage low-level wastes. Table 4.14-5 presents a summary of low-level waste management activities projected for 1995, and details on the facilities used to manage low-level waste are presented in Table 4.14-6.

4.14.4 Hazardous Waste

All three complexes at the ORR generate and manage hazardous wastes. The Y-12 Plant, K-25 Site, and the ORNL manage non-Resource Conservation and Recovery Act wastes (asbestos, oils, and polychlorinated biphenyls) as dangerous substances and include them with the Resource Conservation and Recovery Act-regulated wastes as hazardous wastes. Table 4.14-7 presents a summary of mixed hazardous waste management activities projected for 1995, and details on the facilities used to manage hazardous waste are presented in Table 4.14-8.

4.14.5 Industrial Solid Waste

The K-25 Site and the ORNL industrial solid wastes are disposed of at the Y-12 Plant Sanitary Landfill (PAI Corporation 1994; PAI Corporation 1993a). Table 4.14-9 presents a summary of industrial solid waste management activities projected for 1995 at the Y-12 Plant, and details on the facilities used to manage industrial solid waste are presented in Table 4.14-10.

4.14.6 Hazardous Materials

The ORR uses a variety of chemical raw materials for activities associated with metal finishing/plating, uranium recovery, laboratory services, cooling tower operation, and facility cleaning/maintenance operations. Examples of chemicals used at the ORR include acids (hydrochloric, nitric), organics (methanol, perchloroethylene), and inorganics (hydrogen fluoride, chlorine). Currently, 309 specific chemicals and 20 chemical categories are being reviewed for possible reporting under the Superfund Amendments and Reauthorization Act Section 313 requirements. For 1992, the ORR reported 7 extremely hazardous substances and 39 hazardous chemicals for the Y-12 Plant; 5 extremely hazardous substances and 16 hazardous chemicals for the K-25 Site; and 20 extremely hazardous substances and hazardous chemicals for ORNL (MMES 1993a).

In addition, diesel fuel and gasoline, used to fuel site service and construction vehicles, are stored in bulk containers (55-gallon drums, aboveground storage tanks, and underground storage tanks).

The Y-12 Plant underground storage tank program includes seven in-service petroleum tanks. In addition, there are seven active petroleum underground storage tanks at the K-25 Site. At the ORNL there is one active underground storage tank containing heating oil and 22 active underground storage tanks that will be taken out of service or upgraded by 1998. The contents of these tanks was not reported (MMES 1993a).

The Y-12 underground storage tanks program includes seven in-service petroleum tanks. In addition, there are seven active ptroleum underground storage tanks at the

K-25 Site. At the ORNL there is one active underground storage tank containing heating oil and 22 active underground storage tanks that will be taken out of service or upgraded by 1998. The contents of these tanks was not reported (MMES 1993a).

5. ENVIRONMENTAL CONSEQUENCES

5.1 Overview

This chapter describes the potential environmental consequences from the construction and operation of spent nuclear fuel (SNF) facilities at the Oak Ridge Reservation (ORR) under the Centralization and Regionalization Alternatives. Potential environmental consequences are assessed to the extent necessary to support a programmatic decision concerning the siting of the proposed SNF facilities. More detailed considerations of potential environmental consequences would be performed as necessary prior to initiating construction or operation of the facilities.

Impacts on the operation of the current facilities at ORR that create or store SNF are discussed in Chapter 3.

5.2 Land Use

The proposed site for SNF activities is in the eastern portion of the West Bear Creek Valley area, located in the western portion of the ORR. The SNF program's land requirements are assumed to be 90 acres (0.36 square kilometer), including all facilities and buffer areas. The majority of the land in the West Bear Creek Valley Area can be characterized as vacant, unused, and developable.

5.2.1 Centralization Alternative

Use of the West Bear Creek Valley area of the ORR for program activities would be consistent with the current land use and land use policies and plans for that area. The current land use designation for this area is Natural Areas, a generic category that includes all lands within the ORR not under any other specific land use designation (DOE 1993a). Use of this area for program activities would also be consistent with proposed future land uses as set forth in the ORR Site Development Plan (MMES 1989).

Future land uses proposed for the area of Roane County adjacent to the ORR near the proposed SNF site are low-density residential and public/semi-public uses (Roane County Regional Planning Commission 1992). These low intensity uses would be compatible with development in the western portion of the ORR.

Use of the West Bear Creek Valley site for the placement of SNF facilities may result in irreversible and irretrievable impacts to land use in that area by precluding all but waste management-type uses in the future. However, the placement of SNF facilities at this location would be consistent with U.S. Department of Energy's (DOE's) 1994 future land use plan, which designates the West Bear Creek Valley site for these uses (MMES 1989). Therefore, no mitigation measures are proposed.

5.2.2 Regionalization Alternative

As under the Centralization Alternative, land use impacts resulting from the Regionalization Alternative would not be expected to be significant. Impacts would be similar in character to those described for the Centralization Alternative.

5.3 Socioeconomics

Socioeconomics as addressed in this programmatic environmental impact statement (EIS) encompasses the interaction of economic, demographic, and social conditions. Economic consequences (e.g., technology requirements for operation of an SNF management facility) affect business activities, market structures, procurement methods, and dissemination of commodities within and between regions. Demographic consequences (e.g., in-migration of specialized human resources to support the SNF management program) affect size, distribution, and composition of the population, labor force, and the housing market in the regions. Social consequences (e.g., capacity modifications of public infrastructure to support SNF activity) affect the overall quality of life enjoyed by the residents of a community (Murdock and Leistritz 1979). These conditions are potentially affected either directly or indirectly by actions proposed under the DOE SNF Management Program.

The significance of actions and their intensity are relative to the affected region. A region can be described as a dynamic socioeconomic system, where physical and human resources, technology, social and economic institutions, and natural resources interrelate to create new products, processes, and services to meet consumer demands. The measure of a region's ability to support these demands depends on its ability to respond to changing economic, demographic, and social conditions.

Potential socioeconomic effects are addressed only to the extent that they are interrelated with the natural or physical environment (CFR 1993c). Direct effects include those impacts caused by the action and occurring at the same time and place. Indirect effects include those impacts caused by the action that are later in time or farther removed in distance, but are still reasonably foreseeable (i.e., offsite) (CFR 1993b).

Socioeconomic effects are quantified for regional economic activity and population. Potential impacts to individual communities such as public infrastructure and housing are discussed qualitatively to address programmatic issues.

Economic projections include direct and indirect jobs. Direct jobs are those jobs needed to construct or support operation of the SNF management complex at ORR. Indirect jobs are created throughout the regional economy within the Region of Influence as a result of procurement for materials, services, and other commodities; and induced effects from consumer spending. These direct and indirect impacts reflect both construction and operation phase demands that may occur concurrently or independently throughout the project planning period. Indirect jobs were projected using parameters from the U.S. Bureau of Economic Analysis Regional Input-Output Modeling System.

Two scenarios were analyzed to account for two potential distributions of the SNF facility construction efforts. The construction effort consists of fabricating various structures, each with its own construction labor need and a duration of either three or five years. The Peak Scenario accelerates the construction labor requirements into the first two years of construction. The Average Scenario averages the labor requirements of a structure for the duration of construction. The total construction effort for all structures, in labor years is the same for each scenario. Therefore, for structures with a three year construction duration, the Peak Scenario has high labor needs for the first two years and then a substantial reduction for the third year, while the Average Scenario has a constant labor requirement for the three years. Likewise, for structures with a five year construction duration, the Peak Scenario has a high labor need for the first two years, then a lower need for the remaining three years, while the Average Scenario has a constant requirement for all five years. Because the total construction labor years for each structure is the same for both scenarios, the Average Scenario will have a lower requirement than the Peak Scenario in the first two years, then will have a higher requirement then the Peak Scenario in the remaining construction years.

Regional population projections reflect the potential change in population resulting from an increase in regional economic activity. Detailed assumptions regarding in-migration associated with SNF Management Program were not developed given the programmatic scope of the analysis. Potential in-migration effects resulting from direct job creation are presented qualitatively where appropriate.

5.3.1 Centralization Alternative

The upper and lower bounds of construction and operations related jobs generated from implementation of the Centralization Alternative from 1995 to 2005 are illustrated in Figure 5.3-1 and tabulated in Table 5.3-1. In the initial phases, the Centralization Alternative may create 90 jobs (25 direct, 65 indirect) beginning in 1995 and continuing through the year 1999 to support project planning, engineering design, and environmental permitting and compliance. Construction is expected to begin in the year 2000, requiring a total of 4,352 direct jobs (7,1232 indirect jobs). In that year and 2001, the Peak Scenario requires 1,587 construction laborers, while the Average Scenario needs 1,346. There is no operational labor required for this time period. In 2002 after two years of construction, the Peak Scenario decreases its construction labor requirements to 928 workers, while the Average Scenario maintains its 1,346 laborers. Additionally, 300 operational personnel are needed, raising the total of SNF workers to 1,228 for the Peak Scenario and 1,646 for the Average Scenario. By 2003, the buildings with three year construction durations have been completed; therefore, both the Peak and Average Scenario construction labor requirements decline to 125 and 157, respectively. Operation labor

requirements remain at 300 workers. Total SNF labor requirements are 425 workers for the Peak Scenario and 457 for the Average Scenario. In 2004, construction labor needs for both scenarios remains at their previous level, but operational personnel increase. Total SNF labor requirements are 612 workers in the Peak Scenario and 644 workers in the Average Scenario. By 2005, all construction has been completed and operational personnel have increased to the full staff labor requirement of 800 workers.

The peak scenario reaches it maximum construction labor with 1,587 direct jobs (4,184 total jobs created) over a 2-year period from years 2000 through 2001. The average scenario would have its maximum construction labor with 1,346 direct jobs (3,549 total jobs created) from 2000 through 2002.

Ancillary operation (Table 5.3-1) activity associated with the Centralization Alternative will begin in the year 2002; the initial operations might create approximately 1,080 phase-related jobs (300 direct, 780 indirect). Additional operation activity would also begin, creating an additional 187 phase-related jobs (485 indirect jobs). The remaining operation activities are expected to start in 2005, after construction is finished, creating a total of 2,879 phase-related jobs (800 direct, 2,079 indirect), and the jobs will continue through 2035.

Regional businesses and the workforce will benefit from increased competition for contract procurements and jobs associated with SNF Centralization Alternative. Most of this activity is anticipated to be captured by Anderson, Knox, and Roane counties, with a small share occurring in Loudon County. The impact to the regional economy, however, only represents a portion of the total economic activity generated by the Centralization Alternative. For instance, specialized materials purchases and technology acquisition may occur outside Tennessee. The economic activity occurring outside the region might result in economic benefits for that region. This indirect effect is not captured by this analysis since it occurs outside of the Region of Influence as defined in Section 4.3.

Most of the population change in the Region of Influence above the baseline forecast will be driven by the in-migration of labor and households to support SNF management activities at ORR. It is likely that most of the operation jobs will be filled by SNF personnel relocating from other DOE sites where SNF inventories were stored prior to shipments to ORR. These personnel would be familiar with the processes, technologies, and research involved with SNF operations elsewhere. Other operational jobs not associated with SNF management will probably be filled by the regional labor force. The regional labor force would be likely to fill the demand for construction jobs, except for specialized tasks.

To assess potential population and housing impacts, an in-migration rate per job was estimated using a ratio between forecasted employment and population figures (Table 4.3-1). This ratio was applied to the number of total (direct and indirect) jobs created by SNF management activities at ORR, giving the total estimated number of persons migrating into the Region of Influence per job created (Table 5.3-1).

With initial operation in 1995 under both scenarios, a total of 82 persons will migrate into the Region of Influence. The number of persons migrating into the Region of Influence would be at its largest when construction starts, for the years 2000 through 2001; (a total of 4,366 in-migrants for the peak scenario and 3,688 for the average scenario). For the years 2002 and 2003, after most of the construction has finished, people might migrate out of the Region of Influence. The number of in-migrants might increase as more of the SNF management operations start in the years 2004 and 2005. After the year 2005, in-migration due to SNF management activities would cease due to the fact that SNF management activities would not create any more jobs.

Assuming one housing unit per household, and an average family size of 2.6 persons per family (U.S. Department of Commerce 1991), the number of houses demanded in 1995, when preliminary operations start, might be 32. Between the year 2000 and 2002, a total of 1,679 housing units might be demanded. Even though this demand is only a temporary demand, the Region of Influence may have difficulty providing new housing during this time period. By the year 2003 and 2004, however, there might be a surplus of 1,236 housing units due to the phasing out of construction. In 2005, once SNF operational activities are under way, there will be a demand for 1,167 housing units associated with SNF management activities.

The greatest impact to the Region of Influence housing market may occur between the years 2000 and 2002, when construction starts. The demand for housing during the SNF facility construction period would be for transitional housing. While the population in the Region of Influence under baseline conditions has historically been growing and is projected to grow at less than 1 percent annually, recent vacancy rates for housing in the Region of Influence have been low (Census 1982, 1991). Therefore the in-migration associated with SNF construction might cause shortages in the housing market, and might cause shortages in construction supplies. However, due to decreasing employment levels on ORR between 1990 and 1999 (Section 4.3.1.5), additional housing units above the baseline may be available, thus reducing the potential strain on the housing market. Since construction will only be temporary, there may be excess capacity in the regional infrastructure when all SNF management operations begin in 2005.

5.3.1.1 Potential Public Service and Education Impacts. Given the population growth

associated with the SNF Management Program, increases in capital expenditure may be required to meet the increased demand of housing utilities, including electricity generation, wastewater treatment, and water (see Section 5.13), transportation infrastructure (see Section 5.11), and education or service levels, assuming current conditions are constant through the analysis.

Assuming that the Centralization Alternative would be an addition to the ORR's current operations, security and fire protection on the site would need to be investigated at a minimum to determine whether or not current capacity could accommodate the requirements of the SNF Management Program.

5.3.2 Regionalization Alternative

Socioeconomic impacts resulting from the Regionalization Alternative are expected to be similar to the Centralization Alternative. The construction and operation cycles for each alternative would be the same; therefore, the same issues identified for the Centralization Alternative would apply. Labor requirements may be slightly reduced for the Regionalization Alternative. Although the volume of SNF stored would be less for the Regionalization Alternative, an economy of scale occurs for both alternatives, so that differences in labor and capital between the two alternatives would be minimized.

5.3.3 Mitigation Measures

5.3.3.1 Coordination with Local Jurisdictions. To reduce construction- and operation-

related impacts, possible coordination with local communities could address potential impacts from increased labor and capital requirements. The knowledge of the extent and effect of growth due to SNF management activities could greatly enhance the ability of affected jurisdictions to plan effectively. Effective planning would address changes in levels of service for housing, infrastructure, utilities, transportation, and public services and finances.

5.3.3.2 Enhance Labor Force Availability. To alleviate potential impacts associated with

the in-migration of labor, local labor force availability could be increased through various employment training and referral systems. The goal of these systems would be to reduce the potential for in-migration of labor to support SNF management activities.

5.4 Cultural and Paleontological Resources

5.4.1 Centralization Alternative

Under the Centralization Alternative, the proposed construction area for the SNF facilities is not expected to exceed 100 acres. There are no known historical, archeological, paleontological or Native American traditional sites in the proposed area (Fielder 1975). No impacts to cultural or paleontological resources are expected due to ground disturbance, noise, or air emissions during construction or operation of the SNF facilities. Consultation with the Tennessee State Historic Preservation Officer prior to project implementation is required by section 106 of the National Historic Preservation Act.

5.4.2 Regionalization Alternative

Under the Regionalization Alternative, the location of the SNF facilities would remain the same, but would be reduced in area. As with the Centralization Alternative, impacts are not anticipated.

5.5 Aesthetics and Scenic Resources

5.5.1 Centralization Alternative

When fully constructed and under operation, the proposed SNF facilities associated with the Centralization Alternative would consist of a series of buildings set within a 90-acre site. The maximum height of the buildings contained at the site would not exceed 42 feet above ground level, or two to three stories. The entrance to the site and security fencing will be visable to traffic on Bear Creek Road.

Since the buildings would be set into the south face of Pine Ridge, between Pine Ridge and Chestnut Ridge, the site would not be visible from areas outside the reservation, with the possible exception of a limited section of Gallaher Road on the west side of the Clinch River, looking east along Bear Creek Valley (TVA 1987). However, since the approximate distance from the boundary of the reservation to the proposed location is in excess of 2 miles, and includes hilly terrain and heavy vegetation, public views looking on to the site from off-site are not expected to be affected. Impacts to aesthetics and scenic resources on and off ORR are not anticipated.

5.5.2 Regionalization Alternative

Under the Regionalization Alternative, proposed SNF facilities are reduced in area and intensity of operations, and environmental effects to aesthetics and scenic resources would be less than those under the Centralization Alternative. Therefore, adverse environmental impacts from the Regionalization Alternative are also not anticipated.

5.6 Geologic Resources

This section describes any incremental or additional impacts on geology and geologic resources that might result from the construction and operation of the new facilities associated with the storage of SNF at the ORR.

For the most part, geologic impacts from construction activities would be limited to soil disturbance, although in some areas, ripping or blasting of limestone, dolomite, or chert layers might be required. Since no extensive or unique geologic or mineral resources are known to occur on the West Bear Creek Valley site, impacts to geologic resources would not be expected.

Because previously undisturbed areas would be used for new construction, some soil impacts from siting SNF facilities at the West Bear Creek Valley site would occur as a result of grading. Potential impacts from sediment runoff generated during construction activities would be minimized by implementation of soil erosion and sediment control measures. During operations, impacts to soil resources would be controlled by the planting or landscaping of land surfaces not covered by pavement and buildings.

Major seismic activity and associated mass movement and subsidence are unlikely to occur during the construction or operation phases, because although ground-shaking has occurred at the ORR due to earthquakes in other parts of the country, faults in the area have not been active since the late Paleozoic.

5.7 Air Resources

The proposed SNF management facility would be composed of a wet and dry storage facility and a technology development facility, with construction to take place in the calendar years 2000-2004. Air quality is assessed for construction and operation with regard to radiological and nonradiological air emissions. This section characterizes the impacts and expected air quality effects resulting from an SNF facility. This section also discusses the quantitative impacts under the Regionalization Alternative. The Centralization Alternative qualitative impacts are compared with the regionalization impacts in order to determine exceedances, if any, of existing local and Federal standards for both alternatives.

5.7.1 Releases

Emissions of radiological and nonradiological air pollutants might result from the construction and operation of a SNF management facility. These emissions might include airborne radionuclides, criteria pollutants, and hazardous air pollutants.

The impact of air emissions from construction activities might include criteria air pollutants of particulate matter (fugitive dust) primarily from the moving of soil, and exhaust emissions of particulate matter with an aerodynamic diameter equal to or less than 10 microns (PM10); carbon monoxide; sulfur dioxide; volatile organic compounds; and nitrogen dioxide from earth-moving and equipment-handling machinery and equipment. During construction, a small increment in traffic volume above existing levels might result in a small increase in air pollutant emissions. (Section 5.11 discusses the level of traffic activity projected for the construction and operation phases of the SNF facility.)

During operations, the transport of SNF within the ORR from points of generation or storage sites to the disposal site would result in emissions of criteria air pollutants from various vehicles as well. Some emissions of air pollutants from worker vehicles would also occur both within and beyond the ORR.

5.7.1.1 Radiological Emissions. There are no expected contributions to radiological air

emissions during the construction phases of the proposed SNF management facility. During operations, the facility would be expected to generate negligible radiological emissions. The potential radiological emissions associated with the proposed SNF management facility and those associated with the baseline are presented in Table 5.7-1 by isotope.

5.7.1.2 Nonradiological Emissions. The construction phase of the SNF facility for the

Receipt/Storage Facility and Canning Factory is estimated to be complete in about 8-10 years. Short-term emissions, such as fugitive dust and heavy equipment exhaust emissions, would be generated temporarily, and would only affect receptors close to construction areas. Fugitive dust emissions would be minimized by watering. Under the operational phase of the SNF management facility, criteria and hazardous air pollutants might be emitted. Table 5.7-2 lists total expected annual emissions associated with the SNF storage facility. These nonradioactive emissions are primarily from the technology development facility and were estimated based on a previous design for a similar facility proposed at INEL.

Table 5.7-1. Isotopic release additions due to SNF management facility presence (Ci/yr) at ORR.

	(Baseline) ORR	(SNF) ISF	ORR+ ISF

Cobalt, chromium, antimony, and nickel compounds	2.0 x 10-10

a. Source: Johnson, V. (1994).

b. It is assumed that PM10 (particulate matter less than 10 microns in diameter) data are total suspended particulate data.

5.7.2 Air Quality

5.7.2.1 Radiological. The GENII Environmental Transport and Dose Assessment Model,

along with 1992 Y-12 west meteorological data and 1992 source terms (Table 5.7-1), was used to calculate the effective dose equivalent for the year 2005. A population of 988,754 persons within 80 kilometers (50 miles) is estimated. A radiation background level of 306 millirem per year is used.

Based on model results, 1 year of operation at the SNF management facility might result in a calculated dose of 9.5 millirem per year to the maximally exposed member of the public. This dose is below the National Emission Standards for Hazardous Air Pollutants limit of 10 millirem per year and is 3.1 percent of the natural background radiation received by the average person near the ORR.

The annual population dose from operation in the year 2005 was calculated to be 5.7 x 101 person-rem. The population dose from operation of this option in 2005 is approximately 2.1 x 10-2 percent of the dose received by the surrounding population from natural background radiation.

Table 5.7-3 summarizes the effective dose equivalents for the maximum boundary dose and to the population with 80 kilometers (50 miles) of the proposed SNF facility. Compared to the background radiation, these increased doses are very small. The total doses are well within the regulatory limits.

5.7.2.2 Nonradiological. The Industrial Source Complex Short-Term Air Dispersion

model was used with 1992 meteorological data from the Y-12 west meteorological monitoring station at ORR to determine pollutant concentrations resulting from the centralization portion of nonradiological emissions listed in Table 5.7-2. An emissions baseline was established to characterize conditions at ORR using actual emission rates (MMES 1993a). It is also assumed that 1995 operations at the ORR will result in the same baseline nonradiological emissions as the 1992 operations at the ORR. The results of modeling are presented in Table 5.7-4, where the existing ORR site contribution concentration is compared to the existing DOE site contribution concentration plus the proposed SNF contribution. Table 5.7-5 presents the annual maximum concentration for hazardous air pollutants for offsite receptors. These concentrations are used in Section 5.12 for calculation of health effects. The increases in pollutant concentrations from the proposed action are negligible in magnitude. The concentrations of nonradiological air pollutants from operation of the SNF facilities, under that alternative, and from existing sources would remain within all applicable regulatory guidelines.

If a Regionalization Alternative SNF facility is operated at the ORR, the incremental contribution to maximum concentrations of pollutants would be less than for the Centralization Alternative. The concentrations of nonradiological air pollutants from operation of the SNF facilities, under this alternative, and from existing sources would remain within all regulatory guidelines.

Table 5.7-3. Summary of effective dose equivalents to the public from ORR operations and the proposed SNF management facility.

	Maximally exposed individual dosea	Collective dose to population within 80 km of ORR sources
Dose	9.5 mrem per yearb	5.7 x 101 c
Location	Site boundary 1.2 km SW of ORR storage facility	9.1 x 105 people within 80 km of SNF storage facility
NESHAPb standard	10 mrem per year	-
Percentage of NESHAP	95	-
Natural background dose	306 mrem	2.79 x 105 person-rem
Percentage of natural background dose	3.1	2.1 x 10-2

a. The maximum boundary dose is the hypothetical individual exposed continuously during the year at ORR boundary located 1.2 km SW from the SNF site.

b. The SNF management facility contributes 6.2 mrem to this dose.

c. The SNF management facility contributes 5.2 person-rem to this dose.

NESHAP: National Emission Standards for Hazardous Air Pollutants.

km: kilometer

mrem: millirem

Note: Effective dose equivalents computed using GENII (PNL 1988).

5.8 Water Resources

Construction and operation of SNF management facilities could potentially affect water resources. Potential environmental impacts to surface water and groundwater resources during construction include depletion of water supplies, floodplain encroachment, and surface water sedimentation from erosion runoff occurring after land clearing. Potential normal operational impacts would include depletion of water supplies, and diminished water quality resulting from wastewater discharges from normal operations.

Impacts are analyzed for the Centralization Alternative, which would cause the most impacts to water resources at the ORR, if chosen. However, for the Centralization Alternative, no significant impacts are identified with respect to water resources issues. Therefore, no significant impacts are expected from the Regionalization Alternative as the Centralization Alternative is the bounding case.

Table 5.7-4. Comparison of baseline concentrations with most stringent applicable regulations and guidelines at ORR and proposed SNF management facility plus current operations.

Criteria pollutant	Averaging time	Most stringent regulation or guidelinea (-g per m3)	Total existing maximum concentrationb (-g per m3)	Total projected maximum concentration including SNF (-g per m3)	Increase in maximum concentration (-g per m3)
Carbon monoxidec	8-hour	10,000	6.9	6.9	0
	1-hour	40,000	24.1	33.5	9.4
Nitrogen dioxide	Annual	100	2.1	2.7	0.6
Lead	Calendar quarter	1.5	d	3.7 x 10-12	3.7 x 10-12
PM10e	Annual	50	12.0	12.0	0
	24-hour	150	97.9	97.9	0
Sulfur dioxide	Annual	80	29.29	29.34	0.05
	24-hour	365	177.8	178.0	0.2
	3-hour	1,300	401.5	401.5	0
Total suspended particulates	Annual	50a	36.0	36.0	0
	24-hour	150a	116.9	116.9	0
Hydrogen fluoride (as fluorides)	30-day	1.2a	0.06	0.06	0
	7-day	1.6a	0.03	0.03	0
	24-hour	2.9a	d	f	f
	8-hour	3.7a	d	f	f
Hazardous air pollutants					
Selenium	8-hour	20	d	2.18 x 10-7	2.18 x 10-7
Mercury compounds	8-hour	0.5	d	2.18 x 10-3	2.18 x 10-3
Chlorine compounds	8-hour	150	d	1.52	1.52
Cadmium compounds	8-hour	5	d	1.81 x 10-9	1.81 x 10-9
Cobalt, chromium, antimony, and nickel compounds	8-hour	5	d	5.5 x 10-10	5.5 x 10-10

a. State standard.

b. Includes background concentration plus existing DOE facilities impact concentration. This is the baseline concentration.

c. Existing maximum and projected maximum did not occur in the same location.

d. Zero release (no sources indicated).

e. It is assumed that PM10 (particulate matter less than 10 microns in diameter) data are total suspended particulate data.

f. Not estimated because the potential release is negligible.

Table 5.7-5. Calculated annual maximum concentrations for hazardous air pollutants at ORR for offsite receptors.

Hazardous air pollutant	Maximum average concentration(-g/m3)
Selenium compounds	8.85 x 10-8
Mercury compounds	8.85 x 10-4
Chlorine compounds	0.62
Hydrogen fluoride	1.53 x 10-3
Cadmium compounds	7.35 x 10-10
Cobalt, chromium, antimony and nickel compounds	2.21 x 10-10

a. Offsite includes public access roads within the ORR. All impacts from proposed source only. No hazardous air pollutant emissions information available for existing sources.

5.8.1 Surface Water Quantity

The ORR currently receives its water supply from the Clinch River basin. Construction and operation of SNF management facilities would have very minimal impact on the quantity of water in the river and in local surface streams.

Construction of SNF management facilities would require some water consumption. However, the amount of water required would not significantly affect the Clinch River water level.

Stormwater runoff associated with both the construction and operation of SNF facilities is expected to have a negligible impact on surface water quantity. During construction, standard stormwater management techniques would be employed to attenuate runoff. A site drainage and stormwater management system consisting of perimeter drainage ditches and a retention pond would be included as part of SNF operations (Johnson, V. 1994). This system would provide for runoff and erosion control, which could otherwise affect receiving water courses or SNF operations.

As discussed in Section 4.8.1, analysis of available data indicates that the proposed SNF management facilities would be sited outside the 500-year floodplain. The SNF management facilities would be located and constructed to minimize any floodplain impact, as required by Executive Order 11988 (Floodplain Management) and DOE Orders. Site-specific surveys would be performed to more accurately determine precise locations of flooding elevations.

Operation of SNF management facilities would require approximately 9,863 gallons (37,335 liters) of water per day. This would mean that an additional 3.6 million gallons (13.6 million liters) of water would be used at the ORR per year. This figure is significantly less than the minimum monthly release for 1992 which was 3.5 billion cubic feet (100 million cubic meters) in May of that year (MMES 1993a). Therefore no impacts to water supply from SNF operations are expected.

Operation of SNF management facilities would involve the discharge of almost all water withdrawn, as very little would be consumed. A new onsite sanitary wastewater treatment plant would be required at the SNF facility. If all water withdrawn were to be treated and released at a constant rate over the course of a year, the increased flow from SNF operations would be approximately 0.13 gallon (0.5 liter) per second. Flow in Grassy Creek at its confluence with the Clinch River has been estimated at 20 gallons (80 liters) per second. Water discharge points and other appropriate mitigation measures would be selected in accordance with state and Federal requirements so as not to impact surface water quantity and flow in streams receiving discharges.

5.8.2 Surface Water Quality

During construction of SNF management facilities, 90 acres (36 hectares) would be disturbed, all in previously undisturbed areas. This would create the potential for increased sediment runoff into wetlands, adjacent to the site and along the downstream reaches of Grassy Creek as well as into Grassy Creek and its tributaries, which drain to the Clinch River. However, sediment runoff from construction activities would be controlled and minimized by implementing soil erosion control measures.

Under the Centralization Alternative, SNF management facilities would require a sanitary sewer system comprising a sewage treatment facility equipped with a sewage treatment and ejection pump system with a programmable controller and software. A pressurized sanitary sewer line would be provided that would run to a permitted stream discharge point (Johnson, V. 1994). This would accommodate the estimated 9,863 gallons (37,335 liters) per day of sanitary wastewater generated by SNF facilities and personnel, and would result in no appreciable impact to surface water quality. This system would be operated in accordance with State of Tennessee permitting requirements.

The proposed SNF management facilities are designed to have no liquid release of wastewater with hazardous chemical or radiological characteristics related to SNF management operations. These facilities would be constructed using state-of-the-art technologies, including secondary containment, and leak detection and water balance monitoring equipment. Therefore no environmental consequences related to surface water resources are anticipated from the normal operation of SNF management facilities.

A very low probability release scenario was evaluated to identify the potential environmental consequences of a liquid release to the environment under normal operating conditions. The release scenario was evaluated for information purposes only, as no normal operating releases are planned for the proposed facilities. The scenario evaluated consisted of a maximum potential liquid release to the environment under normal operating conditions such as an undetected secondary containment failure or piping leak. The scenario was developed using conservative estimates of the sensitivity of actual leak detection systems and operational source term data from similarly functioning facilities at the Idaho National Engineering Laboratory

(INEL). The estimates for the hypothetical release included a point release of 5 gallons (19 liters) per day to the environment over the course of 1 month. The release volume and durations are considerably greater than existing leak detection system sensitivities, surveillance activities, and radiological surveys. Source terms were derived at the 95 percent confidence level from 8 years of operational data at the INEL Fluorinel and Storage Facility at the Idaho Chemical Processing Plant.

This release was assumed to occur at 40 feet (12 meters) below the land surface. This would be at either the depth of the vadose zone or the groundwater zone in most cases where SNF management facilities would be sited on the ORR. Any release to the vadose zone would migrate downward to the groundwater zone as described in Section 4.8.2. The upper layers of the groundwater zone in the ORR aquitards (where SNF management facilities would be sited) flow laterally to discharge points in nearby streams.

Most radiological constituents would be below drinking water standards at the point of release. Those radiological constituents above drinking water standards would be diluted in movements through the vadose zone, groundwater zone, and immediately upon entry into the receiving surface water body. Migration of contaminants through the vadose and groundwater zones would also be greatly reduced by sorption.

The short-term scenario evaluated would result in a long-term release of dilute contaminants to local streams and the Clinch River. Any release from the SNF management facilities would discharge to Grassy Creek through the subsurface. Although there are no continuous records of stream discharge for Grassy Creek, the average discharge of Grassy Creek to the Clinch River has been estimated at 20 gallons (80 liters) per second (Bailey and Lee 1991). The worst-case undetected release from the SNF facilities (5 gallons [19 liters] per day) would constitute less than 0.0003 percent of the estimated daily creek discharge to the Clinch River. Therefore, any hazardous constituents would be well below established standards at the confluence of Grassy Creek and the river. Even if a release were to occur during a period of low flow in Grassy Creek, the percentage would still be very small. Additionally, the 1992 minimum monthly release (in May) of 3.5 billion cubic feet (100 million cubic meters) at the Melton Hill Dam on the Clinch River averages to approximately 10,000 gallons (40,000 liters) per second (MMES 1994a). Therefore, no significant contaminant concentrations would be expected at the confluence of Grassy Creek and the Clinch River, or in the river itself.

5.8.3 Groundwater Quantity

No groundwater would be used for SNF management activities given the plentiful surface water supplies at the ORR. Therefore no impacts to groundwater quantity are expected.

5.8.4 Groundwater Quality

As previously mentioned in Section 5.8.2, the proposed SNF management facilities would be designed to have no liquid release to the environment of wastewater with hazardous chemical or radiological characteristics. However, for the purpose of this analysis, a conservative release scenario was analyzed.

As discussed in Section 4.8, virtually all mobile groundwater in the ORR aquitards is discharged to local streams through the upper layers of the groundwater zone. The deeper intervals of groundwater have extremely high residence times. Therefore, even the conservative scenario of a release to groundwater would have negligible impacts to these resources, and no significant impacts to offsite groundwater.

5.9 Ecological Resources

The Centralization and Regionalization Alternatives could affect ecological resources primarily through the alteration or loss of habitat. Potential impacts to terrestrial and aquatic resources and threatened and endangered species are described below for both alternatives.

Radiation doses received by terrestrial biota from SNF activities would be expected to be similar to those received by man. Although guidelines have not been established for acceptance limits for radiation exposure to species other than man, it is generally agreed that the limits established for humans are also conservative for other species (NRC 1979). Evidence indicates that no other living organisms have been identified that are likely to be significantly more radiosensitive than man (Casarett 1968; National Academy of Sciences 1972). Thus, so long as exposure limits protective of man are not exceeded, no significant radiological impact on populations of biota would be expected as a result of SNF activities at the West Bear Creek Site.

5.9.1 Centralization Alternative

Under this alternative, construction of the proposed SNF management facility would result in the disturbance of approximately 90 acres (0.36 square kilometers), or less than 1 percent of the ORR. It is assumed that the area to be disturbed includes construction laydown areas, grading, and new buildings, and that the access road or other rights-of-ways have not been included in total area to be disturbed. Vegetation within the area proposed for the SNF management facility would be destroyed during land clearing activities but may be mitigated by revegetating with native species where possible. Vegetation cover in this area is predominantly oak-hickory forest or pine and pine-hardwood forest. Both forest types are common on the ORR and within the region.

Construction of the proposed SNF management facility would have some adverse effects on animal populations. Less mobile animals, such as amphibians, reptiles, and small mammals, within the project area would be destroyed during land-clearing activities. Larger mammals and birds in construction and adjacent areas would be disturbed by construction activities and would move to nearby suitable habitat. The long-term survival of these animals would depend on whether the area to which they moved was at or below its carrying capacity. Areas that would be revegetated upon completion of construction would be of minimal value to most wildlife but may be repopulated by more tolerant species.

The Migratory Bird Treaty Act is primarily concerned with the destruction of migratory birds, as well as their eggs and nests. It may be necessary to survey construction sites for the nests of migratory birds prior to construction and/or avoid clearing operations during the breeding season.

Activities associated with operation, such as noise, increased human presence and traffic, and night lighting could affect wildlife living immediately adjacent to the site. While these disturbances may cause some sensitive species to move from the area, most animals should be able to adjust.

Construction of the proposed SNF management facility would likely displace the forested wetlands adjacent to tributaries of Grassy Creek flowing through the proposed site. This unavoidable displacement of wetlands would be accomplished in accordance with the U.S. Army Corps of Engineers and Tennessee Water Quality Control Administration requirements. The potential also exists to disturb wetlands further down stream through erosion and sedimentation. Such impacts would be controlled through implementation of a soil erosion and sediment control plan. Construction-related discharges to Grassy Creek would be relatively low and have negligible impacts to wetlands associated with the creek. No impacts to wetlands are anticipated during facility operations.

Construction of the proposed SNF management facility would require the rechanneling of tributaries to Grassy Creek that cross the proposed site and, thus, the loss of this aquatic habitat.
In addition, soil erosion due to construction could cause water quality changes (primarily sediment loading) to Grassy Creek and its tributaries. These impacts could be minimized by implementation of soil erosion and sediment control measures. No operational impacts to aquatic resources are anticipated. It is assumed that the proposed project will have a water retention pond and a sewage lagoon area within the security fence that may provide minimal habitat for amphibians in the area.

No federally listed species are expected to be affected by construction and operation of the SNF management facility. Site surveys will be required to verify the presence of state-listed or other special status species. Land clearing activities may destroy protected plant species, such as purple fringeless orchid and pink lady's-slippers, that may occur within the site. State-listed species including the Cooper's, sharp-shinned, and red-shouldered hawks, the barn owl, and the black vulture, which potentially occur in the area, could be impacted by project activities. Approximately 90 acres (36 hectares) of potential nesting and foraging habitat would be lost as a result of construction activities. Because this type of habitat is abundant in the area, the loss is not expected to affect the viability of populations of these species. However, appropriate steps would be taken to prevent nest disturbance. The DOE would consult with the Tennessee Department of Environment and Conservation as appropriate to avoid or mitigate imminent impacts to state-listed species.

5.9.2 Regionalization Alternative

Impacts under this alternative are expected to be generally the same as under the Centralization Alternative. The major difference between the two is the total area to be disturbed. The Regionalization Alternative is expected to have fewer buildings required and, therefore, fewer acres to be disturbed.

5.10 Noise

As discussed in Section 4.10, noises generated on the ORR do not propagate offsite at levels that impact the general population. Thus, ORR noise impacts for both the Centralization and Regionalization Alternatives are those resulting from the transportation of personnel and materials to and from the site that affect the nearby communities, and those resulting from onsite sources that may affect some wildlife near these sources. The effect of noise on wildlife near SNF management facilities under the Centralization or Regionalization Alternatives would be addressed in a project-specific environmental assessments.

The transportation noises are a function of the size of the work force (e.g., an increase in the size of the work force would result in increased employee traffic and corresponding increases in deliveries by truck and rail, and a decreased work force would result in decreased employee traffic and corresponding decreases in deliveries). This analysis of traffic noise took into account noise from the major roadways that provide access to the ORR. Vehicles used to transport employees and personnel on roadways would be the principal sources of community noise impacts near the ORR from the Centralization and Regionalization Alternatives.

This analysis used the day-night average sound level to assess community noise as suggested by the U.S. Environmental Protection Agency (EPA 1974, 1982) and the Federal Interagency Committee on Noise (FICON 1992). The change in day-night average sound level from the baseline noise level for each alternative was estimated based on the projected change in employment and traffic levels from the baseline levels. The baseline levels are those for 1995. The combination of construction and operation employment was considered. A change in noise level below 3 decibels would not be expected to result in a change in community reaction (FICON 1992).

Under the Centralization Alternative the projected ORR work force might increase by about 9 percent in the years 2000 to 2002, during the peak construction period, and might decrease thereafter (Section 5.3). There would be a corresponding increase in private vehicle and truck trips to the site. The day-night average sound level at 15 meters (50 feet) from the roads that provide access to the ORR would be expected to increase by less than 1 decibel. No change is expected in the community reaction to noise along these routes. No mitigation efforts are necessary.

Under the Regionalization Alternative the traffic noise impacts would be the same as for the Centralization Alternative.

5.11 Traffic and Transportation

5.11.1 Centralization Alternative

The proposed SNF management activities would involve a small increase in the number of employees commuting to the ORR and the transportation of SNF and hazardous chemicals onsite. This section summarizes the potential transportation impacts due to the proposed SNF facilities on the ORR.

5.11.1.1 Level of Service. Levels of service were calculated for construction and

operation of the SNF facility at the ORR. The maximum reasonably foreseeable scenario for operations occurs when the projected combined employees and population are at the highest level. This occurs in 2001, when there are 4,184 employees and a projected population in the Region of Influence of 528,800. The Region of Influence includes Anderson, Blount, Knox, Loudon, and Roane counties. This is the region from which employees can be expected to commute. The employees and population associated with the proposed action generate direct trips in the Region of Influence. These trips to the site are distributed to the Region of Influence road network according to percentages based on a traffic flow to the site from where employees historically have lived. Increase in baseline population and indirect site-related employees will generate indirect traffic trips in the Region of Influence. These trips are distributed based on the current average daily traffic per present population in the region of influence for a given segment. Direct and indirect average daily traffic is added and a new level of service is determined. Construction and operation employees contribute little to the future traffic because they represent such a small percentage of the Region of Influence population growth.

The following segment has a poorer level of service due to site-related impacts over the future baseline. Tennessee State Route 61 between Interstate 75 at Norris and 25W at Clinton will worsen to a level of service of E while Tennessee State Route 62 between Interstate 75 at Knoxville and US 441/TN 33 at Knoxville will worsen to a level of service of F. There are no other site-related impacts on any other segment.

Road reconstruction, widening, modification of interchanges, and new interchange construction projects are planned for segments of Bear Creek Valley Road, Scarboro Road, and Tennessee State Routes 58, 62, and 95 (Johnson, C. 1994; MMES 1991b).

Possible mitigation of impacts on local and regional roads having level of service of F could include adding lanes or employing traffic demand management.

The generic facility design would require rail access for Naval fuel delivery. This would create impacts that would be evaluated in detail if the site were selected for the SNF facility.

5.11.1.2 Transportation of Hazardous Chemicals. The hazardous chemicals required

and hazardous waste generated by the proposed SNF facility operation are assumed to be transported by truck. The onsite transportation impacts for these hazardous chemicals and wastes shipments are calculated based on the assumptions that (a) they do not have any incident free impacts, (b) the material would not leak during transport, (c) only risk is due to traffic fatalities, and (d) the material spill of entire contents is bound by the risk evaluated for the Expended Core Facility considered under facility accidents.

The total distance for onsite shipment of these hazardous chemicals is assumed to be the maximum site boundary distance from the proposed SNF facility to the nearest highway. Based on the unit risk factor (Cashwell et al. 1986) and occupational and nonoccupational fatalities considering a rural setting, the onsite transportation risks are calculated, assuming 10 annual shipments.

The maximum one-way distance from the site to the ORR gate by which trucks would deliver hazardous waste is 16 kilometers (10 miles). Based on 1.5 x 10-8 accident occupational fatalities per kilometer per shipment, 1.92 x 10-4 accident occupational fatalities are estimated over a 40-year period. Based on 5.3 x 10-8 accident non-occupational fatalities per kilometer per shipment, 6.8 x 10-4 accident non-occupational fatalities are estimated for a 40-year period.

5.11.1.3 Transportation of Radioactive SNF. The definition of offsite transportation

includes transportation of radioactive material from the shipping facility to the storage facility at the receiving site; therefore this local transportation does not separately address the onsite transportation impacts due to radioactive materials shipment except for handling at the storage facility. Based on current inventories and expected future generation, DOE estimates approximately 480 spent nuclear shipments over 40 years (1995-2035) from the High Flux Isotope Reactor. The distance between the High Flux Isotope Reactor and the proposed SNF management facility at ORR is about 6 miles (9.75 km). Incident-free onsite radiological transportation impacts from the estimated 480 shipments were calculated for transportation crew members (occupational) and general population. Occupational dose of 0.34 person-rem over 40 years was calculated based on a unit risk factor of 7.16 x 10-5 person-rem per kilometer (Appendix I). This dose results in 1.36 x 10-4 fatal cancers. The general population dose of 8.56 x 10-3 person-rem over 40 years was calculated based on a unit risk factor of 1.83 x 10-6 person-rem per kilometer (Appendix I). This dose results in 4.28 x 10-6 fatal cancers.

5.11.2 Regionalization Alternative

The impacts due to the Regionalization Alternative would be less than those described for the Centralization Alternative.

5.12 Occupational and Public Health and Safety

5.12.1 Centralization Alternative

This section evaluates the impacts to human health resulting from both contaminated emissions and direct exposures associated with the proposed SNF management facility under the Centralization Alternative. Based on current inventories and expected future generation, DOE estimates approximately 480 spent nuclear shipments over 40 years (1995 - 2035) from the High Flux Isotope Reactor. The distance between the High Flux Isotope Reactor and the proposed SNF management facility at ORR is about 6 miles (9.75 km). Incident-free onsite radiological transportation impacts from the estimated 480 shipments were calculated for transportation crew members (occupational) and general population. Occupational dose of 0.34 person-rem over 40 years was calculated based on a unit risk factor of 7.16 x 10-5 person-rem per kilometer (Appendix I). This dose results in 1.36 x 10-4 fatal cancers. The general population dose of 8.56 x 10-3 person-rem over 40 years was calculated based on a unit risk factor of 1.83 x 10-6 person-rem per kilometer (Appendix I). This dose results in 4.28 x 10-6 fatal cancers.

5.12.1.1 Radiological Dose and Cancer Impacts. Computation and modeling (see

Table 5.7-1) have shown that the dose rate (due to atmospheric effluents only) to the maximally exposed individual, conservatively taken to be at the site boundary of the ORR (without the presence of the interim storage facility), is 3.3 millirem per year of site operation with an **associated risk of fatal cancer of 1.7 x 10-6 to this maximally exposed individual.** It has also been established (see Section 4.12.4) that liquid effluents may present an additional plausible dose rate of 15.2 millirem per year of site operation (MMES 1993a) to a potential maximally exposed individual at the site boundary (due to both water consumption [0.2 millirem] and exposure from liquid material [15 millirem]), yielding a corresponding risk of 7.6 x 10-6 per year of operation. Subsequently, an additional 6.2 millirem per year to the postulated maximally exposed individual at the site boundary has been tabulated due to the presence of interim storage facility gaseous effluents (no radioactive liquid effluents are expected from the interim storage facility). Thus, if the spent fuel were brought to the ORR, it could result in a total cumulative dose rate (ORR + interim storage facility) to the maximally exposed individual at the site boundary of 24.7 millirem per year of site operation (see Table 5.12-1), with an associated total risk from ORR operations of 1.2 x 10-5 for fatal cancer; the resulting increase in risk to this individual from ORR operations with SNF management included is 34 percent. The total dose (24.7 millirem) to the maximally exposed individual is well within all applicable DOE limits (i.e., 4 millirem per year from the drinking water pathway, 10 millirem per year from the airborne release pathways, and 100 millirem per year total for all pathways). Table 5.12-1 shows the relationship among the various sources of radiation doses to the maximally exposed individual. The risks are presented there for both 1 and 40 years of exposure. The latter values are approximate and correspond to the operating lifetime of the SNF facility.

The annual population dose (80-kilometer [50-mile] radius) from total site operations (without the interim storage facility) is 54 person-rem, resulting in an increase of fatal cancer of 0.027. The increase in annual population dose from SNF operations is 5 person-rem, resulting in an increase of 2.5 x 10-3 for fatal cancer.

Over 40 years the increase in fatal cancers from SNF operations is 0.10. The increase of 9 percent in fatal cancers to the population from site operations with SNF results in an increase from 0.019 to 0.021 percent in the comparison of the dose received from ORR to that received from background. Table 5.12-1 also includes a summary of these population health impacts.

Table 5.12-1. Critical Interim Storage Facility impacts on radiation dose and cancer risks at ORR.

	Dose rate to the maximally exposed individual (mrem per yr)	Associated fatal cancer risk (yr of operation)a	Associated facility lifetime fatal cancer risk (40 years)a	Population dose from total site operations (person-rem per yr)	Associated total cancer increase (person per yr of operation)	Associated facility lifetime fatal cancer increase (person per 40 years)
Natural background	295	1.5 x 10-4	5.9 x 10-3	279,000	140	5,580
Public						
Baseline site operations	18.5	9.2 x 10-6	3.7 x 10-4	54	0.027	1.1
SNF operations	6.2	3.1 x 10-6	1.2 x 10-4	5.2	2.5 x 10-3	0.10
Baseline & SNF	24.7	1.2 x 10-5	4.9 x 10-4	59	0.030	1.2
Percent increase SNF over baseline	34	34	34	9	9	9
Workers						
Baseline site operations	2.8b	1.1 x 10-6	4.5 x 10-5	48	0.019	0.76
SNF operations	40b	1.6 x 10-5	6.4 x 10-4	32	0.013	0.40a

a. Facility lifetime fatal cancer risk accounts for time-varying number of workers.

b. Dose rate to an average worker.

It has been assumed that the additional doses to SNF workers (due to interim storage facility operations) will be similar in nature to those for major DOE facility Waste Processing/Management personnel. Hence, by examining the dose data from 1989, 1990, and 1991 for Richland, INEL, and Savannah River Site and assuming that the nuclear activity of the SNF would remain fairly constant until it is dealt with at the interim storage facility, it may be asserted that a maximally exposed interim storage facility worker could plausibly receive an additional (above background) annual dose of 3 rem from normal operations; this is equivalent to a risk of 1.2 x 10-3 for fatal cancer per year of operation. However, the average calculated dose (incurred in 1989, 1990, and 1991) to SNF workers was approximately 40 millirem per year; this is equivalent to a risk of 1.6 x 10-5 for fatal cancer per year of operation, and to an approximate risk of 6.4 x 10-4 to a worker who is present during the entire 40-year facility lifetime.

An excess of 0.013 fatal cancer among all SNF facility workers is projected from peak annual operations; exposures to radiation over the lifetime of SNF operations could result in an excess of 0.40 fatal cancer. The maximum health effects due to radiological doses to a noninvolved worker, i.e., an ORR worker at a faciity other than SNF, would be on the order of 1 percent of the occupational exposure to an SNF worker based on analyses for the SRS and INEL sites. Table 5.12-1 includes a summary of the doses and fatal cancer risks to SNF workers.

5.12.1.2 Chemical Exposure Health Impacts. The calculated atmospheric maximum

concentrations of hazardous chemicals (at the site boundary) for the proposed action are presented in Table 5.7-5 in Section 5.7. The maximum concentrations at the site boundary reflect an exposure to a maximally exposed individual, whereas the maximum onsite concentrations reflect an exposure to a worker. Of the potential hazardous chemicals identified for the proposed action, cadmium, nickel and chromium VI (chrome) are carcinogens for which a total cancer risk is calculated. The remaining seven chemicals are noncarcinogens for which a hazard index is calculated. A hazard index value of greater than 1 serves as an indicator for potential adverse health effects.

The offsite concentrations in Table 5.7-5 represent values at public access roads within the reservation. However, a maximally exposed individual is assumed to be unable to take up residence on these roads, but instead takes up residence along the reservation fence line. The concentrations at the fence line are 62 percent of those listed as offsite. On the other hand, the concentrations at the roads, being the highest listed within the fence line, are used here to represent maximum concentrations for ORR workers.

Based on the maximum hazardous chemical concentrations at the site boundary, the lifetime fatal cancer risk and hazard index to the maximally exposed member of the public are 2.5 x 10-12 and 1.2 x 10-2, respectively. Based on the maximum concentrations onsite, the lifetime fatal cancer risk and hazard index to a worker are 4.0 x 10-12 and 1.9 x 10-2, respectively. This indicates that there will be virtually no health impacts from nonradiological releases.

5.12.1.3 Labor and Construction Health Risks. There are expected to be 25,212 total

occupational/total labor worker-years for the 40-year duration of the interim storage facility. Hence, over the 40-year interim storage facility life span, it is estimated that 807 total injuries/illnesses and 0.81 fatality to DOE and contractor personnel would result. The expected 4,352 total construction worker-years for the 40-year duration of the interim storage facility results in 270 total injuries/illnesses and 0.48 fatality to DOE and contractor personnel.

5.12.2 Regionalization Alternative

Although the Regionalization Alternative is not explicitly analyzed, its impacts will be less than those from the Centralization Alternative.

5.13 Utilities and Energy

Direct changes in utility demand as a result of the Centralization and Regionalization Alternatives were compared against the current capacity and peak demand for each utility resource. Impacts to provision of a utility are considered to occur if the current demand, average annual demand, or peak demand for a utility is equal to or exceeds the current available capacity within the designated Region of Influence. For the purpose of analysis, the Region of Influence for each resource area is defined as the area served by the utility provider responsible for meeting the service demands of the ORR.

5.13.1 Centralization Alternative

5.13.1.1 Water Consumption. For the Centralization Alternative, approximately 0.43

liter per second (6.85 gallons per minute) of water is required to operate all the modules within the facility (Harr 1994). The K-25 plant, which would provide water to the site, has a capacity of 184 liters per second (2,917 gallons per minute) (Fritts 1994).

The proposed SNF management facilities would require approximately 0.2 percent of the K-25 plant's water capacity. The K-25 plant would operate at 53 percent of its capacity when the SNF facilities' water requirements are combined with the 1990 peak water usage of 97 liters per second (1,533 gallons per minute).

5.13.1.2 Electrical Consumption. The proposed SNF management facilities under the

Centralization Alternative would require approximately 23,000 megawatt hours of electricity per year or approximately 2.63 megavolt-amperes average demand (Harr 1994). This represents 0.3 percent of ORR's 920 megavolt-ampere connected capacity. Thirty-one percent of the connected capacity of ORR would be utilized when the peak electric requirement of 285 megavolt-amperes was combined with the electrical requirements of the Centralization Alternative.

5.13.1.3 Fuel Consumption. Energy requirements for the proposed SNF management

facilities under the Centralization Alternative were calculated assuming that electrical power purchased from a utility provider was the primary source of energy; however, fossil fuels may be used to power backup generators and during construction. The amount of fuel required for these operations would be small and should not substantially increase ORR fuel requirements.

5.13.1.4 Wastewater Disposal. Under the Centralization Alternative, approximately

0.43 liter per second (6.85 gallons per minute) of wastewater would be generated (Harr 1994). A new onsite sanitary sewage system and wastewater treatment plant might be required at the SNF facility. If a new system is not built, and sanitary sewage and wastewater are treated at K-25, this addition would represent approximately 2 percent of the K-25 sanitary sewer treatment system capacity of 26 liters per second (417 gallons per minute). Ninety-four percent of the wastewater capacity of the K-25 sanitary sewer treatment system would be utilized when the peak wastewater production of 24 liters per second (378 gallons per minute) was combined with the wastewater production of the SNF management facilities.

5.13.2 Regionalization Alternative

5.13.2.1 Water Consumption. The proposed SNF management facilities under the

Regionalization Alternative would require less water than the facilities under the Centralization Alternative; therefore, the impacts would be less.

5.13.2.2 Electrical Consumption. The proposed SNF management facilities under the

Regionalization Alternative would require less electricity than the facilities under the Centralization Alternative; therefore, the impacts would be less.

5.13.2.3 Fuel Consumption. Energy requirements for the proposed SNF management

facilities under the Regionalization Alternative were calculated assuming that electrical power purchased from a utility provider was the primary source of energy; however, fossil fuels may be used to power backup generators and during construction activities. The amount of fuel required for these operations would be small and should not substantially increase ORR fuel requirements.

5.13.2.4 Wastewater Disposal. The proposed SNF management facilities under the Regionalization Alternative would produce less wastewater than the Centralization Alternative; therefore, the impacts would be less.

5.14 Materials and Waste Management

This section discusses the potential environmental consequences of the Centralization and Regionalization Alternatives for the management of chemical raw materials and transuranic, low-level radioactive, and hazardous waste at the ORR. Nonhazardous (sanitary) wastes are discussed in Section 5.8. Section 4.14 describes the waste categories and outlines the ongoing waste management activities for the ORR. These waste management activities include onsite and offsite waste treatment, onsite and offsite waste disposal, and onsite waste storage. Section 4.14 also describes the chemical raw material management activities for the ORR.

5.14.1 Methodology

This analysis considers the impact of the Centralization and Regionalization Alternatives on current waste management activities at the ORR (baseline conditions). In addition to requiring land area for SNF management, both alternatives would generate transuranic, low-level radioactive, hazardous, and nonhazardous wastes. Neither alternative is projected to generate mixed wastes or high-level wastes. This analysis is based on a comparison of the projected amounts of waste generated by the Centralization and Regionalization Alternatives versus the current waste generation rates and storage capacity at the ORR.

5.14.2 Materials and Waste Management

SNF management activities would require the use of chemicals, and it is conservatively assumed that all chemical raw materials used within the proposed SNF management facility would become hazardous wastes. The proposed SNF management facility would contribute transuranic, solid low-level, and sanitary (sewage) wastes. Table 5.14-1 presents the estimated waste generations by waste classification for each of the two alternatives (Centralization and Regionalization) and by each of two storage options (wet storage, dry storage).

5.14.2.1 Centralization Alternative. Under the Centralization Alternative, all DOE SNF (including Naval and domestic and foreign research reactors) will be transferred to and managed at the ORR.

5.14.2.2 Wet Storage Option. The wet storage option would generate transuranic, low-level, hazardous, and sanitary wastes. The effect that the projected amounts of each of these wastes would have on the ORR waste management is discussed below.

5.14.2.2.1 Transuranic Waste-Over a period of 40 years of operation the projected amount of transuranic waste generated due to the recovery and purification of transuranic products would be 644 cubic meters (22,750 cubic feet). The current storage capacity at the ORR (ORNL) is 833.4 cubic meters (295,000 cubic feet). ORNL will continue to generate transuranic waste, and disposal is eventually planned for the Waste Isolation Pilot Plant unit. If the Waste Isolation Pilot Plant unit does not come on line, the ORR transuranic waste storage

Table 5.14-1. Ten-year cumulative estimated waste generation for SNF alternatives at the ORR (m3).

Alternative/ storage option	Time period			
	1995-2004	2005-2014	2015-2024	2025-2034

a. Source: Harr (1994).

capacity may have to be expanded to accommodate transuranic waste generated at the SNF facility.

5.14.2.2.2 Low-Level Waste-The wet storage option would generate liquid low-level waste as a result of its interim storage in water. Over a period of 40 years of operation, an estimated 7,800 cubic meters (over 2 million gallons) of low-level liquid waste might be generated. The total ORR (Y-12, K-25, ORNL) storage capacity for liquid low-level wastes is about 98,300 cubic meters (about 26 million gallons) (see Tables 4.14-1, 4.14-3, and 4.14-5). Impacts would be small.

5.14.2.2.3 Hazardous Wastes-Installation of the proposed SNF management facility would require additional management of hazardous wastes, including the placement of satellite storage areas within the SNF complex and more frequent offsite shipments of hazardous wastes. It is estimated that the wet storage option will generate approximately 7.4 cubic meters (261 cubic feet) of waste annually. Currently ORR manages about 10,000 cubic meters (about 353,000 cubic feet) of hazardous waste annually (see Tables 4.14-1, 4.14-3, and 4.14-5); therefore, the impact of SNF generated hazardous waste on the management of hazardous waste at the ORR would be minimal.

5.14.2.2.4 Sanitary Waste-Sanitary wastes are covered in Section 5.8.

5.14.2.3 Dry Storage Option. The dry storage option would generate low-level waste and sanitary waste. The effects that the projected amounts of each of these wastes would have on the ORR waste management is discussed below.

5.14.2.3.1 Low-Level Waste-The low-level radioactive contaminated waste stream would result from wastes generated during decontamination operations. Over a period of 40 years of operation, an estimated 304 cubic meters (10,700 cubic feet) of low-level waste might be generated. As reported in Section 5.14.2.2.2 the total ORR storage capacity for liquid low-level waste is about 98,300 cubic meters (about 26 million gallons). Impacts from SNF operations on low-level waste management would be minimal.

5.14.2.3.2 Sanitary Waste-Sanitary wastes are covered in Section 5.

8.

5.14.2.2 Regionalization Alternative. Under the Regionalization Alternative, the ORR

would be the alternate site for the SRS. This alternative would generate less waste from the SNF complex than the Centralization Alternative since it is the alternative that stores less SNF. For either the wet storage or dry storage option, the waste generated would be less than those presented for the Centralization Alternative. Therefore, Table 5.14-1 presents the estimated waste generation for the SNF for the Regionalization Alternative as less than those generated for the Centralization Alternative. The impacts presented for each of the waste categories for its two options (wet storage, dry storage) for the Centralization Alternative apply to the Regionalization Alternative as well.

5.15 Facility Accidents

A potential exists for accidents at facilities associated with the handling, inspection, and storage of spent nuclear fuel at the ORR. Accidents can be categorized into events that are abnormal (for example, minor spills), events a facility was designed to withstand, and events a facility is not designed to withstand. These categories are termed abnormal, design basis, and beyond design basis accidents, respectively. Summarized here are consequences of possible facility accidents for a member of the public at the nearest site boundary and at the nearest road, for the collective population within 80 kilometers (50 miles), for workers, and for the environment. See Section 5.11 for a summary of the assessment of transportation accidents.

A review of the historical record of accidents at the ORR is summarized in the following section. Methods used to assess potential future events are summarized in Section 5.15.2. Evaluations of accident impacts by alternative are summarized in Sections 5.15.3 through 5.15.7. A summary comparison of accident impacts by alternative is given in Section 3.2. Additional supporting documentation for the accident impacts is given in a separate report (HNUS 1995).

This section examines the various activities that have been performed to assess the potential for accidents and their consequences for workers and the public for each alternative. A set of potential reasonably foreseeable accidents over the 40-year period are described which envelop all accidents. Secondary impacts of accidents pertaining to cultural resources, economics, land use, endangered species, water resources, and ecology are also addressed. This section also addresses emergency preparedness plans that have been established to mitigate the primary and secondary effects of accidents.

5.15.1 Historical SNF Accidents at ORR

The records of unusual events, including accidents, at the ORR have been reviewed to determine whether there have been any accidents with offsite impacts. The results indicate that there have been no accidents at the ORR associated with SNF that have had significant offsite consequences for the general public.

5.15.2 Methodology

5.15.2.1 Existing Facilities.

5.15.2.1.1 Assumptions and Approach-The potential accidents associated with

the existing SNF management facilities and operations were screened to determine which ones to include in the accident analysis for the No Action Alternative. Source terms were developed for each accident analysis. The GENII code (PNL 1988) was used to estimate accident consequences for the general public and for individuals onsite or at the site boundary based on both 50 percent and 95 percent meteorology. Accident consequences and risk are described in terms of dose, cancer fatalities, and total health detriments for workers, an individual at the site boundary, and the public residing as far as 80 kilometers (50 miles) from the proposed SNF management facility.

5.15.2.1.2 Accident Screening-The potential accidents associated with the existing

SNF management facilities and operations were screened to determine which ones to include in the accident analysis for the No Action Alternative. Initiating events were reviewed including natural phenomena (earthquakes, tornadoes, etc.), human initiated events (human error), equipment failures, fires, explosions, airplane crashes, and terrorism. One reference design basis fuel handling accident was selected for detailed analysis.

The dam in the High Flux Isotope Reactor fuel pool is removed and stored within the pool during refueling operations. The reference design basis fuel handling accident postulated that during refueling operations, the dam falls and damages all the 62 spent fuel cores, including the most recently discharged core, located in the pool. The fission products from all 62 spent fuel cores are released to the water in the pool (ORNL 1992b).

A beyond design basis tornado accident was considered that resulted in collapse of the High Flux Isotope Reactor bay roof and the roof's major structural member falls into the fuel pool and damages all the 62 spent fuel cores located in the pool. The fission products from all 62 spent fuel cores are released to the water in the pool (Flanagan 1994).

Additional beyond design basis accidents initiated by an airplane crash were postulated for the High Flux Isotope Reactor and Bulk Shielding Reactor but were screened out because the probability of an airplane crash into the fuel pool was estimated to be less than 1.0 x 10-7 per year.

The consequences of postulated operational and reference design basis accidents for the existing facilities are enveloped by the accident consequences presented in Subsection 5.15.4 for the Centralization Alternative.

5.15.2.2 New Facilities. In the absence of suitable design details for new SNF

management facilities during this stage of the SNF Management Program upon which to base an accident analysis, the approach makes use of accident scenarios and associated data that have been analyzed and documented for similar facilities. They include spent nuclear fuel facilities at INEL, Hanford, Savannah River Site, and Naval sites.

5.15.2.2.1 Assumptions and Approach-A number of postulated accidents for the

similar facilities have been selected to serve as a common basis for estimating accident consequences for workers and the public at the ORR site. Although the accident scenarios, source terms, and related assumptions are common for both sites, the estimated consequences are unique to the ORR site because of site differences in modeling parameters pertaining to distances to site boundaries and population centers, population distributions, and meteorology. The GENII code was used to estimate accident consequences for the general public and for individuals onsite or at the site boundary based on both 50 percent and 95 percent meteorology. Accident consequences and risk are described in terms of dose, cancer fatalities, and total health detriments for workers, an individual at the site boundary, a transient individual at the nearest public access, and the public residing as far as 80 kilometers (50 miles) from the proposed SNF facility. The estimated frequency of each selected accident is based on the reference source documentation.

The probability of an airplane crash into the new SNF management facility is considered small because there are no nearby airports with large aircraft activity. The probability is expected to be in the 1 x 10-6 to 1 x 10-8 per year range. For calculational purposes the probability of this accident is conservatively estimated at 1 x 10-6 per year. Potential accidents initiated by an airplane crash into the SNF management facilities and the estimated consequences have been analyzed.

The secondary impacts of accidental releases of radioactive and hazardous materials are also addressed in a qualitative manner. Secondary impacts pertain to effects of accidents on land use, endangered species, water resources, cultural resources, and ecology.

5.15.2.2.2 Accident Screening-The potential accidents associated with existing

SNF management facilities and operations were screened to determine which ones to include in the accident analysis for the ORR.
The source documentation for this purpose was primarily
Appendices A, B, C, and D of Volume 1 of this EIS. The source documentation describes potential accidents for existing and planned SNF management facilities that were selected by a screening process. Initiating events were reviewed including natural phenomena (earthquakes, tornadoes, etc.), human initiated events (human error), equipment failures, fires, explosions, airplane crashes, and terrorism. Accidents associated with the Expended Core Facility operations at the ORR, were analyzed separately and the results are documented in Appendix D of this EIS. For the ORR the maximum reasonably foreseeable criticality and nonradiological accidents are associated with the Expended Core Facility. The potential for a criticality exists while the fuel is in dry storage, during handling, and in the wet storage pool. Although the probability of
any criticality is very low, a hypothetical criticality of 1 x 1019 fissions was postulated in the
Expended Core Facility wet pool as a basis for estimating the maximum reasonably foreseeable consequences of a criticality.

The selected accidents include beyond reference design basis events to reflect the magnitude of accident consequences that envelop all other accidents that have a reasonable probability of occurrence. They also include other accidents with lower consequences and typically higher probabilities of occurrence to show a range of accident types and consequences. The accidents included in this set are reasonably foreseeable, meaning that there are one or more sequences of events that will lead to their occurrence and the sequence with the lowest probability of occurrence is greater than 1 x 10-7 per year. Accidents falling outside of this envelope, such as a meteorite impact, have been judged unreasonable because the probability of occurrence in less than 1 x 10-7 per year.

5.15.2.2.3 Accident Prevention and Mitigation - Under the Centralization and

Regionalization alternatives, the SNF management facilities at the ORR will be of new design and construction and incorporate the latest technology for safety.
The accidents postulated for
the SNF management facilities are based on operations and safety analyses that have been performed at similar facilities. One of the major design goals for the SNF management facilities is to achieve a reduced risk to facility personnel and to public health and safety relative to that
associated with similar functions at the existing SNF management facilities. Significant changes exist between design criteria and safety standards for the new SNF management facilities and those for the current facilities, thus reducing total risk. These changes include design to current
DOE structural and safety criteria and to planned throughput and storage capacity.

The new SNF management facilities would be designed to comply with current Federal, state, and local laws, DOE Orders, and industrial codes and standards. This would provide facilities that are highly resistant to the effects of severe natural phenomena, including earthquake, flood, tornado, high wind, as well as credible events as appropriate to the site, such
as fire and explosions, and man-made threats to its continuing structural integrity for containing
materials.

Emergency preparedness plans have also been prepared for existing facilities and will be revised for new facilities to lower the potential consequences of an accident to workers and the public. All workers receive evacuation training to ensure timely and orderly personnel movement away from high-risk areas. Plans and arrangements with local authorities are also in place to evacuate the general public that may be at risk of exposure to hazardous materials that are accidentally released.

5.15.3 No Action Alternative

There is a potential for the accidental release of radioactive substances during various stages of SNF handling operations and storage. The operations begin with discharge of SNF from the reactor during refueling operations. The discharged SNF is placed in the fuel pool for cooling and short term storage. After an adequate cooldown period, SNF is removed from the pool and transported offsite for long term storage. Accidents that may occur during these handling operations and storage may involve the release of radioactive material to air or water pathways. The cause of accidents may be due to internal initiators, such as operator error, equipment failure, and terrorism, or external initiators, such as an earthquake.

In the event that SNF can not be transported offsite for long term storage, reactor operations will cease when the fuel pool is full. Presently the SNF stored in the ORR fuel pools is sound and has not deteriorated. If the existing SNF were to remain in the ORR fuel pools for an extended period of time and deterioration of the aluminum fuel cladding occurred, there are no existing facilities at the ORR to characterize the SNF.

5.15.3.1 Radiological Impacts. The potential accidents associated with the existing SNF management facilities and operations were screened to determine which ones to include in the accident analysis for the No Action Alternative. One reference design basis accident and one beyond design basis accident were selected for detailed analysis. Although other accidents may occur, their estimated consequences are bounded by this beyond design basis accident or their probability of occurrence is less than 1.0 x 10-7per year. If these accidents were to occur, the dose and risk to the onsite worker and the general population are shown in Tables 5.15-1 and 5.15-2 for 95 percent and 50 percent meteorology respectively. Similarly, cancer fatalities are shown in Tables 5.15-3 and 5.15-4, and the health effects are shown in Tables 5.15-5 and 5.15-6.

5.15.3.1.1 Reference Design Basis Accident-The dam that separates the High Flux Isotope Reactor pool from the clean center pool during normal reactor operation is moved to a position between the east and center clean pools prior to defueling the reactor. The dam is lifted approximately 3 feet above the water over its slot between the reactor and center pools, then moved with the crane across the center clean pool, and then lowered into its slot between the east and center pools. During this movement, and when the dam is being moved back, the fuel in the center pool is subjected to the possibility of dropping the dam and mechanically

damaging the fuel. There is also a possibility that the dam could somehow be dropped as it is being lowered into (or raised from) its place between the clean pools and then fall in a way that would damage the fuel in either pool. The reference design basis fuel handling accident postulated that during refueling operations, the dam falls and damages all the 62 spent fuel cores, including the most recently discharged core, located in the pool. The fission products from all 62 spent fuel cores are assumed to be instantaneously released into the water in the pool. The analysis assumed that the pool area exhaust system was operational, it carried off all evaporated fission products, it filtered the stream, and it released the remaining fission products up the stack.

The source term released up the stack is shown in Table 5.15-7. The frequency of occurrence for this accident is in the range of 1.0 x 10-4 to 1.0 x 10-6 per year (ORNL 1992b).

5.15.3.1.2 Beyond Design Basis Accident-The beyond design basis accident postulated that a beyond design basis tornado with wind speeds of approximately 300 mph struck the High Flux Isotope Reactor reactor bay.

The reactor bay roof collapses and the major structural member in the roof falls into the fuel pool and damages all the 62 spent fuel cores, including the most recently discharged core, located in the pool. The fission products from all 62 spent fuel cores are assumed to be instantaneously released into the water in the pool. The analysis assumed that all evaporated fission products are released directly to the environment at ground level. The source term is similar to the reference design basis accident source term present in Table 5.15-7 except that no credit was taken for filtration of the iodine evaporated from the pool. The iodine released in the beyond design basis source term is 100 times greater than the iodine released in the reference design basis accident source term (Flanagan 1994).

The annual return frequency of a tornado with wind speeds of approximately 300 mph at ORR is 1.4 x 10-5. The conditional probability for collapse of the reactor bay roof during a 300 mph tornado is 0.46. The ratio of the spent fuel area to the reactor bay floor area (i.e., the probability that the falling structural member will fall into the spent fuel area of the fuel pool) is 0.03. The frequency of occurrence for this beyond design basis accident is 1.9 x 10-7 per year (Flanagan 1994).

Due to the dose consequences associated with the postulated accident, protective actions were assumed for the offsite population. The analysis took no credit for evacuation of the public from the affected area. However, credit was taken for removing contaminated food from the general public.

Table 5.15-7. Estimated radionuclide releases for the High Flux Isotope Reactor fuel pool dam drop accident at ORR.

Isotope	Release Duration 0-2 hr Curies	 0-30 day Curies
Hydrogen-3 (Tritium)	3.5 x 102	3.5 x 102
Krypton-83m	1.9 x 102	1.9 x 102
Krypton-85	1.0 x 104	1.0 x 104
Krypton-85m	3.6 x 103	3.6 x 103
Krypton-87	4.2 x 10-1	4.2 x 10-1
Krypton-88	1.1 x 103	1.1 x 103
Iodine-151	3.8 x 100	1.5 x 101

5.15.3.2 Nonradiological Hazards. The two bounding accidents involving nonradiological hazards postulated for the Centralization Alternative in subsection 5.15.4.2 are assumed to be bounding for the No Action Alternative. SNF operations under the No Action Alternative should not introduce any nonradiological hazards unique to the ORR SNF facilities.

5.15.4 Centralization Alternative

There is a potential for the accidental release of radioactive substances during various stages of SNF handling operations and storage. The operations at the new SNF management facilities begin with the receipt of an SNF shipment by truck or rail carrier, followed by the unloading of the shipping cask from the transport vehicle. If the SNF requires cooling, the cask is placed into an unloading pool where the SNF is withdrawn from the cask, moved to a temporary wet storage basin, and placed into a fuel rack. Some SNF that does not require cooling will be handled in a special cell where it will undergo canning and/or characterization. SNF that does not have to be cooled and does not require canning and/or characterization will be loaded into a dry storage canister within a transfer cask and transported to modular above-grade dry storage. Accidents that may occur during these handling operations and storage at the existing or new SNF management facilities may involve the release of radioactive material to air or water pathways. The cause of accidents may be due to internal initiators, such as operator error, terrorism, and equipment failure, or external initiators, such as an airplane crash into a facility.

5.15.4.1 Radiological Impacts. The accidents described below have been chosen to envelop the consequences of potential accidents for the proposed new SNF management facilities at the ORR. Although other accidents may occur, their estimated consequences are bounded by the accidents in the envelope or their probability of occurrence is less than 1 x 10-7 per year. If these accidents were to occur, the dose and risk would be as shown in Tables 5.15-8 and 5.15-9 for 95 percent and 50 percent meteorology respectively. These doses are in addition to the average natural background radiation exposure of 360 millirem per year. Similarly, cancer fatalities are shown in Tables 5.15-10 and 5.15-11, and the health effects are shown in Tables 5.15-12 and 5.15-13.

5.15.4.1.1 Fuel Assembly Breach-Physical damage and breach of a fuel assembly

could accidentally occur from dropping, objects falling on the assembly, or cutting into the fuel

part of an assembly. The fuel cutting accident that has been postulated to occur at Savannah River Site facilities is chosen as representative of the fuel assembly breach accident (E. I. du Pont de Nemours & Co. 1983). During normal operations at the Savannah River Site, the inert, non-uranium-containing extremities of some spent nuclear fuel elements are cutoff in the repackaging basin before the bundling of the elements. The accident occurs when the actual uranium fuel is inadvertently cut, causing a radioactive release. The source term for this accident is shown in Table 5.15-14. The estimated frequency of occurrence for this accident is 1.6 x 10-1 per year based on the Savannah River Site's operating experience with SNF. However, because of anticipated differences in operations and facilities at the ORR, the actual frequency is expected to be much less than 1.6 x 10-1 per year.

5.15.4.1.2 Dropped Fuel Cask-The dropped fuel cask accident that has been

postulated to occur at the Hanford Site (reference Volume 1, Appendix A) is chosen as representative of the dropped fuel cask/fuel handling accident for the new Centralization Alternative facility at the ORR.
This accident is initiated when a fuel cask is dropped and overturned in the fuel transfer area and broken fuel elements spill out of the cask, within the pool building but away from the pool. It is assumed that the shipping cask ruptures, exposing all of the broken fuel elements in three canisters--42 fuel elements, each containing 22.5 kilograms (50 pounds) of fuel. The source term for this accident is shown in Table 5.15-15. The probability of this accident is estimated to be less than 1 x 10-4 per year.

5.15.4.1.3 Severe Impact and Fire-The severe impact and fire accident that has

been postulated to occur at the Hanford Site (reference Volume 1, Appendix A) is chosen as representative of the severe impact and fire/onsite transportation accident for the new Centralization Alternative facility at the ORR.
This accident assumes an unspecified initiating event that subjects the fuel assemblies to a severe impact, breach of the transport cask, and a fire. During the accident, the fuel pins rupture on impact or upon heating in the fire, which burns for an hour before being extinguished. Volatiles, particulates, and noble gases are released to the atmosphere. The source term for a release of 540 curies is shown in Table 5.15-16. The estimated probability of occurrence for this accident, reflecting the fact that the facilities at

this site would be new, is less than 1 x 10-6 per year.

5.15.4.1.4 Wind-driven Missile Impact into Storage Casks-The wind-driven missile impact into storage casks accident that has been postulated to occur at the Naval Site (reference Volume 1, Appendix D) is chosen as representative of the wind-driven missile accident for the new Centralization Alternative facility at the ORR. This accident is initiated by natural phenomena: a major wind storm or tornado in excess of the facility design basis. In this scenario, a large object is propelled by the wind into a storage container, causing the container seal to be breached. No fuel damage would result from the impact because of the strength of the containers used. The source term is based on the spent nuclear fuel corrosion film. One percent of the original corrosion film on the fuel would be released from the cask into the atmosphere. The source term is shown in Table 5.15-17. The probability of this event is estimated to be less than 1 x 10-5 per year based on a design basis tornado probability of 1 x 10-3 per year and a missile impact with damage probability of less than 1 x 10-2.

Table 5.**15-14.** Estimated radionuclide releases for a fuel assembly breach accident at ORR.

5.15.4.1.5 Airplane Crash Into Dry Storage-The airplane crash into dry storage

accident that has been postulated to occur at the Naval Site (reference Volume 1, Appendix D) is chosen as representative of the airplane crash into the dry storage area accident for the new Centralization Alternative facility at the ORR. This accident is externally initiated by an airplane crash into the SNF dry storage facility. The accident is postulated to cause damage to a single storage cask. Due to the severity of the impact, the cask seal is assumed to be breached, resulting in damage to the fuel and the release of corrosion products, located on the SNF exteriors, to the environment. The impact also causes a fire and a release of fission products. It is assumed that 1 percent of all of the fuel units stored inside the cask are damaged either by the impact or by the fire and that those fission products are available for release. Of the available fission products, 100 percent of the noble gases, 3 percent of the halogens, 1.1 percent of the cesium, and 0.1 percent of the remaining solids are released to the environment. Also, 10 percent of the original corrosion products from the fuel units are released from the cask to the atmosphere. The source term for this accident is shown in Table 5.15-18. The probability of this accident, based on analyses of other facilities at the site (Flanagan 1994), is small and assumed to be less than 1 x 10-6 per year.

5.15.4.1.6 Airplane Crash into Dry Cell Facility-The airplane crash into the dry

cell facility accident that has been postulated to occur at the Naval Site (reference Volume 1, Appendix D) is chosen as representative of the airplane crash into the canning and characterization cell accident for the new Centralization Alternative facility at the ORR. This accident is initiated by an airplane crash into the dry cell facility. The accident was postulated to cause significant damage to the building, resulting in the loss of containment and filtered exhaust systems. The fuel units inside the dry cell could also be damaged due to mechanical impacts and potential fire. The mechanical impact also could result in the release of corrosion products to the environment. For this accident scenario, 1 percent of the fuel units stored inside of the dry cell are assumed to be damaged by either the impact or resultant fire and those fission products would be available for release. Of the fission products available for release, 100 percent of the noble gases, 3 percent of the halogens, 1.1 percent of the cesium, and 0.1 percent of the remaining solids could be released to the environment. Ten percent of the available corrosion products could be released to the environment. The source term for this accident is shown in **Table 5.15-19.** The probability of this accident is estimated to be less than 1 x 10-6 per year.

5.15.4.1.7 Airplane Crash into Water Pool-The airplane crash into the SNF water

pool accident that has been postulated to occur at the Naval Site (reference Volume 1,

Appendix D) is chosen as representative of the airplane crash into the SNF water pool accident for the new Centralization Alternative facility at the ORR. This externally initiated accident occurs when an airplane crashes into an SNF water pool and damages the fuel units stored there. Fission products and corrosion products are released from the fuel units into the water pool but the pool water is not released to the environment. The presence of the pool water results in a release only of gaseous fission products into the atmosphere. In this accident scenario, 1 percent of all the fuel units stored inside the pool were postulated to be damaged and those fission products are available for release. Of the available fission products, 100 percent of the noble gases and 25 percent of the halogens are released to the pool water. Due to the presence of pool water, there is a reduction of the halogen release by a factor of 10 prior to release into the atmosphere. The source term for this accident is shown in Table 5.15-20. The probability of this accident is estimated to be less than 1 x 10-6 per year.

5.15.4.1.8 Integration of Existing Facilities- Existing SNF management facilities

will be integrated into the Centralization, Regionalization, and Planning Basis Alternative SNF storage functions until the existing ORR operating reactors are shutdown. The accident consequences postulated for the No Action Alternative in subsection 5.15.3 can occur as long as the High Flux Isotope Reactor is operational. After the High Flux Isotope Reactor is no longer operational, the accident consequence will decrease as the spent reactor cores, stored in the pool, age. The reference design basis accident frequency of occurrence and risk will be reduced because refueling operations have ceased and requirements for movement of the dam are reduced. Since the beyond design accident is initiated by natural phenomenon (i.e., tornado), the beyond design basis accident frequency of occurrence will remain the same as long as spent High Flux Isotope Reactor cores remain in the spent fuel pool area.

Iodine-131	1.6 x 10-2
Hydrogen-3 (Tritium)	4.3 x 102

a. Source: See Section F.1.4.2.1.4, Appendix D to Volume 1.

5.15.4.2 Nonradiological Hazards. The two bounding accidents involving nonradiological

hazards are a chemical spill and fire and a diesel fuel fire. Both of these accidents are associated with the Expended Core Facility operations and the accident frequencies and impacts are addressed in Volume 1, Appendix D. The analyses of these accidents considered the impacts to workers on the site as well as to the offsite population. The impacts were measured in terms of potential health effects due to exposure to toxic chemicals released during these accidents. Since the Expended Core Facility at this site will be a new design and construction, it will incorporate all applicable standards and regulations and therefore limit the potential exposures to the workers and the public in the event of an accident.

5.15.4.3 Secondary Impacts. In the event of an accidental release of radioactive

substances, there is a potential for secondary impacts to cultural resources, endangered species, water resources, public and agricultural land use, the ecology in the vicinity of the accident, national defense, and local economics. Figure 5.15-1 illustrates the radiological impacts to the environment in the event of a severe accident at a new SNF management facility and the release of radioactive material with 50 percent meteorology. The accident chosen for this purpose is an airplane crash into the Centralization Alternative canning and characterization (dry) cell. Figure 5.15-1 shows several isodose lines ranging from 870 millirem per year down to 87 millirem per year. The solid line represents the site boundary, and it can be seen from the figure that some doses exceeding background would exist outside the site boundary.

Table 5.15-21 presents a summary of the postulated severe accident secondary impacts on the environment, economy, and national defense. The evaluation was performed using 50 percent meteorology.

5.15.5 Decentralization Alternative

The Decentralization Alternative is not applicable for the ORR.

Figure 5.15-1. Isodose lines for an airplane crash into dry cell accident with 50 percent meteorlogy at Oak Ridge Reservation.

Table 5.15-21. Secondary impacts of Centralization Alternative accidents at the ORR.

Environmental or social factor	Impact
Land use	Yes. Major portions of the ORR, including the ORNL and K-25 areas, will be contaminated. Offsite contamination will occur. Industrial, residential, forest, and agricultural areas will be contaminated.
Cultural resources	Yes. Archaeological sites, cemeteries, and historic sites will be contaminated.
Aesthetic and scenic resources	Possible impact. Scenic public viewing areas are within 2 miles of the ORR border.
Water resources	Yes. The Clinch River will be contaminated. It is used for industrial and public water supplies, navigation, fishing, boating, and swimming.
Ecological resources	Possible impact. Many endangered or threatened plants and animals are potentially on or near the ORR.
Treaty rights	No impact. There are no ORR areas subject to Native American Treaty rights.
National defense	Possible impact. With the 50 percent meteorology, the area of contamination does not envelop U.S. military facilities or the Y-12 area. However, with the 95 percent meteorology, the Y-12 area will be contaminated.
Economic impacts	Yes. Offsite contamination will occur. Industrial, residential, forrest, and agricultural areas will be contaminated. Major portions of the ORR will be contaminated. The accident consequences may require the evacuation and cleanup of onsite facilities, including but not limited to the ORNL and K-25 areas, and adjacent residential, industrial, forest, and agricultural areas. The Clinch River will be contaminated. The associated industrial and residential water supplies will be contaminated. The commercial and recreational fishing industries may be impacted.

5.15.6 1992/1993 Planning Basis Alternative

The facility accident consequences and risks for the ORR No Action Alternative envelop the facility accident consequences and risks for the 1992/1993 Planning Basis Alternative.

5.15.7 Regionalization Alternative

Under the Regionalization Alternative, new facilities will be constructed and operated for SNF. Details for the new facilities needed have not been defined, but it is reasonable to expect that they will be similar to but with less storage requirements than those needed for the Centralization Alternative. Due to smaller throughput and storage requirements, the potential for accidents (i.e., probability of occurrence) will be similar to but less than those described for the Centralization Alternative. The accident consequences will be similar for both alternatives. Consequently, it is reasonable to assume that the accident consequences and risks described for the Centralization Alternative envelop the Regionalization Alternative.

5.15.8 Emergency Preparedness and Plans

The DOE has issued a series of Orders specifying the requirements for emergency preparedness (DOE 5500.1A, DOE 5500.2A, DOE 5500.3, draft DOE 5500.3A, DOE 5500.4, and DOE 5500.9), and each DOE site has established an emergency management program. These programs are developed and maintained to ensure adequate response for most accident conditions and to provide the framework to readily extend response efforts for accidents not specifically considered. The emergency management program incorporates activities associated with planning, preparedness, and response.

Officials at each DOE site have specified the emergency preparedness requirements for the DOE facilities under their jurisdiction in a manner consistent with the relevant DOE Orders. All existing facilities have emergency plans and procedures that either implement the DOE and site requirements or are integrated with the site planning.

DOE-Oak Ridge Operations has overall responsibility at the plant and laboratory sites for emergency response. However, primary authority for event response has been delegated to Martin Marietta Energy Systems, Inc., DOE's operating contractor. Although their primary responsibility is onsite, they have agreed to provide offsite assistance if requested under the terms of existing mutual aid agreements or Martin Marietta policies. If a hazardous materials event occurs at a DOE-Oak Ridge Operations facility, the Governor of Tennessee is responsible for the State's response efforts. The Governor's Executive Order No. 4 establishes the Tennessee Emergency Management Agency as the agency given responsibility for coordinating state emergency services. If a hazardous materials accident at DOE-Oak Ridge Operations facilities is beyond the capability of the local government, and assistance is requested, the Tennessee Emergency Management Agency Director may direct that assistance from state agencies be provided to local governments. To accomplish this task and ensure prompt initiation of emergency response actions, the Director may cause the State Emergency Operations Center and Field Coordination Center as well as any local Emergency Operations Center to be activated.

5.16 Cumulative Impacts and Impacts From Connected

or Similar Actions

The ORR already contains several major DOE and non-DOE facilities, unrelated to SNF, that would continue to operate throughout the operating life of the proposed SNF management facilities. A number of offsite industrial and research facilities in surrounding areas would also continue to operate throughout this period. The activities associated with these existing facilities produce environmental consequences that have been included in the baseline environmental conditions (Chapter 4) against which Sections 5.1 through 5.15 have assessed the environmental consequences of the Centralization and Regionalization alternatives. This section uses the environmental baseline conditions presented in Chapter 4 to assess potential cumulative impacts from the proposed SNF management facilities, if constructed at the ORR, plus other reasonably foreseeable activities planned by government agencies or private concerns for areas on or near the ORR.

In addition to the proposed SNF management facilities, reasonably foreseeable activities considered in this cumulative impact assessment include the proposed Expended Core Facility, proposed hazardous waste remediation activities on the ORR, and activities proposed in the present Five-Year Plan for the ORR. Major programmatic initiatives planned for the ORR in the Five-Year Plan (MMES 1994a) consist of constructing the following: the proposed Advanced Neutron Source Facility; the proposed Uranium-Atomic Vapor Laser Isotope Separation Facility; facilities proposed for construction as a part of Complex-21; proposed low-level waste disposal facilities; the proposed Mixed Waste Treatment Facility; the proposed Environmental, Life, and Social Sciences Complex; the proposed Materials, Science, and Engineering Complex; and the proposed Solid Waste Storage Area-7. Several minor construction projects such as the refurbishment or expansion of existing facilities, widening of roadways, and installation of utilities are also included in the Five-Year Plan.

The ORR is part of the City of Oak Ridge, which also includes an urban area to the north of the ORR and several industrial areas in various locations around the perimeter of the ORR. Additional construction and expanded operational activities is anticipated in these industrial areas. For example, the Scientific Ecology Group, a private business in the Bear Creek Industrial Park on Bear Creek Road west of the ORR, is considering expanding its operations and is presently constructing a second radioactive waste incinerator. The City of Oak Ridge Comprehensive Plan encourages further development of several presently undeveloped lots in several industrial parks (City of Oak Ridge 1989). The Comprehensive Plan also anticipates additional residential and commercial development in the City. The City of Oak Ridge is presently proposing construction of a golf course and residential development on approximately 700 acres (2.8 square kilometers) east of the ORR.

The following cumulative impacts analysis considers in detail the potential incremental effects from the proposed SNF management facilities; the proposed Expended Core Facility; and the proposed Advanced Neutron Source facility. Adequate information is not available to consider in detail the other proposed Five-Year Plan activities or the proposed activities for areas in the City of Oak Ridge outside of the ORR. The potential incremental impacts from these activities are therefore assessed in a more qualitative manner.

5.16.1 Centralization Alternative

Separate analyses of potential cumulative impacts from the Centralization Alternative to each of the environmental resources addressed in Chapter 5 are provided below.

5.16.1.1 Land Use. Construction of the proposed SNF management facilities would

require the dedication of 90 acres (0.36 square kilometer) of undeveloped land on Bear Creek Road in the western part of the ORR. Construction of the proposed Expended Core Facility would require the dedication of an additional 30 acres (0.12 square kilometer) of undeveloped land on the ORR. Construction of the proposed Advanced Neutron Source facilities would require the dedication of an additional 75 to 115 acres (0.30 to 0.46 square kilometer) of land on the ORR (MMES 1992c). The cumulative land area dedicated to these three projects would total as much as 235 acres (0.95 square kilometer), which represents only about 1 percent of the roughly 20,600 acres (83 square kilometers) of undeveloped land remaining on the 34,667-acre (140 square kilometer) ORR. Additional unspecified areas of undeveloped land, generally parcels of under 100 acres (0.40 square kilometer), would have to be dedicated to some of the activities proposed in the Five-Year Plan. Many of these proposed activities do not require the dedication of undeveloped land. Additional undeveloped land on the ORR might have to be dedicated to the other planned activities, but their land requirements have not yet been quantified.

Although large areas of undeveloped land remain both on the ORR and in the City of Oak Ridge, much of this land is steep or otherwise has constraints that limit its future development potential. The City of Oak Ridge indicates in its Comprehensive Plan that it seeks to have additional ORR land declared excess by the DOE and made available for urban expansion by the City (City of Oak Ridge 1989). Demand for buildable land on the ORR by the City of Oak Ridge represents another cumulative demand for ORR land. The site of the proposed residential development and golf course east of the ORR is land recently sold by the DOE to the City of Oak Ridge since adoption of the Comprehensive Plan.

5.16.1.2 Occupational and Public Health. The annual collective effective dose

equivalent from the existing ORR facilities to the population within 50 miles (80 kilometers) of the ORR is 52 person-rem (MMES 1994a). Added to this baseline, operation of the proposed SNF management facilities might contribute an additional 5 person-rem, and operation of the proposed Advanced Neutron Source facilities might contribute an additional 4.3 person-rem (MMES 1992c), resulting in a cumulative effective dose of 61 person-rem to the population within 50 miles of the ORR.

The annual collective effective dose equivalent from the existing ORR facilities to a potential maximally exposed individual at the site boundary is 3.3 millirem per year. Operation of the proposed SNF management facilities might contribute an additional 6.2 millirem per year, resulting in a cumulative annual dose of 9.5 millirem per year to this maximally exposed individual.

The total annual baseline worker dose seen from normal ORR operations is about 48 person-rem. The total annual SNF management facility worker dose is expected to be roughly 32 person-rem. Hence, the cumulative annual dose might be 80 person-rem.

Over the planned 40-year operational lifetime of the SNF management facility, a total population dose of roughly 2,500 person-rem will be observed from continuous operation of the existing ORR facilities and the SNF management facility. This equates to a total health detriment (the summated risk of fatal cancer, nonfatal cancer, and genetic effects) of 1.8 over the 40-year span. For the maximally exposed individual, a total dose of 380 millirem will be observed over the 40-year period, which equates to a total detriment of 2.8 x 10-4. For the SNF management worker, a total dose of 3,200 person-rem will be observed over the 40-year span; this corresponds to a total health detriment of 1.8.

Additional radiological impacts are not expected from operation of the proposed Expended Core Facility. Analysis has shown that the dose to all individuals considered (workers and offsite individuals) from Oak Ridge Expended Core Facility operations might be much less than 1 millirem per year.

5.16.1.3 Noise. Cumulative increases in noise levels from the proposed SNF

management facilities, the proposed Expended Core Facility, and the proposed Advanced Neutron Source facilities would be limited to temporary, minor construction noise and small increases in traffic noise occurring along various access routes to the ORR due to increases in employment. This increase is not expected to result in any increased annoyance to the public. Noise levels from other planned activities have not yet been determined. Each would, at a minimum, involve temporary periods of construction noise, but information on operational noise is not available.

5.16.1.4 Groundwater and Surface Water Resources. Operation of the proposed SNF

management facilities would require the withdrawal of an estimated 4 million gallons per year (15 million liters per year) of groundwater. Operation of the proposed Expended Core Facility would require the withdrawal of an estimated additional 2 million gallons per year (8 million liters per year). Although the specific water demands of the proposed Advanced Neutron Source facility and other proposed activities are not known, the combined water demands would likely represent a small percentage of the total average discharge of the Clinch River, as measured at Melton Hill Dam, of 5,300 cubic feet per second (150 cubic meters per second).

Discharges of wastewater from the SNF management facilities would increase the flow of Grassy Creek by an estimated average of less than 1 percent. Discharge points would be selected in accordance with permit requirements to minimize impacts to surface water resources. The sanitary wastewater and cooling water from the Advanced Neutron Source facility would be discharged to separate streams and therefore would not contribute to cumulative impacts to Grassy Creek. Discharges from other planned facilities have not yet been designed. There are no expected cumulative impacts to groundwater quality and quantity.

5.16.1.5 Biotic Resources. Construction of the proposed SNF management facilities

would require the disturbance of approximately 90 acres (0.36 square kilometer) of mostly forested terrestrial habitat, construction of the proposed Expended Core Facility would require the disturbance of an additional 30 acres (0.12 square kilometer), and construction of the proposed Advanced Neutron Source facilities would require the disturbance of an additional 75 to 115 acres (0.30 to 0.46 square kilometer). This would result in a combined conversion of as much as 235 acres (0.94 square kilometer) of forested habitat to developed uses. Additional areas of forested habitat on the ORR would be lost during construction of activities proposed in the Five-Year Plan. Additionally, losses of similar forested habitat off of the ORR are anticipated due to future construction in the City of Oak Ridge. For example, construction of the proposed golf course and residential development east of the ORR by the City of Oak Ridge would result in the conversion of several hundred acres of forested habitat to structures and lawns.

The total losses would represent only a small percentage of the total forested area on the ORR and in the surrounding vicinity. However, the several scattered areas of habitat disturbance planned for the ORR, including that associated with the SNF management facilities, would increase fragmentation of the relatively contiguous forest cover over much of the ORR. This fragmentation could affect the suitability of the forested habitat on the ORR for several species.

5.16.1.6 Air Resources. The potential cumulative air emissions from the proposed SNF

management facility, Expended Core Facility, and Advanced Neutron Source facilities would not result in an exceedance of the National Ambient Air Quality Standards or Tennessee state criteria. Also, there would be no exceedance of Federal National Emissions Standards for Hazardous Air Pollutants or DOE radiological standards. Air emission data for the other planned activities (Five-Year Plan or offsite) are not available.

5.16.1.7 Socioeconomics. Operation of the proposed SNF management facilities might

generate up to 800 new jobs during the year 2005. Operation of the proposed Expended Core Facility might generate up to 562 additional jobs during that year, resulting in a combined increase of up to 1,362 new jobs. The 16,980 jobs presently forecasted for the ORR in the year 2005 would be increased by 8 percent, to as much as 18,342 jobs. The 360,000 jobs presently forecasted for the surrounding area in the year 2005 might be increased by less than 1 percent, to as much as 361,352 jobs. Additional employment increases could also result from the proposed Advanced Neutron Source facility project, activities proposed in the Five-Year Plan, and new offsite activities, but specific estimates are not available.

The proposed SNF management facilities could cause cumulative growth-inducing effects when coupled with the proposed Advanced Neutron Source facilities or with other planned activities on the ORR. Previous actions at the ORR have had a modest effect on long-term growth and productivity in Knox County and Loudon County, but they did not have a greater effect on long-term growth and productivity in Anderson County and Roane County.

5.16.1.8 Transportation. For transportation, minor levels of service changes might occur

due to employment increases associated with the proposed SNF management facilities, the proposed Expended Core Facility, the proposed Advanced Neutron Source facility, some of the proposed onsite activities in the Five-Year Plan, and some of the proposed offsite activities. Maps included in the Five-Year Plan show several road improvements on the ORR to accommodate presently projected regional traffic increases.

5.16.1.9 Waste Management. Operation of the proposed SNF management facilities

would generate an estimated 203 cubic meters per year of low-level waste and an estimated 16 cubic meters per year of transuranic waste. Operation of the proposed Expended Core Facility would generate an additional 425 cubic meters of low-level waste (for a combined total by both facilities of 628 cubic meters) but would not generate any additional transuranic waste. No other radioactive waste, including high-level waste or mixed waste, would be generated by either facility. Although it is known that the proposed Advanced Neutron Source facility would generate low-level waste, comparable quantitative data are not available for it or for offsite activities, or for activities proposed in the Five-Year Plan. All wastes generated by the proposed SNF management facilities and other planned activities on the ORR would be treated and disposed of in accordance with all applicable Federal and state regulations.

5.16.1.10 Other Resources. The absence of impacts, or the potential for very minimal

impacts, from the proposed SNF management facilities to cultural resources, aesthetic and scenic resources, utilities, and geologic resources ensures that their potential contribution to cumulative impacts affecting these resources would be negligible. No further analysis is necessary.

5.16.2 Regionalization Alternative

The Regionalization Alternative would have similar or fewer cumulative impacts than the Centralization Alternative. Generally, the alternative requires less construction and smaller scale operations, and the potential for cumulative impacts is therefore less.

5.17. Adverse Environmental Effects That Cannot Be Avoided

5.17.1 Overview

This section discusses potentially unavoidable adverse impacts to the environment resulting from construction and operation of the proposed spent nuclear fuel (SNF) management facilities at the Oak Ridge Reservation (ORR) under the Centralization and Regionalization Alternatives. Unavoidable adverse impacts are impacts that cannot be mitigated by changes in project design, operation, construction, or by other measures.

5.17.2 Centralization Alternative

Operation of the proposed SNF facilities at the ORR under the Centralization Alternative would increase the radiation dose rate to the maximally exposed individual by 6.2 millirem per year, resulting in a 34 percent increase in cancer risk to this individual from ORR operations. These cancer risks still would be minimal. The number of fatal cancers resulting from 1 year of operations on the ORR from all sources (including baseline and the SNF facilities) would be 3.0 x 10-2, the number of nonfatal cancers per year would be 5.9 x 10-3, and the number of genetic effects per year would be 7.7 x 10-3.

Construction of the proposed SNF management facilities would require the disturbance of approximately 90 acres (0.36 square kilometer) of mostly forested undeveloped land and the long-term dedication of approximately 85 acres (0.34 square kilometer) of land. Although this represents less than 1 percent of the undeveloped land on ORR, it would eliminate potential foraging and nesting habitat and would destroy plant species in the area. It would also require the dedication of a reasonably level land parcel that could have otherwise accommodated other construction projects.

The potential impacts from the Centralization Alternative to the other environmental resources discussed in Chapter 5 are not unavoidable adverse impacts.

5.17.3 Regionalization Alternative

Potential unavoidable adverse impacts associated with the Regionalization Alternative would resemble those discussed above for the Centralization Alternative. The extent of the impacts could be less due to the reduced land requirements, reduced extent of construction disturbance, and reduced scale of operations.

5.18 Relationship Between Short-Term Use of the Environment and

the Maintenance of Long-Term Productivity

Implementation of any of the SNF management alternatives would cause some adverse impacts to the environment and permanently commit certain resources. These resources include use of the environment and those associated with construction and operation of the SNF management facilities.

The proposed alternatives for SNF management would require the short-term use of resources including energy, construction materials, and labor in order to achieve the objective of safety managing SNF to minimize the risk to workers, the public, and the environment.

The premature shutdown of research reactors due to a lack of sufficient SNF interim storage space under the No Action Alternative could have an impact upon the ORR regional communities. The ORR High Flux Isotope Reactor is an important source of radiopharmaceuticals. The reactors are unique research and training facilities for researchers and students in many fields of research and development: materials science, environmental science, physics, biology, and electronics.

Development of new SNF interim management facilities would commit lands to those uses from the time of construction through the cessation of operations, at which time the facilities could be converted to other uses or decontaminated, decommissioned, and the site restored to its original land use. Existing SNF management facilities could also be converted to other uses, or the lands could be restored following decommissioning.

5.19. Irreversible and Irretrievable Commitments of Resources

5.19.1 Overview

This section discusses the irreversible and irretrievable commitments of resources resulting from the use of materials that cannot be recovered or recycled, or that must be consumed or reduced to irrecoverable forms.

5.19.2 Centralization Alternative

Construction and operation of spent nuclear fuel (SNF) management facilities under the Centralization Alternative would require commitments of electrical energy, fuel, concrete, steel, sand, gravel, and miscellaneous chemicals. Most of the water that would be withdrawn from the Clinch River to operate the SNF management facilities would be returned to surface water in the Clinch River watershed, although some evaporative losses would be unavoidable. The land dedicated to the SNF management facilities could become available for other urban uses following closure and decommissioning. However, the soils on the site would have to be amended to support land uses such as agriculture, forestry, or wildlife management.

5.19.3 Regionalization Alternative

Irreversible and irretrievable commitments of resources associated with the Regionalization Alternative would resemble those discussed above for the Centralization Alternative. However, the extent of these resource commitments could be less due to the reduced land requirements and reduced scale of operations.

5.20 Potential and Mitigation Measures

5.20.1 Pollution Prevention

The DOE Oak Ridge Field Office established a Waste Minimization and Pollution Prevention Awareness Plan to reduce the quantity and toxicity of hazardous, mixed, and radioactive wastes generated at Oak Ridge. The plan is designed to reduce the possible pollutant releases to the environment and thus increase the protection of employees and the public. All contractors and users that exceed the EPA criteria for small-quantity generators are establishing their own waste minimization and pollution prevention awareness programs. Contractor programs ensure that waste minimization activities are in accordance with Federal, state, and local environmental laws and regulations, and DOE Orders.

Additional goals include the promotion and use of nonhazardous materials, establishment of a baseline of waste generation data, calculations of annual reductions of waste generated, and implementation of recycling programs. Goals also include incorporation of waste minimization concepts and technologies in planning and design of new processes and facilities, and in upgrades of existing facilities. A waste minimization task force composed of representatives from each contractor has been established to coordinate waste minimization and pollution awareness activities.

5.20.2 Potential Mitigation Measures

Potential impact avoidance and mitigation measures are addressed in Chapter 5, Sections 1 through 15 as appropriate.

Glossary

Terms in this glossary are defined based on the context in which they are used in this EIS.

100-year flood : A flood event of such magnitude it occurs, on average, every 100 years (equates to a 1 percent probability of occurring in any given year).

500-year flood : A flood event of such magnitude it occurs, on average, every 500 years (equates to a 0.2 percent probability of occurring in any given year).

abnormal condition : Any deviation from normal conditions.

accident : An unplanned sequence of events that results in undesirable consequences.

actinide : Any of a series of chemically similar, mostly synthetic, radioactive elements with atomic numbers ranging from actinium-89 through lawrencium-103.

alpha-emitter : A radioactive substance that decays by releasing an alpha particle.

alpha-low-level waste : Waste that was previously classified as transuranic waste but has a transuranic concentration lower than the currently established limit for transuranic waste. Low-level waste requires additional controls and special handling. This waste stream cannot be accepted for onsite disposal under the current waste acceptance criteria; therefore, it is special-case waste.

alpha particle : A positively charged particle ejected spontaneously from the nuclei of some radioactive elements. It is identical to a helium nucleus that has a mass number of 4 and an electrostatic charge of +2.

as low as reasonably achievable (ALARA) : A process by which a graded approach is applied to maintaining dose levels to workers and the public, and releases of radioactive materials to the environment as low as reasonably achievable.

atomic number : The number of positively charged protons in the nucleus of an atom and the number of electrons on an electrically neutral atom.

background radiation : Radiation from cosmic sources; naturally occurring radioactive materials, including radon (except as a decay product of source or special nuclear material), and global fallout as it exists in the environment from the testing of nuclear explosive devices.

baseline : For purposes of this EIS, the conditions projected to exist in June 1995, the scheduled date for the Record of Decision, against which the environmental consequences of the various alternatives are evaluated.

beta-emitter : A radioactive substance that decays by releasing a beta particle.

beta particle : A charged particle emitted from a nucleus during radioactive decay, with a mass equal to 1/1837 that of a proton. A negatively charged beta particle is identical to an electron. A positively charged beta particle is called a positron.

boiling water reactor : A type of nuclear reactor that uses fission heat to generate steam in the reactor to drive turbines and generate electricity.

breeder reactor : A type of nuclear reactor that creates more fissionable fuel than it uses.

by-product material : (a) Any radioactive material (except special nuclear material) yielded in, or made radioactive by, exposure to the radiation incident to the process of producing or utilizing special nuclear material, and (b) the tailings or wastes produced by the extraction or concentration of uranium or thorium from any ore processed primarily for its source material content [Atomic Energy Act 11(e)]. By-product material is exempt from regulation under the Resource Conservation and Recovery Act.

calcination : The process of converting high-level waste to unconsolidated granules or powder (also called calcining).

calcine : The material produced by a calcination.

canning : The process of placing spent nuclear fuel in canisters to retard corrosion, contain radioactive releases, or control geometry.

capable fault : In part, a capable fault is one that may have had movement at or near the ground surface at least once within the past 35,000 years, or has had recurring movement within the past 500,000 years.
Further definition can be found in 10 CFR 100, Appendix A.

characterization : The determination of waste composition and properties, whether by review of process knowledge, nondestructive examination or assay, or sampling and analysis, generally done for the purpose of determining appropriate storage, treatment, handling, transport, and disposal requirements.

cladding : The outer jacket of fuel elements and targets usually made of aluminum, stainless steel, or zirconium alloy, used to prevent fuel corrosion and retain fission products during reactor operation, or to prevent releases into the environment during storage.

co-located workers : Workers in a fixed population outside the day-to-day process safety management controls of a given facility area. In practice, this fixed population is normally the workers at an independent facility area located some distance from the reference facility area.

committed dose equivalent (H50) : The dose equivalent to organs or tissues of reference that will be received from an intake of radioactive material by an individual during the 50-year period following the intake. The International Commission on Radiological Protection defines this as the committed equivalent dose.

committed effective dose equivalent (HE,50) : The sum of the products of the weighting factors applicable to each of the body organs or tissues that are irradiated and the committed dose equivalent to these organs or tissues. The International Commission on Radiological Protection defines this as the committed effective dose.

Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA) : A Federal law (also known as "Superfund") that provides a comprehensive framework to deal with past or abandoned hazardous materials. The Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA) provides for liability, compensation, cleanup, and emergency response for hazardous substances released into the environment that could endanger public health, welfare, or the environment, as well as the cleanup of inactive hazardous waste disposal sites. CERCLA has jurisdiction over any release or threatened release of any "hazardous substance" to the environment. Under CERCLA, the definition of "hazardous" is much broader than under the Resource Conservation and Recovery Act, and the hazardous substance need not be a waste. If a site meets the CERCLA requirements for designation, it is ranked along with other "Superfund" sites and listed on the National Priorities List. This ranking and listing is the U.S. Environmental Protection Agency's way of determining which sites have the highest priority for cleanup.

contact-handled waste : Packaged waste whose external surface dose rate does not exceed 200 millirem per hour.

contamination : The deposition of unwanted radioactive material on the surfaces of structures, areas, objects, or personnel.

coolant : A gas or liquid circulated through a nuclear reactor to remove or transfer heat.

core : The central portion of a nuclear reactor containing the fuel elements, moderator, neutron poisons, and support structures.

curie (Ci) : The basic unit used to describe the intensity of radioactivity in a sample of material. The curie is equal to 37 billion disintegrations per second, which is approximately the rate of decay of 1 gram of radium. A curie is also a quantity of any radionuclide that decays at a rate of 37 billion disintegrations per second.

decay, radioactive : The decrease in the amount of any radioactive material with the passage of time, due to the spontaneous emission from the atomic nuclei of either alpha or beta particles, often accompanied by gamma radiation (see half-life, radioactive).

decommissioning : The process of removing a facility from operation, followed by decontamination, entombment, dismantlement, or conversion to another use.

decontamination : The actions taken to reduce or remove substances that pose a substantial present or potential hazard to human health or the environment, such as radioactive contamination from facilities, soil, or equipment by washing, chemical action, mechanical cleaning, or other techniques.

degraded (spent nuclear fuel) : Spent nuclear fuel whose external cladding has cracked, pitted, corroded, or potentially allows the leakage of radioactive materials.

DOE orders : Requirements internal to the U.S. Department of Energy (DOE) that establish DOE policy and procedures, including those for compliance with applicable laws.

DOE site boundary : A geographic boundary within which public access is controlled and activities are governed by the U.S. Department of Energy (DOE) and its contractors, not by local authorities. Based on the definition of exclusion zone, a public road traversing a DOE site is considered to be within the DOE site boundary if DOE or the site contractor has the capability to control the road at any time necessary.

dosage : The concentration-time profile for exposure to toxicological hazards.

dose (or radiation dose) : A generic term that means absorbed dose, dose equivalent, effective dose equivalent, committed dose equivalent, committed effective dose equivalent, or total effective dose equivalent, as defined elsewhere in this glossary.

driver fuel : These fuel tubes or assemblies usually contain enriched uranium, plutonium, or thorium materials, which can be fissioned (or split) by neutrons. Because this fuel drives neutron bombardment of targets in a production or research reactor, these fuels are called drivers.

dry storage : Storage of spent nuclear fuel in environments where the fuel is not immersed in liquid for purposes of cooling and/or shielding.

effective dose equivalent (EDE) : The sum of the products of the dose equivalent to the organ or tissue and the weighting factors applicable to each of the body organs or tissues that are irradiated. It includes the dose from radiation sources internal and/or external to the body and is expressed in units of rem. The International Commission on Radiation Protection defines this as the effective dose.

enriched uranium : Uranium that has greater amounts of the fissionable isotope uranium-235 than occurs naturally. Naturally occurring uranium is 0.72 percent uranium-235.

environmental monitoring : The process of sampling and analysis of environmental media in and around a facility being monitored for the purpose of (a) confirming compliance with performance objectives, and (b) early detection of any contamination entering the environment to facilitate timely remedial action.

existing facilities : Facilities that are projected to exist as of the Record of Decision for this EIS, scheduled for June 1995.

external accident : Accidents initiated by manmade energy sources not associated with operation of a given facility. Examples include airplane crashes, induced fires, transportation accidents adjacent to a facility, and so forth.

facility worker : Any worker whose day-to-day activities are controlled by process safety management programs and a common emergency response plan associated with a facility or facility area. This definition includes any individual within a facility/facility area or its 0.4-mile exclusion zone. This definition can also include those transient individuals or small populations outside the exclusion zone but inside the radius defined by the maximally exposed co-located worker if reasonable efforts to account for such people have been made in the facility or facility area emergency plan. For facility accident analyses, the facility worker is defined as an individual located 100 meters (328 feet) downwind of the facility location where an accidental release occurs.

fissile material : Although sometimes used as a synonym for fissionable material, this term has acquired a more restricted meaning; namely, any material fissionable by thermal (slow) neutrons. The three primarily fissile materials are uranium-233, uranium-235, and plutonium-239.

fission : The splitting of a nucleus into at least two other nuclei and the release of a relatively large amount of energy. Two or three neutrons are usually released during this type of transformation.

fission products : The nuclei (fission fragments) formed by the fission of heavy elements, plus the nuclides formed by the fission fragments' radioactive decay.

fissionable material : Commonly used as a synonym for fissile material, the meaning of this term has been extended to include material that can be fissioned by fast neutrons, such as uranium-238.

gamma-emitter : A radioactive substance that decays by releasing gamma radiation.

gamma ray (gamma radiation) : High-energy, short wavelength electromagnetic radiation (a packet of energy) emitted from the nucleus. Gamma radiation frequently accompanies alpha and beta emissions and always accompanies fission. Gamma rays are very penetrating and are best stopped or shielded against by dense materials, such as lead or uranium. Gamma rays are similar to x-rays, but are usually more energetic.

geologic repository : A system that is intended to be used for, or may be used for, the disposal of radioactive waste or spent nuclear fuel in excavated geologic media. A geologic repository includes (a) the geologic repository operations area, and (b) the portion of the geologic setting that provides isolation. A near-surface disposal area is not a geologic repository.

groundwater : Generally, all water contained in the ground. Water held below the water table available to freely enter wells.

grouting : Grouting is the process of immobilizing or fixing solid forms of waste so they can be more safely stored or disposed.

half-life : The time in which half the atoms of a particular radioactive substance disintegrate to another nuclear form. Measured half-lives vary from millionths of a second to billions of years. Also called physical half-life.

hazardous chemical : A term defined under the Occupational Safety and Health Act and the Emergency Planning and Community Right-to-Know Act as any chemical that is a physical hazard or a health hazard.

hazardous material : A substance or material, including a hazardous substance, which has been determined by the U.S. Secretary of Transportation to be capable of posing an unreasonable risk to health, safety, and property when transported in commerce.

hazardous substance : Any substance that when released to the environment in an uncontrolled or unpermitted fashion becomes subject to the reporting and possible response provisions of the Clean Water Act and the Comprehensive Environmental Response, Compensation, and Liability Act.

hazardous waste : Under the Resource Conservation and Recovery Act, a solid waste, or combination of solid wastes, which because of its quantity, concentration, or physical, chemical, or infectious characteristics may (a) cause, or significantly contribute to an increase in mortality or an increase in serious irreversible, or incapacitating reversibile, illness; or (b) pose a substantial present or potential hazard to human health or the environment when improperly treated, stored, transported, or disposed of, or otherwise managed. Source, special nuclear material, and by-product material, as defined by the Atomic Energy Act, are specifically excluded from the definition of solid waste.

heterogeneous : Pertaining to a substance having different characteristics in different locations. A synonym is nonuniform.

high-efficiency particulate air (HEPA) filter : A filter with an efficiency of at least 99.95 percent used to separate particles from air exhaust streams prior to releasing that air into the atmosphere.

high-level waste : The highly radioactive waste material that results from the reprocessing of spent nuclear fuel, including liquid waste produced directly from reprocessing and any solid waste derived from the liquid that contains a combination of transuranic and fission product nuclides in quantities that require permanent isolation. High-level waste may include other highly radioactive material that the U.S. Nuclear Regulatory Commission, consistent with existing law, determines by rule requires permanent isolation.

hot cell/hot cell facility : A heavily shielded enclosure for handling and processing (by remote means or automatically), or storing highly radioactive materials.

hydrogeology : The study of the geological factors relating to water.

hydrology : The study of water, including groundwater, surface water, and rainfall.

incineration : The efficient burning of combustible solid and liquid wastes to destroy organic constituents and reduce the volume of the waste. Incinerators are designed to burn with an extremely high efficiency. The greater the burning efficiency, the cleaner the air emission. Incineration of radioactive materials does not destroy the radionuclides but does significantly reduce the volume of these wastes. High-efficiency particulate air (HEPA) filters are used to prevent radionuclides and heavy metals from going out of the stack and into the atmosphere.

inconel : A metal alloy containing nickel, chromium, and iron, which exhibits good resistance to corrosion in aqueous environments.

interim action (NEPA) : An action that may be undertaken while work on a required program EIS is in progress, and the action is not covered by an existing program statement. An interim action may not be undertaken unless such action: (a) is justified independently of the program; (b) is itself accompanied by an adequate EIS or has undergone other NEPA review; and (c) will not prejudice the ultimate decision on the program. Interim action prejudices the ultimate decision on the program when it tends to determine subsequent development or limit alternatives.

intermittent surface water : A stream, creek, or river that does not contain water during part or all of the year.

internal accidents : Accidents that are initiated by man-made energy sources associated with the operation of a given facility. Examples include process explosions, fires, spills, criticalities, and so forth.

involved worker : Workers that would be involved in a proposed action as opposed to workers that would be on the site of a proposed action but not involved in the action.

isotope : One of two or more atoms with the same number of protons, but different numbers of neutrons, in their nuclei. Thus, carbon-12, carbon-13, and carbon-14 are isotopes of the element carbon, the numbers denoting the approximate atomic weights. Isotopes have very nearly the same chemical properties, but often different physical properties (for example, carbon-12 and -13 are stable, carbon-14 is radioactive).

life cycle : The entire time period from generation to permanent disposal or elimination of waste.

liquid metal cooled breeder reactor : A reactor that creates more fissionable material than it consumes and uses liquid metal as a coolant. Liquid sodium is a common metal used to cool this type of reactor.

liquid metal fast breeder reactor : A reactor that operates using a type of fission known as fast fission where the neutrons that are used to split the atoms are not slowed down or moderated as is usually the case with normal fission. It creates more fissionable material than it consumes and uses liquid metal as a coolant. Liquid sodium is a common metal used to cool this type of reactor.

long-term storage : The storage of hazardous waste (a) onsite (a generator site) for a period of 90-days or greater, other than in a satellite accumulation area, or (b) offsite in a properly managed treatment, storage, or disposal facility for any period of time.

low-level waste : Waste that contains radioactivity and is not classified as high-level waste, transuranic waste, or spent nuclear fuel. Test specimens of fissionable material irradiated for research and development only, and not for the production of power or plutonium, may be classified as low-level waste, provided the concentration of transuranic elements is less than 100 nanocuries per gram of waste.

major radionuclides : The radioisotopes that together comprise 95 percent of the total curie content of a waste package by volume and have a half-life of at least 1 week. Radionuclides that are important to a facility's radiological performance assessment and/or a safety analysis and are listed in the facility's waste acceptance criteria are considered major radionuclides.

management (of spent nuclear fuel) : Emplacing, operating, and administering facilities, transportation systems, and procedures to assure safe and environmentally responsible handling and storage of spent nuclear fuel pending (and in anticipation of) a decision on ultimate disposition.

maximally exposed co-located worker (MCW) : A hypothetical individual defined to allow dose or dosage comparison with numerical criteria for co-located workers. This individual is located at whichever is the greater of 0.4 miles from the facility area boundary (that is, the exclusion zone boundary) or 75 percent of the distance to the nearest independent facility area (that is, the low population zone boundary). The MCW is irrelevant if the DOE site boundary is closer than the MCW location.

maximally exposed individual (MEI) : A hypothetical individual defined to allow dose or dosage comparison with numerical criteria for the public. This individual is located at the point on the DOE site boundary nearest to the facility in question. Sometimes called maximally exposed offsite individual (MOI).

maximally exposed offsite individual (MOI) : A hypothetical individual defined to allow dose or dosage comparison with numerical criteria for the public. This individual is located at the point on the DOE site boundary nearest to the facility in question. Sometimes called the maximally exposed individual (MEI).

maximum contaminant level (MCL) : Under the Safe Drinking Water Act, the maximum permissible concentrations of specific constituents in drinking water that is delivered to any user of a public water system that serves 15 or more connections and 25 or more people. The standards set as maximum contaminant levels take into account the feasibility and cost of attaining the standard.

metric tons of heavy metal (MTHM) : Quantities of unirradiated and spent nuclear fuel and targets are traditionally expressed in terms of metric tons of heavy metal (typically uranium), without the inclusion of other materials, such as cladding, alloy materials, and structural materials. A metric ton is 1,000 kilograms, which is equal to about 2,200 pounds.

millirem : One thousandth of a rem (see rem).

mixed waste : Waste that contains both hazardous waste under the Resource Conservation and Recovery Act and source, special nuclear, or by-product material subject to the Atomic Energy Act of 1954.

mitigation : Those actions that avoid impacts altogether, minimize impacts, rectify impacts, reduce or eliminate impacts, or compensate for the impact.

nanocurie : One billionth of a curie (see curie).

National Priorities List (NPL) : A formal listing of the nation's most hazardous waste sites, as established under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), that have been identified for remediation.

natural phenomena accidents : Accidents that are initiated by phenomena such as earthquakes, tornadoes, floods, and so forth.

near-surface disposal : Disposal in the uppermost portion of the earth, approximately 30 meters. Near-surface disposal includes disposal in engineered facilities that may be built totally or partially above-grade provided that such facilities have protective earthen covers. A near-surface disposal facility is not considered a geologic repository.

nitrogen oxides (NOx) : Gases formed in great part from atmospheric nitrogen and oxygen when combustion takes place under conditions of high temperature and high pressure; considered a major air pollutant. Two major nitrogen oxides, nitric oxide (NO) and nitrogen dioxide (NO2) are important airborne contaminants. In the presence of sunlight, nitric oxide combines with atmospheric oxygen to produce nitrogen dioxide, which in high enough concentrations can cause lung damage.

normal conditions : All activities associated with a facility mission, whether operation, maintenance, storage, and so forth, which are carried out within a defined envelope. This envelope can be design process conditions, performance in accordance with procedure, and so forth.

normal operation : All normal conditions and those abnormal conditions that frequency estimation techniques indicate occur with a frequency greater than 0.1 events per year.

NOx : A generic term used to describe the oxides of nitrogen (see nitrogen oxides).

nuclear criticality : A self-sustaining chain reaction, which releases neutrons and energy, and generates radioactive by-product material.

nuclear fuel : Materials that are fissionable and can be used in nuclear reactors to make energy.

nuclide : A general term referring to all known isotopes, both stable (279) and unstable (about 5,000), of the chemical elements.

off-link doses : Doses to members of the public within 800 meters (2,625 feet) of a road or railway.

offsite facility : A facility located at a different site or location than the shipper.

on-link doses : Doses to members of the public sharing a road or railway.

onsite : The same or geographically contiguous property that may be divided by public or private right-of-way, provided the entrance and exit between the properties is at a cross-roads intersection, and access is by crossing as opposed to going along the right-of-way. Non-contiguous properties owned by the same person but connected by a right-of-way that he/she controls and to which the public does not have access is also considered onsite property.

onsite facilities : Buildings and other structures, their functional systems and equipment, and other fixed systems and equipment installed onsite.

operator : The organization that operates a facility.

passivation : The process of making metals inactive or less chemically reactive. For example, to passivate the surface of steel by chemical treatment.

perennial stream : A water course that flows year-round.

performance objectives : Parameters within which a facility must perform to be considered acceptable.

permeability : The degree of ease with which water can pass through a rock or soil.

playa : The shallow central basin of a desert plain in which water gathers and then evaporates.

picocurie : One trillionth of a curie (see curie).

pollutant migration : The movement of a contaminant away from its initial source.

pollution prevention : The use of any process, practice, or product that reduces or eliminates the generation and release of pollutants, hazardous substances, contaminants, and wastes, including those that protect natural resources through conservation or more efficient utilization.

polychlorinated biphenyls (PCBs) : A class of chemical substances formerly manufactured as an insulating fluid in electrical equipment that is highly toxic to aquatic life. In the environment, PCBs exhibit many of the characteristics of dichloro diphenyl trichloroethane (DDT); they persist in the environment for a long time and accumulate in animals.

population dose : The overall dose to the offsite population.

porosity (n) : Porosity is an index of relative pore volume. It is the total unit volume of the soil or rock divided into the void volume.

pressurized water reactor : A nuclear power reactor that uses water under pressure as a coolant. The water boiled to generate steam is in a separate system.

probable maximum flood : The largest flood for which there is any reasonable expectancy in a specific area. The probable maximum flood is normally several times larger than the largest flood of record.

process knowledge : The set of information that is used by trained and qualified individuals who are cognizant of the origin, use, and location of waste-generating materials and processes in sufficient detail so as to certify the identity of the waste.

processing (of spent nuclear fuel) : Applying a chemical or physical process designed to alter the characteristics of the spent nuclear fuel matrix.

production reactor : A nuclear reactor that is used to irradiate target material to produce special nuclear material or by-product material.

public : Anyone outside the DOE site boundary at the time of an accident or during normal operation. With respect to accidents analyzed in this EIS, anyone outside the DOE site boundary at the time of an accident.

rad : The special unit of absorbed dose. One rad is equal to an absorbed dose of 100 ergs/gram.

radiation (ionizing radiation) : Alpha particles, beta particles, gamma rays, x-rays, neutrons, high-speed electrons, high-speed protons, and other particles capable of producing ions. Radiation, as it is used here, does not include nonionizing radiation such as radio- or microwaves, or visible, infrared, or ultraviolet light.

radiation worker : A worker who is occupationally exposed to ionizing radiation and receives specialized training and radiation monitoring devices to work in such circumstances.

radioactive waste : Waste that is managed for its radioactive content.

radioactivity : The property or characteristic of material to spontaneously "disintegrate" with the emission of energy in the form of radiation. The unit of radioactivity is the curie (or becquerel).

radioisotope : An unstable isotope of an element that decays or disintegrates spontaneously, emitting radiation. Approximately 5,000 natural and artificial radioisotopes have been identified.

radiological survey : The evaluation of the radiation hazard accompanying the production, use, or existence of radioactive materials under a specific set of conditions. Such evaluation customarily includes a physical survey of the disposition of materials and equipment, measurements or estimates of the levels of radiation that may be involved, and a sufficient knowledge of processes affecting these materials to predict hazards resulting from unexpected or possible changes in materials or equipment.

radionuclide : See radioisotope.

Record of Decision (ROD) : A public document that records the final decision(s) concerning a proposed action. The Record of Decision is based in whole or in part on information and technical analysis generated either during the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) process or the National Environmental Policy Act (NEPA) process, both of which take into consideration public comments and community concerns.

recycling : Recycling techniques are characterized as use, reuse, and reclamation techniques (resource recovery). Use or reuse involves the return of a potential waste material either to the originating process as a substitute for an input material or to another process as an input material. Reclamation is the recovery of a useful or valuable material from a waste stream. Recycling allows potential waste materials to be put to a beneficial use rather than going to treatment, storage, or disposal.

regulated substances : A general term used to refer to materials other than radionuclides that are regulated by Federal, state, (or possibly local) requirements.

rem : The dosage of an ionizing radiation that will cause the same biological effect as 1 roentgen of x-ray or gamma-ray exposure.

remote-handled waste : Packaged waste whose external surface dose rate exceeds 200 millirem per hour.

remote handling : The handling of wastes from a distance so as to protect human operators from unnecessary exposure.

repository : A permanent deep geologic disposal facility for high-level or transuranic wastes and spent nuclear fuel.

reprocessing (of spent nuclear fuel) : Processing of reactor irradiated nuclear material (primarily spent nuclear fuel) to recover fissile and fertile material, in order to recycle such materials primarily for defense programs. Historically, reprocessing has involved aqueous chemical separations of elements (typically uranium or plutonium) from undesired elements in the fuel.

research reactor : A nuclear reactor used for research and development.

Resource Conservation and Recovery Act (RCRA) : A Federal law addressing the management of waste. Subtitle C of the law addresses hazardous waste under which a waste must either be "listed" on one of the U.S. Environmental Protection Agency's (EPA's) hazardous waste lists or meet one of EPA's four hazardous characteristics of ignitability, corrosivity, reactivity, or toxicity, as measured using the toxicity characterization leaching procedure (TCLP). Cradle-to-grave management of wastes classified as RCRA hazardous wastes must meet stringent guidelines for environmental protection as required by the law. These guidelines include regulation of transport, treatment, storage, and disposal of RCRA defined hazardous waste. Subtitle D of the law addresses the management of nonhazardous, nonradioactive, solid waste such as municipal wastes.

retrieval : The process of recovering wastes that have been stored or disposed of onsite so they may be appropriately characterized, treated, and disposed of.

risk : Quantitative expression of possible loss that considers both the probability that a hazard causes harm and the consequences of that event.

safety analysis report : A report, prepared in accordance with DOE Orders 5481.1B and 5480.23, that summarize the hazards associated with the operation of a particular facility and defines minimum safety requirements.

sanitary waste : Liquid or solid wastes that are generated as a result of routine operations of a facility and are not considered hazardous or radioactive.

saturated zone : That part of the earth's crust in which all naturally occurring voids are filled with water.

scaling factor : A multiplier that allows the inference of one radionuclide concentration from another that is more easily measured.

scientific notation : A notation adopted by the scientific community to deal with very large and very small numbers by moving the decimal point to the right or left so that only one number above zero is to the left of the decimal point. Scientific notation uses a number times 10 and either a positive or negative exponent to show how many places to the left or right the decimal place has been moved. For example, in scientific notation, 120,000 would be written as 1.2 x 105, and 0.000012 would be written as 1.2 x 10-5. In a variation of scientific notation often used in computer printouts, the multiplication sign and number 10 are replaced by the letter E. The above numbers would be written as 1.2E5 and 1.2E-5, respectively.

segregation : The process of separating (or keeping separate) individual waste types and/or forms in order to facilitate their cost-effective treatment and storage or disposal.

seismicity : The phenomenon of earth movements; seismic activity. Seismicity is related to the location, size, and rate of occurrence of earthquakes.

seiche : A wave that oscillates in partially or totally enclosed bodies of water from a few minutes to a few hours, caused by seismic or atmospheric disturbances.

sole source aquifer : A designation granted by the U.S. Environmental Protection Agency when groundwater from a specific aquifer supplies at least 50 percent of the drinking water for the area overlying the aquifer. Sole-source aquifers have no alternative source or combination of sources that could physically, legally, and economically supply all those who obtain their drinking water from the aquifer. Sole-source aquifers are protected from federally financially assisted activities determined to be potentially unhealthy for the aquifer.

solid waste : Any garbage, refuse, or sludge from a waste treatment plant, water supply treatment plant, or air pollution control facility and other discarded material, including solid, liquid, semisolid, or contained gaseous material resulting from industrial, commercial, mining, and agricultural operations and from community activities. It does not include solid or dissolved material in domestic sewage, or solid or dissolved materials in irrigation return flows or industrial discharges, which are point sources subject to permits under Section 402 of the Federal Water Pollution Control Act, as amended, or source, special nuclear, or by-product material as defined by the Atomic Energy Act of 1954, as amended [Public Law 94-580, 1004(27) (Resource Conservation and Recovery Act)].

solvents : Liquid chemicals, usually organic compounds, that are capable of dissolving another substance. Exposure to some organic solvents can produce toxic effects on body tissues and processes.

source material : (a) Uranium, thorium, or any other material that is determined by the U.S. Nuclear Regulatory Commission pursuant to the provisions of the Atomic Energy Act of 1954, Section 61, to be source material; or (b) ores containing one or more of the foregoing materials, in such concentration as the U.S. Nuclear Regulatory Commission may by regulation determine from time-to-time [Atomic Energy Act 11(z)]. Source material is exempt from regulation under to Resource Conservation and Recovery Act.

SOx : A generic term used to describe the oxides of sulfur. The combination of sulfur oxides with water vapor produces acid rain (see sulfur oxides).

special-case commercial reactor spent nuclear fuel : Complete or partial spent nuclear fuel assemblies from commercial nuclear power plants that were to be used to support DOE-sponsored research and development programs. This includes spent nuclear fuel from development reactors (Shippingport, Peach Bottom Unit 1, and Fort St. Vrain); spent nuclear fuel used for destructive and nondestructive examination and testing; spent nuclear fuel remaining at the West Valley Demonstration Project; and spent nuclear fuel remnants (Three-Mile Island Unit 2).

special nuclear material : (a) Plutonium, or uranium enriched in the isotope 233 or in the isotope 235, and any other material that the U.S. Nuclear Regulatory Commission, pursuant to the provisions of the Atomic Energy Act of 1954, Section 51, determines to be special nuclear material; or (b) any material artificially enriched by any of the foregoing, but does not include source material. Special nuclear material is exempt from regulation under the Resource Conservation and Recovery Act (RCRA).

specimen : A small sample of material (fuel or non-fuel) inserted into a reactor for testing to characterize the material's performance. Test specimens may be constructed of plant materials, reactor structural materials, or fuel materials.

spent nuclear fuel : Fuel that has been withdrawn from a nuclear reactor following irradiation, the constituent elements of which have not been separated. For the purposes of this EIS, spent nuclear fuel also includes uranium/neptunium target materials, blanket subassemblies, pieces of fuel, and debris.

stabilization (of spent nuclear fuel) : Actions taken to further confine or reduce the hazards associated with spent nuclear fuel, as necessary for safe management and environmentally responsible storage for extended periods of time. Activities that may be necessary to stabilize spent nuclear fuel include canning, processing, and passivation.

stakeholder : Any person or organization with an interest in or affected by DOE activities. Stakeholders may include representatives from Federal agencies, State agencies, Congress, Native American Tribes, unions, educational groups, industry, environmental groups, other groups, and members of the general public.

storage : The collection and containment of waste or spent nuclear fuel in such a manner as not to constitute disposal of the waste or spent nuclear fuel for the purposes of awaiting treatment or disposal capacity (that is, not short-term accumulation).

subsurface : The area below the land surface (including the vadose zone and aquifers).

sulfur oxides : Pungent, colorless gases formed primarily by the combustion of fossil fuels; considered major air pollutants; sulfur oxides may damage the respiratory tract as well as vegetation (see SOx).

target : A tube, rod, or other form containing material that, on being irradiated in a nuclear reactor would produce a designed end product (that is, uranium-238 produces plutonium-239 and neptunium-237 produces plutonium-238).

total effective dose equivalent : The sum of the external dose equivalent (for external exposures) and the committed effective dose equivalent (for internal exposures).

transient : A change in the reactor coolant system temperature and/or pressure. Transients can be caused by adding or removing neutron poisons, by increasing or decreasing the electrical load on the turbine generator, or by accident conditions.

transuranic waste : Waste containing more than 100 nanocuries of alpha-emitting transuranic isotopes, with half-lives greater than 20 years, per gram of waste, except for (a) high-level radioactive waste; (b) waste that the U.S. Department of Energy has determined, with the concurrence of the Administrator of the U.S. Environmental Protection Agency, does not need the degree of isolation required by 40 CFR 191; or (c) waste that the U.S. Nuclear Regulatory Commission has approved for disposal on a case-by-case basis in accordance with 10 CFR 61.

transuranium radionuclide : Any radionuclide having an atomic number greater than 92.

tsunami : A huge ocean wave caused by an underwater earthquake or a volcanic eruption.

ultimate disposition : The final step in which a material is either processed for some use or disposed of.

vadose zone : The zone between the land surface and the water table. Saturated bodies, such as perched groundwater, may exist in the vadose zone. Also called the zone of aeration and the unsaturated zone.

vitrification : The process of immobilizing waste material that results in a glass-like solid.

volatile organic compound (VOC) : Chemical containing mainly carbon, hydrogen, and oxygen that readily evaporates at ambient temperature. Exposure to some organic compounds can produce toxic effects on body tissue and processes.

Volcanic Rift Zones : Linear belts of basaltic vents marked by open fissures, monoclines, and small normal faults. Volcanic rift zones were produced during the propagation of vertical molten basaltic dikes that fed surface eruptions.

vulnerabilities : Conditions or weaknesses that may lead to radiation exposure to the public, unnecessary or increased exposure to the workers, or release of radioactive materials to the environment. For example, some DOE facilities have had leakage from spent fuel storage pools, excessive corrosion of fuel causing increased radiation levels in the pool, or degradation of handling systems. Vulnerabilities are also caused by loss of institutional controls, such as cessation of facility funding or reductions in facility maintenance and control.

waste acceptance criteria (WAC) : The requirements specifying the characteristics of waste and waste packaging acceptable to a waste receiving facility; and the documents and processes the generator needs to certify that waste meets applicable requirements.

waste certification : A process by which a waste generator certifies that a given waste or waste stream meets the waste acceptance criteria of the facility to which the generator intends to transport waste for treatment, storage, or disposal. Certification is accomplished by a combination of waste characterization, documentation, quality assurance, and periodic audits of the certification program.

waste characterization : See characterization.

Waste Isolation Pilot Plant (WIPP) : A facility near Carlsbad, New Mexico, authorized to demonstrate safe disposal of defense-generated transuranic waste in a deep geologic medium.

waste management : The planning, coordination, and direction of those functions related to generation, handling, treatment, storage, transport, and disposal of waste, as well as associated surveillance and maintenance activities.

waste management facility : All contiguous land, structures, other appurtenances, and improvements on the land, used for treating, storing, or disposing of waste or spent nuclear fuel. A facility may consist of several treatment, storage, or disposal operational units (for example, one or more landfills, surface impoundments, or combinations of them).

waste management program : A systematic approach to organize, direct, document, and assess activities associated with waste generation, treatment, storage, or disposal. A waste management program consists of all the functional elements, organizations, and activities that comprise the system needed to properly manage waste. These functions and activities can be performed by various organizations.

waste management systems assessment : A systems assessment of the entire low-level waste management (or all of waste management) structure/program at a given site that considers treatment, storage, disposal, as well as onsite and offsite points of generation with an emphasis on optimization of all aspects of the operations, including, but not limited to, protection of human health and the environment, regulatory compliance, and cost effectiveness.

waste minimization : An action that economically avoids or reduces the generation of waste by source reduction, reducing the toxicity of hazardous waste, improving energy usage, or recycling. These actions will be consistent with the general goal of minimizing present and future threats to human health, safety, and the environment.

water pool : A type of facility usually used for the storage of irradiated nuclear materials and spent fuel. The water shields the material being stored while allowing it to be accessible for handling. Sometimes referred to as a water pit.

wet storage : Storage of spent nuclear fuel in a pool of water, generally for the purposes of cooling and/or shielding.

APPENDIX I Offsite Transportation of Spent Nuclear Fuel

CONTENTS

FIGURES

TABLES

Appendix I Offsite Transportation of Spent Nuclear Fuel

I-1 INTRODUCTION

This appendix summarizes the methods and results of analysis for determining the environmental impacts of spent nuclear fuel (SNF) transportation on public highways and rail systems outside the boundaries of U.S. Department of Energy (DOE) sites (offsite). The impacts are presented by alternative and include doses and health effects.

This appendix does not address the impacts of SNF transport within the boundaries of DOE sites (onsite). Onsite transport impacts are addressed in site-specific Appendices A through F. This appendix addresses offsite shipments of naval-type SNF stored at the Idaho Chemical Processing Plant as of June 1995 to storage locations at other sites as identified by certain alternatives. Transport of naval SNF from shipyards and prototypes to the equivalent expended core facility at the alternative sites are addressed in this EIS in Appendix D in Volume 1, along with transport of naval test specimens.

This appendix also includes the impacts of shipments of foreign research reactor SNF from the six points of entry identified in the Implementation Plan for this EIS (Hampton Roads, Virginia; Charleston, South Carolina; Savannah, Georgia; Seattle-Tacoma, Washington; Portland, Oregon; and Oakland, California) and the points of entry at the Military Ocean Terminal at Sunny Point, North Carolina; and Galveston, Texas. The six points of entry identified in the Implementation Plan were chosen using the following criteria: (a) adequacy of harbor and dock characteristics to satisfy the cask-carrying ship requirements, (b) availability of safe and secure lag storage, (c) adequacy of overland transportation systems from points of entry to the storage sites, (d) experience in safe and secure handling of hazardous cargo, (e) emergency preparedness status at the point of entry and nearby communities, and (f) proximity of the proposed storage sites. The Military Ocean Terminal at Sunny Point, North Carolina, was chosen because it was recently used for foreign research reactor SNF shipments. Galveston, Texas was chosen as a point of entry because it was on the Gulf Coast and has container-handling experience. A full range of alternative points of entry, including these and other points of entry, is being evaluated in the

Environmental Impact Statement on a Proposed Nuclear Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel,and no decision concerning the choice of points of entry will be made until both the Programmatic Spent Nuclear Fuel Management and the Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement and the Environmental Impact Statement on a Proposed Nuclear Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel are completed. The ocean-going portion of foreign research reactor SNF shipments and a detailed evaluation of point of entry activities are also not assessed in this appendix, but will be assessed in the Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel.

The impacts of historical shipments of SNF to the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and the Nevada Test Site and cumulative transportation impacts are also discussed in this appendix. The historical impacts and cumulative impacts include shipments of naval SNF and test specimens.

I-2 TRANSPORTATION REGULATIONS

The regulatory standards for packaging and transport of SNF are designed to achieve four primary objectives:

- Protect persons and property from radiation emitted from packages during transportation, by specific limitations on the allowable radiation levels
- Provide proper containment of the SNF in the package (achieved by packaging design requirements based on performance-oriented packaging integrity tests and environmental criteria)
- Prevent nuclear criticality (an unplanned nuclear chain reaction that may occur as a result of concentrating too much fissile material in one place)
- Provide physical protection against theft and sabotage during transit.

The U.S. Department of Transportation regulates the transportation of hazardous materials (including SNF) in interstate and intrastate commerce by land, air, and on navigable water. As outlined in a 1979 Memorandum of Understanding with the U.S. Nuclear Regulatory Commission, the U.S. Department of Transportation specifically regulates the carriers of SNF and the conditions of transport, such as routing, handling and storage, and vehicle and driver requirements. The U.S. Department of Transportation also regulates the labeling, classification, and marking of all SNF packages.

The U.S. Nuclear Regulatory Commission regulates the packaging and transport of SNF for its licensees, which includes commercial shippers of SNF. In addition, under an agreement with the U.S. Department of Transportation, the U.S. Nuclear Regulatory Commission sets the standards for packages containing fissile materials and SNF.

The DOE, through its management directives, orders, and contractual agreements, assures the protection of public health and safety by imposing on its transportation activities standards equivalent to those of the U.S. Department of Transportation and the U.S. Nuclear Regulatory Commission. The DOE has authority, granted by a 1973 Memorandum of Understanding between the U.S. Department of Transportation and the Atomic Energy Commission, to certify DOE SNF packages. The DOE may design, procure, and certify its own SNF packages to be used by the DOE and its contractors if the packages provide equivalent safety to that provided in 10 CFR Part 71.

The U.S. Department of Transportation also has requirements that help to reduce transportation impacts. For example, there are requirements for drivers, routing, packaging, labeling, marking, and placarding. There are also requirements that specify the maximum dose rate associated with radioactive material shipments, which help to reduce incident-free transportation doses.

The Federal Emergency Management Agency is responsible for establishing policies for and coordinating civil emergency management, planning, and interaction with Federal executive agencies that have emergency response functions in the event of a SNF transportation incident. The Federal Emergency Management Agency coordinates Federal and state participation in developing emergency response plans and is responsible for the development of the interim Federal Radiological Emergency Response Plan. The Federal Radiological Emergency Response Plan is designed to coordinate Federal support to state and local governments, upon request, during the event of a SNF transportation incident.

The Interstate Commerce Commission is responsible for the regulation of the economic aspects of SNF transportation for land shipments. The Comission issues operating authorities to carriers and also monitors and approves freight rates.

Spent nuclear fuel is transported in Type B packages, which are designed and constructed to retain their radioactive contents in both normal and severe accident conditions.

Under normal conditions a cask must withstand:

- Hot [100F (38C)] and Cold [-40F (-40C)] temperatures
- External pressure changes from 3.5 to 20 pounds per square inch (24.5 to 140 kilopascal)
- Normal vibration experienced during transportation
- Simulated rainfall of 2 inches (5 centimeters) per hour for 1 hour
- Free drop from 1 to 4 feet (0.3 to 1.2 meters), depending on the package weight
- Compression loading (the greater of 5 times the weight of package or 1.85 pounds per square inch (12.75 kilopascal) times the vertical projected area of the package) applied uniformly to the top and bottom of the package for a period of 24 hours.
- Impact of a 13-pound (6-kilogram) steel cylinder with rounded ends dropped from 40 inches (1 meter) onto the most vulnerable surface of the cask.

Under accident conditions a cask must withstand:

- Free drop for 30 feet (9 meters) onto an unyielding surface in a way most likely to cause damage to the cask
- Free drop from 40 inches (1 meter) onto the end of a 6-inch-diameter (15-centimeter-diameter) vertical steel bar
- Exposure for not less than 30 minutes to temperatures of 1475F (802C)
- Immersion in at least 50 feet (15 meters) of water for 8 hours and, for criticality considerations, immersion in at least 3 feet (0.9 meters) of water for 8 hours in the attitude for which maximum leakage is expected.

Compliance with these requirements is demonstrated by using a combination of simple calculational methods, computer modeling techniques, or full-scale or scale-model testing of casks.

I-3 SNF TRANSPORTATION MODES AND ROUTES

I-3.1 SNF Transportation Routing Models

To assess incident-free and transportation accident impacts, route characteristics were determined for each of the origins and destinations associated with SNF shipments. Each origin represents a facility that generates or stores SNF that must be transported, and each destination represents a facility that stores SNF. For offsite transport, representative highway and rail routes were analyzed using the routing computer codes HIGHWAY (Johnson et al. 1993a) and INTERLINE (Johnson et al. 1993b). The routes were calculated conforming to current routing practices and applicable routing regulations and guidelines. Route characteristics include total shipment distance between each origin and destination and the fractions of travel in rural, suburban, and urban population density zones (see Table I-1). The HIGHWAY and INTERLINE routing computer codes are described below.

The HIGHWAY computer code predicts highway routes for transporting radioactive materials within the United States. The HIGHWAY database is a computerized road atlas that currently describes approximately 240,000 miles of roads. A complete description of the Interstate Highway System, United States highways, most of the principal state highways, and a number of local and community highways are identified in the database. The HIGHWAY computer code calculates routes that maximize the use of interstate highways. This feature allows the user to predict routes for transport of radioactive materials that conform to U.S. Department of Transportation regulations, as specified in 49 CFR Part 177, (CFR 1994a). The routes calculated conform to applicable guidelines and regulations; therefore, they represent routes that could be used. However, they may not be the actual routes used in the future. The code is updated periodically to reflect current road conditions, and it has been benchmarked against reported mileage and observations of commercial truck firms.

The INTERLINE computer code is designed to simulate routing of the United States rail system. The INTERLINE database consists of 94 separate subnetworks and represents various competing rail companies in the United States. The database used by INTERLINE was originally based on Federal Railroad Administration data and reflected the United States railroad system in 1974. The database has since been expanded and modified over the past two decades. The routes used for this study used the standard assumptions in the INTERLINE computer code that simulate the selection process railroads use to direct transport of radioactive material. Currently, there are no specific routing regulations for transporting radioactive material by rail. INTERLINE is updated periodically to reflect current track conditions, and it has been benchmarked against reported mileage and observations of commercial rail firms.

Table I-1. Transportation distances between facilities for spent nuclear fuel shipments.

Route		Miles	Rural (%)	Suburban (%)	Urban (%)
	Truck routes				
Idaho National Engineering Laboratory	Hanford Site	599.0	91.3	7.6	1.1

I-3.2 Spent Nuclear Fuel Shipments

In the transportation analyses, SNF was divided into a number of categories: (a) commercial, (b) DOE research, (c) foreign research reactor, (d) graphite, (e) N Reactor, (f) naval-type, (g) Savannah River Site production reactor, and (h) university research reactor. More details on these fuel types may be found in Appendix J of Volume 1 of this EIS. The estimated number of SNF shipments are presented by fuel type, origin-destination pair, and transport mode for each alternative in Tables I-2 and I-3 (Heiselmann 1995). Each shipment, whether by truck or rail, was assumed to consist of one shipping container. However, the size of shipping container was variable, depending on the type of SNF and the transport mode (truck or rail). At this time, insufficient data exist to determine the transport mode for all shipments. Therefore, the number of truck or rail shipments was based on either 100 percent transport by truck or 100 percent transport by rail to bound potential impacts.

The shipments in this appendix include offsite transport of naval-type SNF stored at the Idaho Chemical Processing Plant as of June 1995 to storage locations at other sites as identified in the alternatives. Transport of naval SNF from shipyards and prototypes to the equivalent Expended Core Facility at the alternative sites are addressed in Appendix D of Volume 1 of this EIS, along with transport of naval test specimens.

This appendix also includes transport of foreign research reactor SNF from the six points of entry identified in the Implementation Plan for this EIS (Hampton Roads, Virginia; Charleston, South Carolina; Savannah, Georgia; Seattle-Tacoma, Washington; Portland, Oregon; and Oakland, California) to sites as identified in the alternatives. Impacts of shipments to the Military Ocean Terminal at Sunny Point, North Carolina, were analyzed because this terminal was recently used for foreign research reactor SNF shipments. Impacts of shipments to Galveston, Texas, were analyzed because this point of entry is on the Gulf Coast and has container-handling experience. The ocean-going portion of foreign research reactor SNF shipments and a detailed evaluation of point of entry activities are not assessed in this EIS, but will be assessed in the Environmental Impact Statement on a Proposed Nuclear Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel.

The No Action alternative considers only transport of naval SNF and test specimens. These shipments are addressed in Appendix D of Volume 1 of this EIS. For the Decentralization alternative, university research reactor, foreign research reactor, and non-DOE research reactor SNF would be transported to the Idaho National Engineering Laboratory or the Savannah River Site.

For the 1992/1993 Planning Basis alternative, commercial, DOE research, and graphite SNF would be transported to the Idaho National Engineering Laboratory or the Savannah River Site. University research reactor, foreign research reactor, and non-DOE research reactor SNF would also continue to be transported to the Idaho National Engineering Laboratory or the Savannah River Site.

For the Regionalization alternatives, SNF would be consolidated based on fuel type or geography. More shipments of SNF would occur than for the 1992/1993 Planning Basis alternative and all types of SNF would be transported. For the Regionalization by Fuel Type alternative, N-Reactor SNF, naval-type SNF, and Savannah River Site production reactor SNF and targets would not be transported. Generally, aluminum SNF would be transported to the Savannah River Site and stainless steel SNF would be transported to the Idaho National Engineering Laboratory. For the Regionalization by Geography alternative, SNF from west of the Mississippi River would be transported to the Hanford Site, the

Idaho National Engineering Laboratory, or the Nevada Test Site. SNF from east of the Mississippi River would be transported to the Savannah River Site or the Oak Ridge Reservation.

For the Centralization alternatives, all SNF would be transported to the Hanford Site, the Idaho National Engineering Laboratory, the Savannah River Site, the Oak Ridge Reservation, or the Nevada Test Site. The primary difference between these alternatives, in terms of shipments, is the transport of N-Reactor SNF, naval-type SNF, and Savannah River Site production reactor SNF and targets. For Centralization at the Idaho National Engineering Laboratory, the Savannah River Site, the Oak Ridge Reservation, or the Nevada Test Site, N-Reactor SNF would be transported from the Hanford Site. For Centralization at the Hanford Site, the Idaho National Engineering Laboratory, the Oak Ridge Reservation, or the Nevada Test Site, Savannah River Site production reactor SNF and targets would be transported. For Centralization at the Hanford Site, the Savannah River Site, the Oak Ridge Reservation, or the Nevada Test Site, naval-type SNF would be transported from the Idaho National Engineering Laboratory. For Centralization at the Oak Ridge Reservation or the Nevada Test Site, N-Reactor SNF, naval-type SNF, and Savannah River Site production reactor SNF and targets would be transported.

Table I-2. Spent nuclear fuel shipments for the Decentralization, 1992/1993 Planning Basis, Regionalization by Fuel Type, and Centralization alternatives.

		Decentralization		1992/1993 Planning Basis		Regionalization by Fuel Type		Centralization

I-4 INCIDENT-FREE TRANSPORTATION RISKS FOR SPENT NUCLEAR FUEL

I-4.1 Methodology

Radiological dose during normal, incident-free transportation of SNF results from exposure to the external radiation field that surrounds the shipping containers. The dose is a function of the number of people exposed, their proximity to the containers, their length of time of exposure, and the intensity of the radiation field surrounding the containers.

Radiological impacts were determined for crew workers and the general population during normal, incident-free transportation. For truck shipments, the crew were the drivers of the transport vehicle. For rail shipments, the crew were workers in close proximity to the shipping containers during inspection or classification of railcars. The general population was persons within 800 meters (2,625 feet) of the road or railway (off-link), persons sharing the road or railway (on-link), and persons at stops.

Collective doses for the crew and general population were calculated using the RADTRAN 4 computer code (Neuhauser and Kanipe 1992). SNF was assigned a dose rate of 14 millirem per hour at 1 meter (3.28 feet) from the shipping container. This dose rate yields a dose rate of 10 millirem per hour at 2 meters (6.56 feet) from the vehicle, which is the regulatory maximum based on an exclusive use vehicle (see Madsen et al. 1986). A dose rate of 1 millirem per hour at 1 meter (3.28 feet) was used for naval-type SNF shipments, based on measured dose rates from previous naval SNF shipments. Three population density zones (rural, suburban, and urban) were used. These zones correspond to mean population densities of 6,719, and 3,861 persons per square kilometer, respectively (Neuhauser and Kanipe 1992).

Calculating the collective doses is based on developing unit risk factors. Unit risk factors provide an estimate of the impact from transporting one shipment of radioactive material over a unit distance of travel in a given population density zone. The unit risk factors may be combined with routing information, such as the transport distances in various population density zones, to determine the risk for a single shipment (a shipment risk factor) between a given origin and destination. Cashwell et al. (1986) contains a detailed explanation of the use of unit risk factors.

Unit risk factors were developed based on travel within rural, suburban, and urban population zones using RADTRAN 4, using default data (see Neuhauser and Kanipe 1992). Table I-4 contains the unit risk factors for offsite truck and rail shipments of SNF. Table I-5 contains the unit risk factors for offsite truck and rail shipments of naval-type SNF. Shipment risk factors were also developed for offsite shipments by combining the unit risk factors with routing information derived from the HIGHWAY and INTERLINE computer codes.

Table I-4. Incident-free unit risk factors for offsite truck and rail shipments of spent nuclear fuel.

		Unit risk factors (person-rem per kilometer)(a)		
Mode	Exposure group	Rural	Suburban	Urban
Truck

---

a. The methodology, equations, and data used to develop the unit risk factors are discussed in Madsen et al. (1986) and Neuhauser and Kanipe (1992). Cashwell et al. (1986) contains a detailed explanation of the use of unit risk factors.

b. Off-link general population were persons within 800 meters (2,625 feet) of the road or railway.

c. On-link general population were persons sharing the road or railway.

d. The nonlinear component of incident-free rail dose for crew workers because of railcar inspections and classifications is 0.011 person-rem per shipment. Ostmeyer (1986) contains a detailed explanation of the rail exposure model.

e. The nonlinear component of incident-free rail dose for the general population because of railcar inspections and classifications is 0.0087 person-rem per shipment. Ostmeyer (1986) contains a detailed explanation of the rail exposure model.

Table I-5. Incident-free unit risk factors for truck and rail shipments of naval-type spent nuclear fuel.

		Unit risk factors (person-rem per kilometer)(a)		
Mode	Exposure group	Rural	Suburban	Urban
Truck				
	Occupational	1.5 X 10^-5	3.3 X 10^-5	5.4 X 10^-5

	General population total	3.6 X 10^-7	2.7 X 10^-6	2.1 X 10^-5

---

a. The methodology, equations, and data used to develop the unit risk factors are discussed in Madsen et al. (1986) and Neuhauser and Kanipe (1992). Cashwell et al. (1986) contains a detailed explanation of the use of unit risk factors.

b. Off-link general population were persons within 800 meters (2,625 feet) of the road or railway.

c. On-link general population were persons sharing the road or railway.

d. The nonlinear component of incident-free rail dose for crew workers because of railcar inspections and classifications is 0.00080 person-rem per shipment. Ostmeyer (1986) contains a detailed explanation of the rail exposure model.

e. The nonlinear component of incident-free rail dose for the general population because of railcar inspections and classifications is 0.00062 person-rem per shipment. Ostmeyer (1986) contains a detailed explanation of the rail exposure model.

Incident-free nonradiological fatalities were also estimated using unit risk factors. These unit risk factors account for the fatalities associated with exhaust emissions, but the distances used to estimate the impacts must be doubled to reflect the round trip distance because these impacts occur whether or not the shipment contains radioactive material. Two sets of data were evaluated: (a) data from the Non-Radiological Impacts of Transporting Radioactive Material (Rao et al. 1982), and (b) data from the Motor Vehicle-Related Air Toxics Study (EPA 1993). In Rao et al. (1982), the nonradiological unit risk factor for trucks was 1.0 10-7 fatalities per kilometer and the nonradiological unit risk factor for trains was 1.3 10-7 fatalities per kilometer. These unit risk factors are applicable only in urban areas. In EPA (1993), the unit risk factor was calculated to be 7.2 10-11 fatalities per kilometer; this unit risk factor is applicable in all areas (i.e., rural, suburban, and urban). Based on the routes analyzed in this EIS, the unit risk factors from Rao et al. (1982) were found to overestimate impacts by about 20 to 30 times relative to the unit risk factors from EPA (1993). Therefore, the unit risk factors from Rao et al. (1982) were used as a conservative estimate of the incident-free nonradiological fatalities presented in this EIS. It should be noted that the unit risk factors from Rao et al. (1982) account for all fatalities, not just cancer fatalities. Other effects of chronic exposure to diesel exhaust emissions have been followed in occupationally exposed workers, but these data are insufficient to make a correlation between the effects and the exposure experienced (EPA 1993). Therefore, these impacts were not estimated in this EIS.

I-4.1.1 Maximally Exposed Individual Exposure Scenarios

Maximum individual doses were calculated using the RISKIND computer code (Yuan et al. 1993). The maximum individual doses for the routine transport offsite were estimated for transportation workers, as well as members of the general population. For rail shipments, the three general population scenarios were (a) a railyard worker working at a distance of 10 meters (32.8 feet) from the shipping container for 2 hours, (b) a resident living 30 meters (98.4 feet) from the rail line where the shipping container was being transported, and (c) a resident living 200 meters (656.2 feet) from a rail stop where the shipping container was sitting for 20 hours. For train shipments, the maximum exposed transportation worker was an individual in a railyard who spent a time- and distance-weighted average of 0.16 hours inspecting, classifying, and repairing railcars (Wooden 1986).

For offsite truck shipments, the three scenarios for the general population were: (a) a person caught in traffic and located 1 meter (3.28 feet) away from the surface of the shipping container for one-half hour, (b) a resident living 30 meters (98.4 feet) from the highway used to transport the shipping container, and (c) a service station worker working at a distance of 20 meters (65.6 feet) from the shipping container for 2 hours. The hypothetical maximum exposed individual radiological doses were accumulated over the 40-year period. However, for the situation involving an individual caught in traffic next to a truck, the radiological exposures were calculated for only one event because it was considered unlikely that the same individual would be caught in traffic next to all containers for all shipments. For truck shipments, the maximum exposed transportation worker is the driver who was assumed to drive shipments for up to 2,000 hours per year.

I-4.2 Results of Calculations

This section summarizes the results of the incident-free transportation analyses for SNF shipments that occur outside the boundaries of U.S. Department of Energy sites (offsite). These results do not include the impacts of SNF shipments within the boundaries of DOE sites (onsite). Onsite transportation impacts are addressed in site-specific Appendices A, B, C, D, and F of this EIS.

This section includes the impacts of offsite transport of naval-type SNF stored at the Idaho Chemical Processing Plant as of June 1995 to storage locations at other DOE sites, as identified in the alternatives. Shipments of naval SNF and test specimens are addressed in Appendix D of Volume 1 of this EIS.

I-4.2.1 Impacts from the No Action Alternative

Under the No Action alternative, the only offsite transport of SNF involves shipments of naval SNF and test specimens. These shipments are addressed in Appendix D of Volume 1 of this EIS.

I-4.2.2 Impacts from the Decentralization Alternative

For the Decentralization alternative, the incident-free transportation of SNF was estimated to result 0.11 to 0.34 fatalities over the 40-year period 1995 through 2035 (see Table I-6). The statistically estimated fatalities were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions. A range of fatalities occurs because of the option of using truck or rail transport for SNF shipments.

The estimated number of radiation-related latent cancer fatalities for transportation workers ranged from 0.023 to 0.082. The estimated number of radiation-related latent cancer fatalities for the general population ranged from 0.041 to 0.24. The estimated number of nonradiological fatalities from vehicular emissions ranged from 0.017 to 0.044.

I-4.2.3 Impacts from the 1992/1993 Planning Basis Alternative

For the 1992/1993 Planning Basis alternative, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.11 to 0.42 over the 40-year period 1995 through 2035 (see Table I-7). These fatalities were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological

---

a. Maheras (1995a).

b. Maheras (1995b).

c. Maheras (1995c).

d. DOE SNF includes special-case commercial, DOE research, other domestic research, graphite, N-Reactor, naval-type, and Savannah River production reactor SNF (see Tables I-2, I-3).

e. Occupational incident-free nonradiological fatalities are included with the general population incident-free nonradiological fatalities.

fatalities from vehicular emissions. Again, a range of fatalities occurred because of the option of using truck or rail transport for SNF shipments.

The estimated number of radiation-related latent cancer fatalities for transportation workers ranged from 0.024 to 0.10. The estimated number of radiation-related latent cancer fatalities for the general population ranged from 0.043 to 0.30. The estimated number of nonradiological fatalities from vehicular emissions ranged from 0.020 to 0.046.

I-4.2.4 Impacts from the Regionalization Alternative

I-4.2.4.1 Impacts from Regionalization by Fuel Type. For the Regionalization by Fuel

Type, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.14 to 0.58 over the 40-year period 1995 through 2035 (see Table I-8). These fatalities were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions. The reason for a range of fatalities was because of the option of using truck or rail transport for SNF shipments.

The estimated number of radiation-related latent cancer fatalities for transportation workers ranged from 0.026 to 0.14. The estimated number of radiation-related latent cancer fatalities for the general population ranged from 0.053 to 0.41. The estimated number of nonradiological fatalities from vehicular emissions ranged from 0.027 to 0.059.

I-4.2.4.2 Impacts from Regionalization by Geography. For the six Regionalization by

Geography alternatives, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.10 for regionalization at the Idaho National Engineering Laboratory and Oak Ridge Reservation to 0.85 for regionalization at the Nevada Test Site and the Oak Ridge Reservation (see Tables I-9 through I-14). These fatalities were over the 40-year period 1995 through 2035 and were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The reason for a range of fatalities was because of two factors: (a) the option of using truck or rail transport for SNF shipments, and (b) the six regionalization by geography alternatives.

For regionalization at the Idaho National Engineering Laboratory and Oak Ridge Reservation, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.028. The estimated number of radiation-related latent cancer fatalities for the general population was 0.042. The estimated number of nonradiological fatalities from vehicular emissions was 0.034.

For regionalization at the Nevada Test Site and the Oak Ridge Reservation, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.20. The estimated

e. Occupational incident-free nonradiological fatalities are included with the general population incident-free nonradiological fatalities.

number of radiation-related latent cancer fatalities for the general population was 0.60. The estimated number of nonradiological fatalities from vehicular emissions was 0.054.

I-4.2.5 Impacts from the Centralization Alternatives

For the five Centralization alternatives, the incident-free transportation of spent nuclear fuel was estimated to result in total fatalities that ranged from 0.16 for centralization at the Oak Ridge Reservation to 1.7 for centralization at the Savannah River Site (see Tables I-15 through I-19). These fatalities were over the 40-year period 1995 through 2035 and were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The reason for a range of fatalities was because of two factors: (a) the option of using truck or rail transport for SNF shipment and (b) the five Centralization options.

For centralization at the Oak Ridge Reservation, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.042. The estimated number of radiation-related latent cancer fatalities for the general population was 0.067. The estimated number of nonradiological fatalities from vehicular emissions was 0.055.

For centralization at the Savannah River Site, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.42. The estimated number of radiation-related latent cancer fatalities for the general population was 1.2. The estimated number of nonradiological fatalities from vehicular emissions was 0.074.

I-4.2.6 Impacts of Using Alternate Points of Entry for Foreign Research Reactor Spent Nuclear Fuel Shipments

For incident-free transportation (radiological and vehicle-related), shipments from Jacksonville, Florida, and Wilmington, North Carolina, to the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site would yield lower impacts than shipments from Charleston, South Carolina, Galveston, Texas, Hampton Roads, Virginia, Savannah, Georgia, and the Military Ocean Terminal, Sunny Point, North Carolina, to these same sites.

I-5 SPENT NUCLEAR FUEL TRANSPORTATION ACCIDENT RISKS AND MAXIMUM REASONABLY FORESEEABLE CONSEQUENCES

I-5.1 Methodology

The offsite SNF transportation accident analysis considers the impacts of accidents during the transportation of SNF by truck or rail. SNF is transported in specially designed casks that meet U.S. Department of Transportation and U.S. Nuclear Regulatory Commission Type B packaging specifications in 10 CFR Part 71 (CFR 1994b).

Under accident conditions, impacts to human health and the environment may result from the release and dispersal of radioactive material. Because of the rigorous design specifications for SNF shipping casks, the U.S. Nuclear Regulatory Commission has estimated that casks will withstand 99.4 percent of truck or rail accidents without sustaining damage sufficient to breach the cask (Fischer et al. 1987). The 0.6 percent of accidents that could potentially breach the cask are represented by a spectrum of accident severities and radioactive release conditions. Accident analysis methodology has been developed by the U.S. Nuclear Regulatory Commission for calculating the probabilities and consequences from this spectrum of unlikely accidents, but it is not possible to predict where along the shipping route such accidents might occur.

To provide DOE and the public a reasonable assessment of SNF transportation accident impacts, two types of analyses were performed. First, an accident risk assessment was performed that takes into account the probabilities and consequences of a spectrum of accident severities using methodology developed by the U.S. Nuclear Regulatory Commission (Fischer et al. 1987). The accident risk assessment used route-specific information for accident rates and population densities. For the spectrum of accidents considered in the analysis, accident consequences in terms of collective dose to the population within 80 kilometers (50 miles) were multiplied by the accident probabilities to yield dose risk using the RADTRAN 4 computer code. Second, to represent the maximum reasonably foreseeable impacts to individuals and populations should an accident occur, radiological consequences were calculated for an accident of maximum reasonably foreseeable severity in each population zone. An accident is considered reasonably foreseeable if its probability of occurrence is greater than 1 10-7 per year. The accident consequence assessment for maximally exposed individuals and population groups was performed using the RISKIND computer code.

An important variable in the assessment of impacts from SNF transportation accidents is the type of SNF. A wide range of SNF types exists within the DOE complex with significant differences in radioactive material content, fuel material design, cladding design, reactor operating history, and storage (cooling time) history. These differences among SNF types translate into different radioactive material release characteristics under accident conditions. To account for the variation in SNF types, analyses were performed for the following representative SNF types: (a) naval reactor fuels, (b) Savannah River Production Reactor fuels, (c) Hanford N-Reactor fuels, (d) graphite fuels, (e) special-case commercial reactor fuels, (f) university research/test reactor fuels, (g) DOE research/test reactor fuels, (h) foreign research reactor fuels, and (i) non-DOE research reactor fuels.

The impacts for specific alternatives were calculated in units of dose (person-rem) for each origin and destination pair associated with each representative SNF type. The impacts are further expressed as health risks in terms of latent cancer fatalities in exposed populations. The health risk conversion factors used were derived from International Commission on Radiological Protection Publication 60 (ICRP 1991).

I-5.1.1 Accident Rates

For calculating accident shipment-risk factors, state-level accident rates were taken from data provided in Saricks and Kvitek (1994) for rail and heavy combination trucks. For truck transportation, separate accident rates were used for rural, suburban, and urban population density zones in each state. One average accident rate was used for each state for rail transportation. For truck transport, accident fatality risks were based on state-level rates for interstate highways in urban and rural areas (Saricks and Kvitek 1994). Accident fatality risks for rail transportation were calculated using a nationwide average rate of 2.64 10-8 fatalities per rail-kilometer (Cashwell et al. 1986).

I-5.1.2 Accident Severity Categories and Conditional Probabilities

Accident severity categories for potential SNF transportation accidents are described in a U.S. Nuclear Regulatory Commission report commonly referred to as the Modal Study (Fischer et al. 1987). The Modal Study classification scheme for both truck and rail transportation is shown in Figure I-1. Severity is described as a function of the magnitudes of the mechanical forces (impact) and thermal forces (fire) to which a cask may be subjected during an accident. Because all accidents can be described in these terms, severity is independent of the specific accident sequence. In other words, any sequence of events that results in an accident in which a cask is subjected to forces within a certain range of values is assigned to the accident severity category associated with that range. The accident severity scheme is designed to take into account all reasonably foreseeable transportation accidents, including accidents with low probability but high consequences and those with high probability but low consequences.

The severity category matrix represents a set of scenarios defined by a combination of mechanical and thermal forces. A conditional probability is assigned in each category as shown in Figure I-2. For example, Category R(1,1) accidents are the least severe but most frequent, whereas Category R(4,5) accidents are very severe but very infrequent. To determine the expected frequency of each severity category, the conditional probability in each category was multiplied by the baseline accident rate. Each population density zone has a distinct baseline accident rate and distribution

Figure I-1. Matrix of cask response regions for combined mechanical and thermal loads.
(Source: Fischer et al. 1987)

Figure I-2. Fraction of truck and rail accidents expected within each severity category,

assuming an accident occurs. (Source: Fischer et al. 1987).
of accident severities related to differences in average vehicle velocity, traffic density, and other factors, including rural, suburban, or urban location.

For the accident risk assessment, accident risk was generically defined as the consequences of an accident multiplied by the probability of the occurrence of that accident, an approach consistent with the methodology suggested by the existing RADTRAN computer code. Accident unit-risk factors were calculated using the RADTRAN 4 computer code, then summed over the accident conditional probabilities and route characteristics for the origin and destination pairs to yield risk per shipment estimates. These accident risk factors take into account the entire spectrum of reasonably foreseeable transportation accidents, including low probability accidents that have high consequences and high probability accidents that have low consequences.

For the maximum reasonably foreseeable accident consequence assessment, the doses were assessed for populations and individuals assuming the most severe accident scenario with a probability greater than 1 X 10^-7 per year. In terms of the radioactivity released to the environment, the most severe reasonably foreseeable accident is represented by eight accident severity categories [R(4,1) through R(4,5) and R(1,5) through R(3,5)]. Each of the eight most severe accident categories result in the same total release of radioactive material, but the conditional probabilities of occurrence vary. Therefore, the accident consequence assessment is based on a maximum reasonably foreseeable release of radioactivity with a conditional probability that is the sum of the conditional probabilities of the eight most severe accident categories. Accidents of this severity are extremely rare, occurring approximately once per 100,000 truck or 10,000 rail accidents involving a SNF shipment.

I-5.1.3 Atmospheric Conditions

Because it is impossible to predict the specific location of an offsite transportation accident, generic atmospheric conditions were selected for the risk and consequence assessments. For accident risk assessment, neutral weather conditions (Pasquill Stability Class D) were assumed. Neutral weather conditions are typified by moderate windspeeds, vertical mixing within the atmosphere, and good dispersion of atmospheric contaminants. Because neutral meteorological conditions compose the most frequently occurring atmospheric stability condition in the United States, these conditions are most likely to be present in the event of an accident involving a SNF shipment. On the basis of observations from National Weather Service surface meteorological stations at over 300 locations in the United States, on an annual average, neutral conditions (Pasquill Class C and D) occur 50 percent of the time, while stable (Pasquill Class E and F) and unstable (Pasquill Class A and B) conditions occur 33 percent and 17 percent of the time, respectively (Doty et al. 1976). The neutral category predominates in all seasons, but most frequently in the winter (nearly 60 percent of the observations). For the accident consequence assessment, doses were assessed under both neutral (Class D with 4 meters per second windspeed) and stable (Class F with 1 meter per second windspeed) atmospheric conditions. Stable weather conditions are typified by low windspeeds, very little vertical mixing within the atmosphere, and poor dispersion of atmospheric contaminants. Class F meteorology in combination with windspeeds of 1 meter per second generally occur no more than 5 percent of the time. Results calculated for neutral conditions represent the most likely consequences, and the results for stable conditions represent a worst-case weather situation.

I-5.1.4 Population Density Zones

Three population density zones (rural, suburban, and urban) were used for the offsite population risk assessment. These zones respectively correspond to mean population densities of 6, 719, and 3,861 persons per square kilometer. The three population density zones are based on an aggregation of the 12 population density zones provided in the HIGHWAY and INTERLINE output. For calculating, population density information was generated at the state level and used as RADTRAN input for the origin and destination pairs.

I-5.1.5 Exposure Pathways

Radiological doses were calculated for an individual located near the scene of the accident and for populations within 50 miles (80 kilometers) of the accident. Rural, suburban, and urban population densities were assessed. Dose calculations considered a variety of exposure pathways, including inhalation and direct exposure (cloudshine) from the passing cloud, ingestion from contaminated crops, direct exposure (groundshine) from radioactivity deposited on the ground, and inhalation of resuspended radioactive particles from the ground.

I-5.1.6 Health Risk Conversion Factors

The health risk conversion factors used to estimate expected latent cancer fatalities from radiological exposures were derived from International Commission on Radiological Protection Publication 60 (ICRP 1991): 5.0 10-4 and 4.0 10-4 latent fatal cancer cases per person-rem for members of the public and workers, respectively.

I-5.2 Spent Nuclear Fuel Characterization and Radioactive Release Characteristics

I-5.2.1 Characterization of Representative Spent Nuclear Fuel Types

Shipments of naval reactor SNF are addressed in Appendix D of Volume 1 of this EIS, with the exception of naval-type SNF that has been transferred from the U.S. Navy to the DOE and is currently in storage at the Idaho National Engineering Laboratory Idaho Chemical Processing Plant. Characterization data for naval-type SNF were derived from Appendix D of Volume 1 of this EIS.

Savannah River Site production reactor SNF was assumed to include both the spent driver fuel used to power the production reactors, as well as the quantities of irradiated plutonium target material currently in storage at the Savannah River Site. Spent driver fuel stored at the Savannah River Site includes fuel used in tritium and plutonium production. Analysis of these two fuel types showed that typical tritium production SNF contains a higher fission product and transuranic inventory than plutonium production SNF. Analysis of the characteristics of typical irradiated plutonium target material also showed that the radionuclide inventory would be bounded by the inventory in spent tritium production driver fuel. Therefore, for analysis purposes, both spent driver fuel and irradiated plutonium target material at the Savannah River Site was assumed to have the characteristics of spent tritium production driver fuel. Table I-20 shows the radionuclide inventory developed to represent Savannah River Site production reactor SNF based on published reports (WSRC 1991; WSRC 1990).

Characterization data for Hanford N-Reactor SNF were based on Mark IA fuel irradiated to an average burnup of 3,000 megawatt-days per metric ton uranium and assuming a 10-year cooling time since removal from the reactor. The 10-year cooling time is conservative because the Hanford N Reactor was last operated in 1987 and SNF of this type is expected to be at least 10 years old by the time shipments would begin. Table I-21 shows the radionuclide inventory used to represent Hanford N-Reactor SNF.

Most of the graphite SNF under the responsibility of the DOE is from the Fort St. Vrain reactor owned by Public Service of Colorado. Some Fort St. Vrain SNF is already in storage at the Idaho National Engineering Laboratory, but most SNF is still in storage at the Fort St. Vrain site awaiting transport to a DOE facility. In addition to the Fort St. Vrain SNF, smaller amounts of other graphite SNF are currently in storage at the Idaho National Engineering Laboratory. Characteristics for graphite SNF are, therefore, based on Fort St. Vrain SNF. Table I-22 shows the radionuclide inventory used to represent graphite reactor SNF based on six Fort St. Vrain fuel blocks irradiated to an average burnup of 70,000 megawatt-days per metric ton uranium and assuming a cooling time of 1,600 days (Block 1993). The 1,600-day (about 4.3 years) cooling time is conservative because the Fort St. Vrain reactor was shut down in August 1989, and shipments will not be made before June 1995.

SNF from various commercial reactors is currently in storage at various DOE sites, mostly at the Idaho National Engineering Laboratory. Special-case commercial SNF currently in storage at the Idaho National Engineering Laboratory includes core debris from the damaged Three Mile Island Unit 2 reactor. Commercial SNF includes both boiling water reactor and pressurized water reactor SNF. Pressurized water reactor SNF was chosen as most representative because it is most prevalent and typically contains the highest levels of radioactivity (Fischer et al. 1987). Table I-23 shows the radionuclide inventory used to represent commercial SNF based on one pressurized water reactor fuel assembly irradiated to an average burnup of 33,000 megawatt-days per metric ton uranium and assuming a cooling time of 10 years (Fischer et al. 1987). The 10-year cooling time is conservative because the majority of special-case commercial SNF currently in storage at DOE sites will be at least 10 years old by June 1995.

Table I-20. Radionuclide inventory for representative Savannah River Site production reactor spent nuclear fuel.(a)

Isotope	Inventory (curie)

a. Inventory based on one pressurized water reactor fuel assembly, 10 years cooling out of reactor, average burnup 33,000 megawatt-days per metric ton uranium.

Domestic university research and test reactors represent a variety of reactor types and fuel designs. High-enriched training, research, and isotope reactor (TRIGA) SNF was chosen as representative of university reactor SNF because it is one of the largest groups of university SNF to be transported and because it is a rod-type fuel that would be expected to have the highest release of fission products under severe accident conditions. The radionuclide inventory of high-enriched TRIGA fuel was calculated using the ORIGEN2 computer code (Croff 1980) assuming a 17-year reactor operating cycle based on operation of the Texas A&M University TRIGA reactor. To facilitate the modeling of accident consequences, the radionuclide inventory generated by the ORIGEN2 program was truncated to eliminate minor contributors to dose. The radionuclides eliminated accounted for less than 1 percent of the total dose. Additional details are available in Enyeart (1995). Table I-24 shows the radionuclide inventory representative of university research and test reactor SNF based on 19 TRIGA fuel rods irradiated to an average burnup of 20.2 percent and assuming a cooling time of 1 year.

DOE research and test reactors are also represented by a variety of reactor types and fuel designs. Experimental Breeder Reactor-II Mark-V SNF was chosen as representative of DOE research and test reactors because the reactor at the Idaho National Engineering Laboratory is one of the few DOE research and test reactors still operating. Mark-V fuel is the current generation of Experimental Breeder Reactor-II fuel types. The high plutonium content of Mark-V fuel increases the relative hazard of the radionuclide inventory compared to other DOE SNF types. The radionuclide inventory of the Mark-V fuel was calculated using the ORIGEN2 computer code assuming a typical Experimental Breeder Reactor-II operating cycle. To facilitate the modeling of accident consequences, the radionuclide inventory generated by the ORIGEN2 program was truncated to eliminate minor contributors to dose. The radionuclides eliminated accounted for less than 1 percent of the total dose. Additional details are available in Enyeart (1995). Table I-25 shows the radionuclide inventory representative of DOE research and test reactor SNF based on one Mark-V fuel assembly irradiated to a burnup of 7.88 percent and assuming a cooling time of 1 year.

Foreign research and test reactors use a number of different fuel designs. DOE has evaluated the characteristics of foreign research reactor SNF types in a separate EIS on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel. Based on this evaluation, a shipment of 40 TRIGA-type SNF elements was determined to result in the highest potential release of radioactivity in the event of an accident. To provide a bounding analysis for this EIS, foreign TRIGA-type SNF was selected as representative of all foreign research reactor SNF. To facilitate the modeling of accident consequences, the radionuclide inventory generated by the ORIGEN2 program was truncated to eliminate minor contributors to dose. The radionuclides eliminated accounted for less than 1 percent of the total dose. The radionuclide inventory of a single shipping cask, shown in Table I-26, is based on a reactor operating period of 3 years, with a burnup of 31 grams of uranium-235 per fuel element, followed by a cooling period of 1 year.

Table I-24. Radionuclide inventory for representative university research/test reactor spent nuclear fuel.

a. Inventory based on 40 foreign TRIGA fuel elements, 1 year cooling out of reactor, average burnup of 31 grams uranium-235 per fuel element.

Non-DOE research reactor types are generally similar to domestic university research and test reactors. Therefore, TRIGA reactor SNF was also chosen as representative of non-DOE research reactor SNF.

I-5.2.2 Radioactive Release Characteristics

Radiological consequences were calculated by assigning cask release fractions to each accident severity category for each chemically and physically distinct radioisotope. The release fraction is defined as the fraction of the radioactivity in the cask that could be released from the cask in a given severity of accident. Release fractions vary according to SNF type and the physical/chemical properties of the radioisotopes. Most solid radionuclides in SNF are nonvolatile and are, therefore, relatively nondispersible. Gaseous radionuclides, such as krypton-85, are relatively easy to release if the fuel cladding and cask are compromised.

Representative cask release fractions were developed for each of the representative SNF types. The U.S. Nuclear Regulatory Commission Modal Study developed release fractions for commercial pressurized water reactor SNF. The Modal Study release fractions, shown in Table I-27, are based on best engineering judgment and are conservative for most SNF types. For this analysis, the release fractions recommended in the Modal Study were applied only to commercial pressurized-water reactor SNF and TRIGA SNF, both of which are rod-type fuels. Because of the significant differences in fuel designs and the availability of more appropriate fuel-specific release characterization data, less conservative release fractions were applied to the other representative SNF types.

Release fractions for aluminum fuels (aluminum alloy fuel, aluminum cladding) were based on laboratory measurements of release fractions from aluminum fuels at high temperatures (Shibata et al. 1984) and the U.S. Nuclear Regulatory Commission Modal Study (Fischer et al. 1987). Because of the lower melting point of aluminum compared to metals used in other metallic fuels, the aluminum fuel release fractions are considered bounding for metallic fuels (that is, Savannah River Production Reactor, Hanford N-Reactor, and EBR-II Mark V SNF). Release fractions for the aluminum and other metallic fuel types are listed in Table I-28.

Release fractions for graphite fuels, specifically Fort St. Vrain SNF, were based on engineering analyses. Fort St. Vrain fuel is in the form of carbide particles, encased within a highly retentive four-layer ceramic coating. Stress analysis tests have shown that the fuel particles can withstand stresses well in excess of those that might be encountered in severe accidents. Thermal diffusion across the ceramic barrier under extreme temperature conditions is the only significant mechanism for release of fission products from intact Fort St. Vrain fuel. Fuel particles that have failed during reactor operation (less than 1 percent of the inventory) are vulnerable to vaporization and impact-induced releases of particulates, but volatile fission products would have been released within the extreme thermal environment of the operating reactor. Table I-29 summarizes the release fractions applied to Fort St. Vrain SNF, assuming 1 percent fuel failure during reactor operations.

Table I-27. Release fractions for transportation accidents involving special-case commercial, university, foreign, and non-DOE research reactor spent nuclear fuel types for the U.S. Nuclear Regulatory Commission Modal Study cask response regions.

a. Thermally induced, from NUREG/CR-0722, Table 40, all fuel (Lorenz et al. 1980).

b. Empirical data from the Fort St. Vrain Final Safety Analysis Report, Rev. 8, Table A.3-1 (PSC no date).

c. Thermally induced semivolatiles from incore failed fuel; 1 percent fuel failure, 100 percent respirable; release fraction from Lorenz et al. (1980).

d. Impact induced nonvolatiles, 1 percent incore failed fuel, 5 percent respirable, release fraction of 2 10^-6 from Wilmot (1981).

I-5.3 Results of Calculations

I-5.3.1 Impacts from the No Action Alternative

There are no offsite shipments of DOE, university, foreign, or non-DOE research reactor SNF under this alternative. Consequently, there are no transportation accident impacts. The limited number of naval fuel shipments made under the No Action alternative are covered in Appendix D of Volume 1 of this EIS.

I-5.3.2 Impacts from the Decentralization Alternative

The SNF shipments included under this alternative are those of domestic university, foreign, and non-DOE research reactor SNF to the Idaho National Engineering Laboratory and Savannah River Site. Naval fuel shipments made under different options of the Decentralization alternative are covered in Appendix D of Volume 1 of this EIS. Shipments are expected to be made by truck, but the impact analysis also assessed transportation by rail. The same shipping cask was assumed to be used for both truck and rail shipments, and a single shipping cask was assumed for each shipment.

The cumulative accident risk for transportation by truck was calculated to be 0.0009 latent cancer fatality and 0.15 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0003 latent cancer fatality and 0.21 traffic fatality. Table I-30 summarizes the transportation accident risks for the Decentralization alternative.

As shown in Table I-31, the maximum reasonably foreseeable transportation accident has a probability of occurrence of about 1.6 10-7 per year for a suburban population zone. Under normal (neutral) weather conditions, the total population dose is estimated to be about 14 person-rem, which would be expected to result in less than one latent cancer fatality in the exposed population. For comparison, the same population would be expected to experience about 100,000 latent fatal cancers from other causes. The probability of this accident occurring in an urban population zone, or occurring under stable weather conditions in any population zone, is less than 1 10-7 per year.

I-5.3.3 Impacts from the 1992/1993 Planning Basis Alternative

This alternative includes the transport of five types of SNF. It assumes that the Fort St. Vrain SNF currently in storage in Colorado is transported to the Idaho National Engineering Laboratory. Likewise, special-case commercial SNF currently stored at West Valley is transported to the Idaho National Engineering Laboratory. DOE research and test reactor SNF is transported to either the Idaho National Engineering Laboratory or Savannah River Site, with most going to the Idaho National Engineering Laboratory. Shipments of university, foreign, and non-DOE research reactor SNF are split between the Idaho National Engineering Laboratory and the Savannah River Site. Shipments could be by truck or rail, so the analysis addresses the two extremes of all shipments by truck

Table I-30. SNF transportation accident risks for the Decentralization alternative (1995 to 2035).

Transport mode	Dose risk (person-rem)	Latent cancer fatalities(a)	Traffic fatalities(b)
Truck	1.7	0.0009	0.15
Rail	0.57	0.0003	0.21

a. Estimated number of latent fatal cancers as a result of radiation dose from transportation accidents.

b. Estimated number of fatalities from nonradiological effect of transportation accident, for example, physical impact.

Table I-31. Health effects from maximum reasonably foreseeable offsite SNF transportation accident under the Decentralization alternative (1995 to 2035).

Alternative: Decentralization
Maximum reasonably foreseeable accident: University research reactor SNF shipment by rail
Population zone: Suburbana
Maximum reasonably foreseeable accident probability: 1.6 10-7 per year with neutral meteorology, less than 1 X 10^-7 per year with stable meteorology

Doses and health effects	Transport mode	Population		Maximum exposed individual	
		Neutral(b)	Stable(c)	Neutral(b)	Stable(c)
Dose	Rail	14 person-rem	(e)	0.032 rem	(e)
Latent cancer fatalities(d)	Rail	0.007	(e)	1.6 X 10^-5	(e)

a. The maximum reasonably foreseeable accident occurs in a suburban population zone. The probability of the accident occurring in an urban population zone is less than 1 10-7 per year. In a rural population zone, the dose would be approximately 9 percent of the suburban population dose.

b. Neutral meteorological conditions occur greater than 50 percent of the time.

c. Stable meteorological conditions occur less than 5 percent of the time and result in less atmospheric dispersion of radioactivity released to the atmosphere.

d. Results expressed as the estimated number of latent fatal cancers expected in the impacted population as a result of the radiation dose; for the maximally exposed individual, results express the probability of latent fatal cancer as a result of the radiation dose. Fatal cancer risk factor: 5 10-4 fatal cancers per person-rem (ICRP 1991).

e. Consequences not developed for accidents with probabilities less than 1 10-7 per year.

or all shipments by rail.

The cumulative accident risk for transportation by truck was calculated to be 0.0009 latent cancer fatality and 0.19 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0003 latent cancer fatality and 0.22 traffic fatality. Table I-32 summarizes the transportation accident risks for the 1992/1993 Planning Basis alternative.

The maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The accident has a probability of occurrence of about 2.0 X 10^-7 per year for a suburban population zone. Under normal (neutral) weather conditions, the total population dose is estimated to be about 13,000 person-rem (average dose of 26 millirem per person), which could result in an estimated seven latent fatal cancers in the exposed population. For comparison, the same population would be expected to experience about 100,000 latent fatal cancers from other causes. The probability of this accident occurring in an urban population zone, or occurring under stable weather conditions in any population zone, is less than 1 X 10^-7 per year. Table I-33 summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

I.5.3.4 Impacts from the Regionalization Alternative

This alternative includes Regionalization 4A (by fuel type) and Regionalization 4B (by geography). Under Regionalization by Fuel Type, the same SNF types are transported as in the 1992/1993 Planning Basis alternative with differences occurring in the destinations of some SNF based on fuel type. DOE research and test reactor SNF is transported to either the Idaho National Engineering Laboratory or the Savannah River Site, with most SNF going to the Idaho National Engineering Laboratory. Graphite-type and special-case commercial SNF is transported to the Idaho National Engineering Laboratory. As with the 1992/1993 Planning Basis alternative, shipments could be by truck or rail, and the analysis evaluates impacts assuming either of two extremes: all shipments by truck or all shipments by rail.

Under Regionalization by Fuel Type, the cumulative accident risk for transportation by truck was calculated to be 0.0010 latent cancer fatality and 0.26 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0003 latent

Table I-32. SNF transportation accident risks for the 1992/1993 Planning Basis alternative (1995 to 2035).

Transport mode	Dose risk (person-rem)	Latent cancer fatalities[a]	Traffic fatalities[b]
Truck	1.9	0.0009	0.19
Rail	0.61	0.0003	0.22

a. Estimated number of latent fatal cancers as a result of radiation dose from transportation accidents.

b. Estimated number of fatalities from nonradiological effect of transportation accident, for example, physical impact.

Table I-33. Health effects from maximum reasonably foreseeable offsite SNF transportation accident under the 1992/1993 Planning Basis alternative (1995 to 2035).

Alternative: 1992/1993 Planning Basis

Maximum reasonably foreseeable accident: Special-case commercial SNF shipment by rail
Population zone: Suburbana
Maximum reasonably foreseeable accident probability: 2.0 10-7 per year with neutral meteorology, less than 1.0 X 10^-7 per year with stable meteorology

Doses and health effects	Transport mode	Population		Maximum exposed individual	
		Neutral(b)	Stable(c)	Neutral(b)	Stable(c)
Dose	Rail	13,000 person-rem	(e)	54 rem	(e)
Latent cancer fatalities(d)	Rail	7	(e)	0.027	(e)

---

a. The maximum reasonably foreseeable accident occurs in a suburban population zone. The probability of the accident occurring in an urban population zone is less than 1 X 10^-7 per year. In a rural population zone, the dose would be approximately 3 percent of the suburban population dose.

b. Neutral meteorological conditions occur greater than 50 percent of the time.

c. Stable meteorological conditions occur less than 5 percent of the time and result in less atmospheric dispersion of radioactivity released to the atmosphere.

d. Results expressed as the estimated number of latent fatal cancers expected in the impacted population as a result of the radiation dose; for the maximally exposed individual, results express the probability of contracting fatal cancer as a result of the radiation dose. Fatal cancer risk factor: 5 X 10^-4 fatal cancers per person-rem (ICRP 1991).

e. Consequences not developed for accidents with probabilities less than 1 X 10^-7 per year.

cancer fatality and 0.25 traffic fatality. Table I-34 summarizes the transportation accident risk for the Regionalization by Fuel Type.

As in the 1992/1993 Planning Basis alternative, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The accident has a probability of occurrence of about 2.8 10-7 per year for a suburban population zone. The consequences under normal (neutral) weather conditions are the same as those described under the 1992/1993 Planning Basis alternative. Table I-35 summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

The maximum reasonably foreseeable accident under stable weather conditions has a probability less than 1 X 10^-7 per year for all population zones except rural. A total population dose of 3,500 person-rem was estimated for the rural population zone (average dose of 2 rem per person), which could result in an estimated two latent fatal cancers in the exposed population. For comparison, the same population would be expected to experience about 350 latent fatal cancers from other causes.

The Regionalization by Geography alternative contains six separate alternatives, and the transportation impacts of each option have been analyzed for comparison. Under this alternative, the same SNF types are transported as under the 1992/1993 Planning Basis alternative with differences occurring in the destinations of the SNF based on geographical considerations. Non-Navy SNF originating from western United States locations or points of entry would be transported to the Idaho National Engineering Laboratory, Hanford Site, or the Nevada Test Site. Non-Navy SNF originating from eastern United States locations or points of entry would be transported to the Savannah River Site or the Oak Ridge Reservation.

Navy SNF would not be split on an east-west basis because the Navy would operate a facility for examining naval SNF at only one of the DOE sites.

Cumulative accident risks for transportation by truck range from 0.0009 latent cancer fatality and 0.21 traffic fatality for Regionalization at the Idaho National Engineering Laboratory and the Savannah River Site, to 0.0011 latent cancer fatality and 0.39 traffic fatality for Regionalization at the Nevada Test Site and the Oak Ridge Reservation. Cumulative accident risks for transportation by rail range from 0.0002 latent cancer fatality and 0.21 traffic fatality for Regionalization at the Idaho National Engineering Laboratory and the Oak Ridge Reservation to 0.0003 latent cancer fatality and 0.30 traffic fatality for Regionalization at the Nevada Test Site and the Savannah River Site.

As in Regionalization by Fuel Type, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The consequences of the maximum reasonably foreseeable accident are the same for each of the six Regionalization by Geography alternatives. The maximum reasonably foreseeable accident under neutral weather conditions occurs in a suburban population zone because the accident probability for an urban

Table I-34. SNF transportation accident risks for Regionalization by Fuel Type (1995-2035).

b. Estimated number of fatalities from nonradiological effect of transportation accident, for example, physical impact.

Table I-35. Health effects from maximum reasonably foreseeable offsite SNF transportation accident under Regionalization by Fuel Type (1995 to 2035).

Alternative: Regionalization by Fuel Type
Maximum reasonably foreseeable accident: Special-case commercial SNF shipment by rail
Population zone: Suburban (neutral) and rural (stable)a
Maximum reasonably foreseeable accident probability: 2.8 X 10^-7 per year with neutral meteorology; 1.1 X 10^-7 per year with stable meteorology

Doses and health effects	Transport mode	Population		Maximum exposed individual	
		Neutral(b)	Stable(c)	Neutral(b)	Stable(c)
Dose	Rail	13,000 person-rem	3,500 person-rem	54 rem	180 rem
Latent cancer fatalities(d)	Rail	7	2	0.027	0.09

a. The maximum reasonably foreseeable accident occurs in a suburban population zone under neutral weather conditions. The accident probability is less than 1 X 10^-7 per year under stable weather conditions, except in a rural population zone. For urban population zones, the accident probability is less than 1 X 10^-7 per year for both neutral and stable weather conditions.

b. Neutral meteorological conditions occur greater than 50 percent of the time.

c. Stable meteorological conditions occur less than 5 percent of the time and result in less atmospheric dispersion of radioactivity released to the atmosphere.

d. Results expressed as the estimated number of latent fatal cancers expected in the impacted population as a result of the radiation dose; for the maximally exposed individual, results express the probability of contracting fatal cancer as a result of the radiation dose. Fatal cancer risk factor: 5 X 10^-4 fatal cancers per person-rem (ICRP 1991).

---

population zone is less than 1 10-7 per year. The total population dose is estimated to be about 13,000 person-rem (average dose of 26 millirem per person), which could result in an estimated seven latent fatal cancers in the exposed population. For comparison, the same population would be expected to experience about 100,000 latent fatal cancers from other causes.

The probability of the maximum reasonably foreseeable transportation accident varies slightly among the six Regionalization by Geography alternatives. The maximum reasonably foreseeable accident in a suburban population zone has an estimated probability of occurrence ranging from about 2.7 X 10^-7 per year for Regionalization at the Hanford Site and Savannah River Site, to about 3.7 X 10^-7 per year for Regionalization at the Nevada Test Site and Savannah River Site. The maximum reasonably foreseeable accident in a rural population zone has an estimated probability of occurrence ranging from about 1.5 X 10^-7 per year for Regionalization at the Hanford Site and Savannah River Site, to about 3.3 X 10^-7 per year for Regionalization at the Nevada Test Site and Oak Ridge Reservation.

Tables I-36 through I-47 summarize the doses and health effects from the accident risk assessment and the maximum reasonably foreseeable consequence assessment for each of the Regionalization by Geography alternatives.

I-5.3.5 Impacts from the Centralization Alternatives

The impacts from centralization at the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and the Nevada Test Site are presented in this section.

I-5.3.5.1 Centralization at the Hanford Site. Under this alternative, SNF currently stored at

other DOE sites, Fort St. Vrain, university, foreign, and non-DOE research reactors is eventually transported to the Hanford Site. The analysis evaluates impacts assuming either all shipments by truck or all shipments by rail.

The cumulative accident risk for transportation by truck was calculated to be 0.0050 latent cancer fatality and 0.57 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0013 latent cancer fatality and 0.52 traffic fatality. Table I-48 summarizes the transportation accident risks for the Centralization at the Hanford Site alternative.

As in the 1992/1993 Planning Basis and Regionalization alternatives, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The accident has a probability of occurrence of about 5.1 10-7 per year under neutral (normal) weather conditions and 3.6 X 10^-7 per year under stable (worst-case) weather conditions. The consequences are the same as those described under the Regionalization by Geography alternative. Table I-49

summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

I-5.3.5.2 Centralization at the Idaho National Engineering Laboratory. Under this

alternative, all SNF currently stored at other DOE sites, Fort St. Vrain, and university, foreign, and non-DOE research reactors is eventually transported to the Idaho National Engineering Laboratory. The analysis evaluates impacts assuming either all shipments by truck or all shipments by rail.

The cumulative accident risk for transportation by truck was calculated to be 0.0048 latent cancer fatality and 0.49 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0012 latent cancer fatality and 0.44 traffic fatality. Table I-50 summarizes the transportation accident risks for the Centralization at the Idaho National Engineering Laboratory alternative.

As in the 1992/1993 Planning Basis and Regionalization 4A and 4B alternatives, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The accident has a probability of occurring of about 4.7 X 10^-7 per year under neutral (normal) weather conditions and about 3.3 X 10^-7 per year under stable (worst-case) weather conditions. The consequences are the same as those described under Regionalization by Geography alternative. Table I-51 summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

I-5.3.5.3 Centralization at Savannah River Site. Under this alternative, SNF currently stored

at other DOE sites, Fort St. Vrain, university, foreign, and non-DOE research reactors is eventually transported to the Savannah River Site. The analysis evaluates impacts assuming either all shipments by truck or all shipments by rail.

The cumulative accident risk for transportation by truck was calculated to be 0.0016 latent cancer fatality and 0.84 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0004 latent cancer fatality and 0.49 traffic fatality. Table I-52 summarizes the transportation accident risks for the Centralization at Savannah River Site alternative.

As in the 1992/1993 Planning Basis and Regionalization alternatives, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The maximum reasonably foreseeable accident under neutral (normal) weather conditions occurs in an urban population zone and has a probability of occurrence of about 1.7 X 10^-7 per year. A total population dose of 72,000 person-rem was estimated (average dose of 27 millirem per person), which

Maximum reasonably foreseeable accident probability: 4.7 X 10^-7 per year with neutral meteorology, 3.3 X 10^-7 per year with stable meteorology

Doses and health effects	Transport mode	Population(a)		Maximum exposed individual	
		Neutral(b)	Stable(c)	Neutral(b)	Stable(c)
Dose	Rail	13,000 person-rem	3,500 person-rem	54 rem	180 rem
Latent cancer facilitiesd	Rail	7	2	0.027	0.09

a. The maximum reasonably foreseeable accident occurs in a suburban population zone under neutral weather conditions. The accident probability is less than 1 X 10^-7 per year under stable weather conditions, except in a rural population zone. For urban population zones, the accident probability is less than 1 X 10^-7 per year for both neutral and stable weather conditions.

b. Neutral meteorological conditions occur greater than 50 percent of the time.

c. Stable meteorological conditions occur less than 5 percent of the time and result in less atmospheric dispersion of radioactivity released to the atmosphere.

d. Results expressed as the estimated number of latent fatal cancers expected in the impacted population as a result of the radiation dose; for the maximally exposed individual, results express the probability of contracting fatal cancer as a result of the radiation dose. Fatal cancer risk factor: 5 X 10^-4 fatal cancers per person-rem (ICRP 1991).

---

could result in an estimated 36 latent cancer fatalities. For comparison, the same population would be expected to experience about 540,000 latent cancer fatalities from other causes.

The maximum reasonably foreseeable accident under stable (worst-case) weather conditions occurs in a suburban population zone and has a probability of occurring of about 1.2 10-7 per year. A total population dose of 110,000 person-rem was estimated (average dose of 0.53 rem per person), which could result in an estimated 55 latent cancer fatalities. For comparison, the same population would be expected to experience about 42,000 latent cancer fatalities from other causes.

Table I-53 summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

I-5.3.5.4 Centralization at Oak Ridge Reservation. Under this alternative, SNF currently

stored at other DOE sites, Fort St. Vrain, university, foreign, and non-DOE research reactors is eventually transported to the Oak Ridge Reservation. The analysis evaluates impacts assuming either all shipments by truck or all shipments by rail.

The cumulative accident risk for transportation by truck was calculated to be 0.0014 latent cancer fatality and 0.78 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0003 latent cancer fatality and 0.43 traffic fatality. Table I-54 summarizes the transportation accident risks for the Centralization at Oak Ridge Reservation alternative.

As in the 1992/1993 Planning Basis and Regionalization alternatives, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The maximum reasonably foreseeable accident under neutral (normal) weather conditions occurs in an urban population zone and has a probability of occurring of about 1.1 10-7 per year. The accident consequences are the same as those described for the urban zone accident under the Centralization at Savannah River Site alternative.

The maximum reasonably foreseeable accident under stable (worst-case) weather conditions occurs in a rural population zone and has a probability of occurring of about 5.7 10-7 per year. The accident consequences are the same as those described for the rural zone accident under the Regionalization by Geography alternative.

Table I-55 summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

Table I-52. SNF transportation accident risks for the Centralization at the Savannah River Site alternative (1995 to 2035).

Transport mode	Dose Risk (person-rem)	Latent cancer fatalities(a)	Traffic fatalities(b)

b. Estimated number of fatalities from nonradiological effect of transportation accident, for example, physical impact.

Table I-55. Health effects from maximum reasonably foreseeable offsite SNF transportation accident under the Centralization at the Oak Ridge Reservation alternative (1995 to 2035).

Alternative: Centralization at the Oak Ridge Reservation
Maximum reasonably foreseeable accident: Special-case commercial SNF shipment by rail
Population zone: Urban (neutral) and rural (stable)a
Maximum reasonably foreseeable accident probability: 1.1 X 10^-7 per year with neutral meteorology, 5.7 X 10^-7 per year with stable meteorology

Doses and health effects	Transport mode	Population(a)		Maximum exposed individual	
		Neutral(b)	Stable(c)	Neutral(b)	Stable(c)
Dose	Rail	72,000 person-rem	3,500 person-rem	54 rem	180 rem
Latent cancer fatalities(d)	Rail	36	2	0.027	0.09

a. The maximum reasonably foreseeable accident occurs in an urban population zone under neutral weather conditions. The accident probability under stable weather conditions is less than 1 X 10^-7 per year, except in a rural population zone.

b. Neutral meteorological conditions occur greater than 50 percent of the time.

c. Stable meteorological conditions occur less than 5 percent of the time and result in less atmospheric dispersion of radioactivity released to the atmosphere.

d. Results expressed as the estimated number of latent fatal cancers expected in the impacted population as a result of the radiation dose; for the maximally exposed individual, results express the probability of contracting fatal cancer as a result of the radiation dose. Fatal cancer risk factor: 5 X 10^-4 fatal cancers per person-rem (ICRP 1991).

I-5.3.5.5 Centralization at Nevada Test Site. Under this alternative, SNF currently

stored at other DOE sites, Fort St. Vrain, university, foreign, and non-DOE research reactors is eventually transported to the Nevada Test Site. The analysis evaluates impacts assuming either all shipments by truck or all shipments by rail.

The cumulative accident risk for transportation by truck was calculated to be 0.0050 latent cancer fatality and 0.72 traffic fatality. The cumulative accident risk measures the total impact of transportation accidents over the entire shipment campaign (1995 to 2035). The cumulative accident risk for transportation by rail was calculated to be 0.0012 latent cancer fatality and 0.58 traffic fatality. Table I-56 summarizes the transportation accident risks for the Centralization at Nevada Test Site alternative.

As in the 1992/1993 Planning Basis and Regionalization alternatives, the maximum reasonably foreseeable transportation accident involves a rail shipment of special-case commercial SNF. The accident has a probability of occurring of about 1.0 10-7 per year under neutral (normal) weather conditions in a suburban population zone and about 5.0 10-7 per year under stable (worst-case) weather conditions in a rural population zone. The consequences are the same as those described under the Regionalization by Geography alternative. Table I-57 summarizes the doses and health effects from the maximum reasonably foreseeable consequence assessment.

I-5.3.6 Impacts of Using Alternate Points of Entry for Foreign Research Reactor Spent

Nuclear Fuel Shipments

For transportation accident risks (radiological and vehicle-related), shipments from Jacksonville, Florida, to the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site would yield lower impacts than shipments from Charleston, South Carolina, Galveston, Texas, Hampton Roads, Virginia, Savannah, Georgia, and the Military Ocean Terminal, Sunny Point, North Carolina, to these same sites. Shipments from Wilmington, North Carolina, to the Savannah River Site and Oak Ridge Reservation would also yield lower impacts than shipments from Charleston, South Carolina, Galveston, Texas, Hampton Roads, Virginia, Savannah, Georgia, and the Military Ocean Terminal Sunny Point, North Carolina, to these same sites. Shipments from Wilmington, North Carolina, to the Hanford Site, Idaho National Engineering Laboratory, and Nevada Test Site would yield slightly higher impacts (about 6 percent) than shipments from Charleston, South Carolina, Galveston, Texas, Hampton Roads, Virginia, Savannah, Georgia, and the Military Ocean Terminal, Sunny Point, North Carolina, to these same sites.

Table I-56. SNF transportation accident risks for the Centralization at the Nevada Test Site alternative (1995 to 2035).

Latent cancer fatalities[d]	Rail	36	2	0.027	0.09

---

a. The maximum reasonably foreseeable accident occurs in an urban population zone under neutral weather conditions. The accident probability is less than 1 X 10^-7 per year under stable weather conditions, except in a rural population zone.

b. Neutral meteorological conditions occur greater than 50 percent of the time.

c. Stable meteorological conditions occur less than 5 percent of the time and result in less atmospheric dispersion of radioactivity released to the atmosphere.

d. Results expressed as the estimated number of latent fatal cancers expected in the impacted population as a result of the radiation dose; for the maximally exposed individual, results express the probability of contracting fatal cancer as a result of the radiation dose. Fatal cancer risk factor: 5 X 10^-4 fatal cancers per person-rem (ICRP 1991).

I-6 POTENTIAL MITIGATION MEASURES

The possible impacts from transportation associated with the alternatives could be mitigated in a number of different ways. For example, the routes used for truck shipments could be chosen using

U.S. Department of Transportation routing guidelines. These guidelines are designed to reduce the radiological impacts associated with transportation. The guidelines consider as primary factors (a) the radiation exposure from incident-free transport, (b) the risk to general population from an accidental release of radioactive material, and (c) the economic risk from an accidental release of radioactive material. The guidelines consider as secondary factors (a) emergency response effectiveness, (b) evacuation capabilities, (c) location of special facilities such as schools or hospitals, and (d) traffic fatalities and injuries unrelated to the radioactive nature of the cargo.

Impact mitigation is also provided through the use of approved shipping containers. For shipments containing large amounts of radioactivity, such as SNF, Type B containers will be used. These containers are designed to withstand normal transport conditions and hypothetical accident conditions.

If an accident did occur, Federal, state, local, and Tribal authorities are trained in emergency response. For example, the Shoshone-Bannock Tribes, the State of Idaho, Bingham County, Bingham Memorial Hospital, Bannock Regional Medical Center, Pocatello Regional Medical Center, Idaho Power Company, Intermountain Gas Company, and the U.S. Department of Energy participated in a comprehensive, cooperative Transportation Accident Exercise held in Idaho in 1992 (TRANSAX '92).

The U.S. Environmental Protection Agency has developed protective action guides (EPA 1991) and protective actions that are designed to limit doses in the event of a nuclear incident. Use of these guides and actions also mitigates the impacts of transportation accidents involving radioactive material.

I-7 SPENT NUCLEAR FUEL TRANSPORTATION BY BARGE

As an alternative to truck or rail transport of SNF, barge transport of 71 SNF shipments from Brookhaven National Laboratory, located on Long Island, New York, to the Savannah River Site was evaluated. This section summarizes the impacts from transporting the 71 shipments from Brookhaven National Laboratory to the Savannah River Site.

I-7.1 Transportation Routes

Several routing options were evaluated for the barge shipments from Brookhaven National Laboratory to the Savannah River Site:

- Truck transport from Brookhaven National Laboratory to the Shoreham, New York, dock or Port Jefferson, New York. Shoreham and Port Jefferson are both located on Long Island near Brookhaven National Laboratory.
- Barge transport from Shoreham or Port Jefferson, New York, to Hampton Roads, Virginia; the Military Ocean Terminal, Sunny Point, North Carolina; Charleston, South Carolina; Savannah, Georgia; or directly to the Savannah River Site.
- Truck transport from Hampton Roads, Virginia; the Military Ocean Terminal, Sunny Point, North Carolina; Charleston, South Carolina; or Savannah, Georgia to the Savannah River Site.

The HIGHWAY computer code (Johnson et al. 1993a) was used to estimate the truck routes and the INTERLINE computer code (Johnson et al. 1993b) was used to estimate the barge routes. The truck and barge routes are summarized in Pippen (1995).

I-7.2 Incident-Free Transportation

Incident-free transportation assessments were conducted for barge shipments from Brookhaven National Laboratory to the Savannah River Site and included transport by truck, transport by barge, and intermodal transfers (e.g., truck to barge and barge to truck transfers). The methods and data used to estimate the radiological and nonradiological impacts of these shipments are discussed in Pippen (1995).

For barge shipments using the Shoreham, New York, dock as a point of departure from Long Island, the cumulative number of total fatalities (radiological plus nonradiological fatalities) ranged from 0.0048 to 0.0092. The lower number of fatalities was estimated when the barge shipments were made directly to the Savannah River Site. The larger number of fatalities was estimated when the barge shipments were made from Brookhaven National Laboratory to Shoreham, New York, to Hampton Roads, Virginia, to the Savannah River Site.

For barge shipments using Port Jefferson, New York, as a point of departure from Long Island, the cumulative number of total fatalities (radiological plus nonradiological fatalities) ranged from 0.0052 to 0.0093. The lower number of fatalities was estimated when the barge shipments were made directly to the Savannah River Site. The larger number of fatalities was estimated when the barge shipments were made from Brookhaven National Laboratory to Port Jefferson to Hampton Roads, Virginia, to the Savannah River Site.

I-7.3 Transportation Accidents

Transportation accident assessments were conducted for barge shipments from Brookhaven National Laboratory to the Savannah River Site. These assessments included evaluations of accident risks (both radiological risks and traffic fatalities) and accident consequences. The methods and data used to estimate the accident risks and consequences of these shipments are discussed in Pippen (1995).

For barge shipments using the Shoreham, New York, dock as a point of departure from Long Island, the cumulative accident risk (radiological plus nonradiological fatalities) ranged from 0.0011 to 0.0019. The lower number of fatalities was estimated when the barge shipments were made directly to the Savannah River Site. The larger number of fatalities was estimated when the barge shipments were made from Brookhaven National Laboratory to Shoreham, New York, to Hampton Roads, Virginia, to the Savannah River Site.

For barge shipments using Port Jefferson, New York, as a point of departure from Long Island, the cumulative accident risk (radiological plus nonradiological fatalities) ranged from 0.00087 to 0.0018. The lower number of fatalities was estimated when the barge shipments were made directly to the Savannah River Site. The larger number of fatalities was estimated when the barge shipments were made from Brookhaven National Laboratory to Shoreham, New York, to Hampton Roads, Virginia, to the Savannah River Site.

The consequences of the maximum reasonably foreseeable accident for barge shipments were less than the consequences of the maximum reasonably foreseeable accident for truck shipments, as discussed in Section I-5. This was because the barge routes are further from populations than truck routes.

I-8 TRANSPORTATION IMPACTS OF FOREIGN PROCESSING OF SPENT NUCLEAR FUEL CURRENTLY LOCATED AT THE HANFORD SITE

This section summarizes the transportation impacts of processing the Hanford Site N-Reactor SNF at a foreign processing facility. The detailed assessment of this transportation option, including a description of the foreign processing option and the methods and assumptions used in the analysis, is contained in Volume 1, Appendix A, Attachment B of this EIS.

I-8.1 Radiological Dose to Workers

This subsection describes expected radiological consequences to workers during transportation of N-Reactor SNF currently stored at the Hanford Site. The transportation analysis included shipment from the Hanford Site to representative West and East Coast points of entry (Portland, Oregon; Seattle, Washington; and Norfolk, Virginia) followed by overseas transport to a representative commercial processing facility in the United Kingdom. Overland shipment by barge, truck, or rail was considered as appropriate for each point of entry.

I-8.1.1 Worker Dose from Shipment Preparation Activities at the Hanford Site

Packaging of the K Basin fuel for overseas shipment was estimated to result in worker doses of approximately 140 person-rem (5.5   10-2 latent cancer fatalities) over a period of approximately 2 years. However, if stabilization of the fuel before transport were necessary, an additional 180 person-rem might be accumulated by onsite workers over a 4-year period, resulting in 7.0 10-2 latent cancer fatalities. Consequences of fuel-handling accidents of the K basins are addressed in Volume 1, Appendix A.

I.8.1.2 Worker Doses from Transportation

Collective worker impacts from incident-free transportation were estimated to range from 1.3 X 10^-3 latent cancer fatalities for barge transportation between the Hanford Site and the point of entry at Portland, Oregon, to 4.3 X 10^-2 latent cancer fatalities for the option of transport by truck between the Hanford Site and the point of entry at Norfolk, Virginia. These impacts account for transport of SNF leaving the Hanford Site as well as the return transport of high-level waste, plutonium oxide, and uranium oxide.

Radiological consequences to workers from activities at the point of entry for transport of SNF to the United Kingdom were evaluated based on commercial experience during the last 9 months of 1994.

The consequences for loading and unloading 408 casks during shipment from the United States to the United Kingdom were estimated to be approximately 1.2 person-rem to all workers over the expected 5-year campaign. An additional two fuel-handling activities per cask at the Hanford Site and at the United Kingdom process facility would approximately double that estimate, resulting in a collective dose of 2.4 person-rem and a potential for 9.8 X 10^-4 latent cancer fatalities for all shipments. The maximum dose to an individual worker, assuming that worker was involved in handling all 408 casks at one point in the shipping sequence, would be approximately 0.4 rem over 5 years.

The consequences to a nearby worker were evaluated for accidents at, or on the approach to, the representative points of entry considered in the overland transportation analysis. In addition, the point of entry at Newark, New Jersey, was included in this part of the analysis because of its large surrounding population (it is adjacent to New York City) whereas the other points of entry are located in smaller population centers. The consequences of the maximum reasonably foreseeable accident (frequency >1 10-7 per year) to a worker at a distance of 100 meters (328 feet) ranged from 1.7 rem (6.8 10-4 latent cancer fatalities) at Seattle/Tacoma, Washington, to 2.1 rem (8.4 10-4 latent cancer fatalities) at Portland, Oregon, or Norfolk, Virginia. The corresponding total risks from accidents of all severity categories for 17 SNF shipments were 8.0 x 10^-9 latent cancer fatalities at Seattle/Tacoma to 1.0 10-8 latent cancer fatalities at Norfolk or Portland.

Radiological consequences were estimated for workers as a result of normal transport operations and accidents during overseas shipments of SNF from the Hanford Site to the United Kingdom. The primary impact of routine (incident-free) marine transport of SNF would be potential radiological exposure to crew members of the ships used to carry the casks. While at sea, the crew dose would be limited to those individuals who may enter the ship's hold during transit and receive external radiation in the vicinity of the packaged fuel. The consequences to crew members would depend on the duration of the voyage and the time spent inspecting each cask. Assuming surface dose rates at the regulatory limit, the collective dose to the inspection crew from all SNF shipments could range from 2.4 to 12 person-rem, depending on the routing. Return shipments of high-level waste, uranium, and plutonium would result in lower doses to the crew. All doses to individual crew members would be within administrative control and regulatory limits for radiation workers. Actual commercial experience indicates that worker consequences could be much lower than these bounding estimates.

The consequences of accidents during ocean transit would likely be similar to those of point of entry workers who are near the scene of an accident. Individuals in the immediate vicinity of the impact would probably not survive an accident severe enough to release radioactive materials from a SNF shipping cask. Effects on the ocean environment would not be expected to be discernable because of dispersion during an airborne release.

The frequency of accidents on the open ocean was estimated to be 4.6 X 10^-5 for an average duration voyage of approximately 20 days to transport SNF from foreign research reactors to the United States. The frequency of accidents for overseas shipment of SNF and process materials via ships built for this purpose would likely be within a factor of 2 or 3 of this estimate.

I-8.2 Consequences to Members of the Public

This subsection describes expected consequences to the public from activities required to transport N-Reactor SNF to the United Kingdom.

I-8.2.1 Public Impacts from Shipment Preparation Activities at the Hanford Site

Activities at the Hanford Site before and during preparation for shipment of N-Reactor SNF would result in generally small consequences to the public, as discussed in Volume 1, Appendix A, of this EIS. Removal and packaging of SNF at the K Basins was estimated to result in offsite consequences comparable to those observed during initial segregation of the fuel, or less than 3 X 10^-7 rem (1.5 X 10^-10 probability of latent cancer fatalities) to the maximally exposed offsite individual. The risk from accidents involving handling of N-Reactor fuel at the K Basins is presented in Volume 1, Appendix A, of this EIS.

I-8.2.2 Public Impacts from Transportation Activities

Members of the public exposed to radiation during transportation include persons on the highway, railroad, or waterway with the shipment; persons residing near these transport links; and persons at intermediate stops along the route (such as refueling stops and stops at rail classification yards).

Public impacts from incident-free transportation include radiological impacts from direct radiation as well as nonradiological impacts from vehicle emissions. Radiological impacts from incident-free transportation were estimated to range from 2.1 X 10^-4 latent cancer fatalities for barge transportation between the Hanford Site and the point of entry at Portland, Oregon, to 1.3 X 10^-1 latent cancer fatalities for the option of transport by truck between the Hanford Site and the point of entry at Norfolk, Virginia. Nonradiological impacts from incident-free transportation were estimated to range from 1.2 X 10^-3 latent cancer fatalities for the option of truck transport from the Hanford Site to the point of entry at Seattle/Tacoma, Washington, to 1.6 X 10^-2 latent cancer fatalities for the option of truck transport from the Hanford Site to the point of entry at Norfolk, Virginia.

Public impacts from potential transportation accidents include radiological risks from radioactive materials that could be released to the environment as well as nonradiological risks associated with traffic accidents (i.e., vehicle collisions). Cumulative radiological transportation accident risks range from 1.8 X 10^-6 latent cancer fatalities for the option of rail transport between the Hanford Site and the point of entry at Seattle/Tacoma, Washington, to 4.2 X 10^-5 latent cancer fatalities for either truck or rail transport between the Hanford Site and the point of entry at Norfolk, Virginia. Traffic accident risks range from 8.9 X 10^-3 fatalities for the option of truck transport between the Hanford Site and the point of entry at Seattle/Tacoma, Washington, to 1.3 X 10^-1 fatalities for the option of truck transport between the Hanford Site and the point of entry at Norfolk, Virginia.

The maximum reasonably foreseeable transportation accident involves a return shipment of high-level waste transported by rail from the point of entry at Seattle/Tacoma, Washington, to the Hanford Site. If this accident were to occur in an urban population zone, it could result in an estimated one latent cancer fatality within the affected population. The probability of this accident is about 1.3 X 10^-7 per year.

Normal port activities during transport of N-Reactor SNF are not expected to have any consequences for members of the public other than point of entry workers. The consequences to the public from accidents during point of entry transit were estimated using the same assumptions as for worker consequences. The highest risk to the public from point of entry activities was estimated to result from accidents at the dock. Under stable atmospheric dispersion conditions, the maximum risk to the public was estimated to be 8.4 X 10^-5 latent cancer fatalities. The maximum foreseeable accident resulted in an estimated 380 latent cancer fatalities in the population within 80 kilometers (50 miles) of Newark, New Jersey. The estimated frequency of this accident was 2.2 X 10^-7 for 17 overseas shipments of SNF.

There is not expected to be any dose to members of the public or marine life resulting from incident-free ocean transport of N-Reactor SNF to the United Kingdom. The effects of losing a cask at sea are estimated to be comparable to those evaluated for transporting foreign research reactor SNF to the United States based on similar shipping inventories of long-lived radionuclides per cask. The maximum dose to an individual for a cask lost in coastal waters was expected to be 11 millirem per year if the cask was left in place until all its contents dispersed. The corresponding consequences to marine biota were 0.24 millirad per year for fish, 0.32 millirad per year for crustaceans, and 13 millirad per year for mollusks. The consequences resulting from loss of a cask in the deep ocean would be many orders of magnitude lower than the estimates for coastal waters.

I-9 HISTORICAL SPENT NUCLEAR FUEL TRANSPORTATION ACCIDENTS

Transportation incidents for 1949 through 1970 were surveyed using summary reports prepared by the U.S. Atomic Energy Agency (AEC 1957, Patterson and DeFatta 1962, Patterson and Mehn 1963, AEC 1966, McCluggage 1971). In these summary reports, incidents are classified into six classes based on the extent of radioactive material release (Patterson and DeFatta 1962) and accidents and incidents are not differentiated. For 1949 through 1970, there were 14 incidents involving irradiated fuel elements. No packages approximating a Type B shipping cask were breached as a result of these incidents (McCluggage 1971). Two representative incidents are summarized below.

On November 15, 1960, a tractor-trailer carrying 7 steel-jacketed lead casks containing 25 irradiated fuel elements was involved in an accident with a station wagon. The station wagon was completely demolished and the driver killed. The tractor was badly damaged and the driver suffered a broken hand and abrasions. The irradiated fuel elements were undisturbed. This incident was classified as a Class I radiation release, which means that no radioactive material was released and there was no loss of integrity to the package.

In another case (June 2-6, 1960), leakage of contaminated cooling water from a rail shipment consisting of irradiated fuel elements and some ruptured elements in aluminum cans resulted in contamination of three railroad yards. This incident was classified as a Class IV radiation release, which means that radioactive material was released to the ground or trafficway with no runoff or aerial dispersion. There were no injuries associated with this incident.

Spent nuclear fuel transportation accidents for 1971 through 1993 were surveyed based on data in the Radioactive Materials Incident Report database. This database contains information on radioactive materials transportation incidents and accidents from the U.S. Department of Transportation, U.S. Nuclear Regulatory Commission, U.S. Department of Energy, state radiation control offices, and media coverage of radioactive materials transportation incidents and accidents (Cashwell and McClure 1992). The Radioactive Materials Incident Report database contains information on transportation accidents, handling accidents, and reported incidents; this discussion is limited to transportation accidents involving SNF.

Between 1971 and 1993, there were seven transportation accidents involving SNF. Three of these accidents involved rail shipments, and four of these accidents involved truck shipments. These accidents were summarized in Cashwell and McClure (1992). Only one of these accidents resulted in more than minor damage to the SNF cask. On December 8, 1971, a truck transporting a SNF element in a Type B shipping cask on U.S. Highway 25 in Tennessee swerved to avoid a head-on collision with another vehicle and was forced off the road. The driver of the truck was killed by the impact and the SNF cask was thrown into a ditch. The DOE Radiological Assistance Team from Oak Ridge, Tennessee, arrived and surveys indicated that the structural integrity of the cask was intact and there was no release of contents.

I-10 CUMULATIVE IMPACTS OF TRANSPORTATION

I-10.1 Radiological Impacts

The cumulative impacts of the transportation of SNF consist of impacts from (a) historical shipments of SNF to the Hanford Site, Savannah River Site, Idaho National Engineering Laboratory, Oak Ridge Reservation, and the Nevada Test Site; (b) the alternatives evaluated in this EIS; (c) other reasonably foreseeable actions that include transportation of radioactive material; and (d) general radioactive materials transportation that is not related to a particular action. The discussion of cumulative transportation impacts concentrates on the cumulative impacts of offsite transportation, because offsite transportation yields potential doses to a greater portion of the general population than does onsite transportation. The collective dose to the general population and workers is the measure used to quantify cumulative transportation impacts. This measure of impact was chosen because it can be directly related to latent cancer fatalities using a cancer risk coefficient and because of the difficulty in identifying a maximally exposed individual for shipments throughout the United States spanning the period 1943 through 2035 (93 years).

Collective doses from historical shipments of SNF to the Hanford Site, Savannah River Site, Oak Ridge Reservation, and the Nevada Test Site were summarized in Jones and Maheras (1994a, 1994b, 1994c, 1994d). Data for these shipments were available for 1971 through 1993 and were linearly extrapolated back to the start of operations at each site because data before 1971 were not available. For the Hanford Site and Oak Ridge Reservation, the start of operations was 1943; for the Savannah River Site, the start of operations was 1953; and for the Nevada Test Site, the start of operations was 1951. The results of these analyses are summarized in Table I-58.

The historical shipments of SNF to the Idaho National Engineering Laboratory consisted of shipments of naval SNF and test specimens from 1957 through 1995 (see Attachment A to Appendix D of Volume 1 of this EIS). Extrapolation of naval shipments was not necessary because a detailed records search accounted for all shipments. Historical SNF also consisted of shipments of other DOE SNF to the Idaho National Engineering Laboratory besides naval shipments, such as research reactor SNF and special-case commercial SNF (Maheras 1994). Data for these shipments were available for 1973 through 1993 and were linearly extrapolated back to 1953, the start of operations at the Idaho Chemical Processing Plant, because data for 1953 through 1972 were not available. The results of these analyses are also summarized in Table I-58.

There are considerable uncertainties in these historical estimates of collective dose. For example, the population densities and transportation routes used in the dose assessments were based on census data for 1990 and the United States highway and rail system as it existed in 1993.

Table I-58. Cumulative transportation-related radiological collective doses and latent cancer fatalities (1943 to 2035).

Category	Collective occupational dose (person-rem)	Collective general population dose (person-rem)
Historical spent nuclear fuel		
Hanford Site (1943 to 1993)	52	27
Savannah River Site (1953 to 1993)	50	29
Idaho National Engineering Laboratory (1953 to 1993)		
DOE spent nuclear fuel	56	30
Naval spent nuclear fuel	62	1.6
Oak Ridge Reservation (1943 to 1993)	35	18
Nevada Test Site(a) (1951 to 1993)	1.4	0.70
Spent nuclear fuel shipments for Alternatives 1-5		
Naval(b)	1.5 to 15	0.34 to 12
DOE truck (100%)(c) (1995 to 2035)	0.0 to 1,000	0.0 to 2,300
DOE train (100%)(c) (1995 to 2035)	0.0 to 130	0.0 to 170
Reasonably foreseeable actions		
Geologic repository(c,d)		
Truck (100%)	8,600	48,000
Train (100%)	750	740
Waste Isolation Pilot Plante		
Test phase (100% truck)	110	48
Disposal phase		
Truck (100%)	1,800	1,500
Train (maximum)(f)	68	940
Submarine reactor compartment disposalg	--	0.053
Return of cesium-137 isotope capsulesh	0.42	5.7
Uranium billets(i)	0.50	0.014
General transportation		
1943 to 1982	220,000	170,000
1983 to 2035	89,000	98,000
Summary		
Historical	200	110
Spent nuclear fuel shipments for Alternatives 1-5		
Truck	1.5 to 1,000	0.34 to 2,400
Train	1.5 to 150	0.34 to 190
Reasonably foreseeable actions		
Truck	11,000	50,000

Train	820	1700
General transportation (1943 to 2035)	310,000	270,000
Total collective dose	320,000	320,000
Total latent cancer fatalities	130	160

---

a. Shipments from Turkey Point Power Plant in Florida to the Engine Maintenance, Assembly, and Disassembly Facility at the Nevada Test Site.

b. Naval SNF and test specimen shipments based on a combination of truck and rail transport.

c. Shipments based on 100 percent transport by truck or 100 percent transport by rail.

d. Reference: DOE (1986)

e. Reference: DOE (1990)

f. The maximum rail case is based on rail transport where rail access is available and truck transport where rail access is not available.

g. Reference: USN (1984)

h. Reference: DOE (1994).

i. Reference: DOE (1992).

Using census data for 1990 overestimates historical collective doses because the United States population has continuously increased over the time covered in these assessments. Basing collective dose estimates on the United States highway and rail system as it existed in 1993 may slightly underestimate doses for shipments that occurred in the 1940s, 1950s, and 1960s, because a larger portion of the transport routes would have been on non-interstate highways where the population may have been slightly closer to the road. Data were not available that correlated transportation routes and population densities for the 1940s, 1950s, 1960s, and 1970s; therefore, it was necessary to use more recent data to make dose estimates. By the 1970s, the structure of the interstate highway system was largely fixed and most shipments would have been made on interstates.

Shipment data were linearly extrapolated for years when data were unavailable, which also results in uncertainty. However, this technique was validated by linearly extrapolating the data in SAIC (1991) for 1973 through 1989 to estimate the number of shipments that took place during the time period 1964 through 1972 (also contained in SAIC 1991). The 1973 through 1989 time period corresponded to the time period when data were available for the Idaho Chemical Processing Plant. The data in SAIC (1991) could not be used directly because only shipment counts are presented for 1964 through 1982 and no origins or destinations were listed for years before 1983. Based on the data in SAIC (1991), linearly extrapolating the data for 1973 through 1989 overestimates the shipments for 1964 through 1972 by 20 percent when compared to the actual shipment counts for 1964 through 1972.

Collective doses for SNF shipments associated with Alternatives 1 through 5 were summarized previously in this appendix and in Appendix D of Volume 1 of this EIS (for naval spent nuclear fuel). For truck shipments, the collective dose to workers ranged from 1.5 person-rem (the No Action alternative) to 1,000 person-rem (Centralization at Savannah River), or 0.00060 to 0.40 latent cancer fatalities. Collective dose to the general population ranged from 0.34 person-rem (the No Action alternative) to 2,400 person-rem (Centralization at Savannah River), or 0.00017 to 1.2 latent cancer fatalities. These doses and latent cancer fatalities include shipments of naval SNF and test specimens.

For train shipments, the collective dose to workers ranged from 1.5 person-rem (the No Action Alternative) to 150 person-rem (Centralization at Nevada Test Site), or 0.00060 to 0.060 latent cancer fatalities. Collective dose to the general population ranged from 0.34 person-rem (the No Action Alternative) to 190 person-rem (Centralization at Savannah River), or 0.00017 to 0.095 latent cancer fatalities. These doses and latent cancer fatalities include shipments of naval SNF and test specimens.

Transportation impacts may also result from reasonably foreseeable projects. Two major proposed projects that involve extensive transportation of radioactive material are: (a) shipments of SNF and defense high-level waste to a geologic repository, and (b) shipments of transuranic waste to the Waste Isolation Pilot Plant, located in Carlsbad, New Mexico. DOE is presently determining the suitability of Yucca Mountain, Nevada, as a site for a geologic repository for commercial SNF and defense high-level waste; therefore, the geologic repository was assumed to be located in Yucca Mountain, Nevada, for the transportation cumulative impacts analysis.

Based on the transportation dose assessments presented in DOE (1986), the worker collective dose for truck shipments to a repository was 8,600 person-rem or 3.4 latent cancer fatalities. The collective dose to the general population from truck shipments to a repository was 48,000 person-rem or 24 latent cancer fatalities. The worker collective dose for train shipments to a repository was 750 person-rem or 0.30 latent cancer fatalities. The collective dose to the general population from train shipments to a repository was 740 person-rem or 0.37 latent cancer fatalities.

Based on the transportation dose assessments presented in DOE (1990), the worker collective dose from truck shipments to the Waste Isolation Pilot Plant was 1,900 person-rem or 0.76 latent cancer fatalities. The collective dose to the general population from truck shipments to the Waste Isolation Pilot Plant was 1,500 person-rem or 0.75 latent cancer fatalities. The worker collective dose from train shipments to the Waste Isolation Pilot Plant was 180 person-rem or 0.072 latent cancer fatalities. The collective dose to the general population from train shipments to the Waste Isolation Pilot Plant was 990 person-rem or 0.50 latent cancer fatalities. These collective doses include the 5-year Test Phase and the 20-year Disposal Phase.

There are three other reasonably foreseeable projects that involve limited transportation of radioactive material: (a) 100 shipments of submarine reactor compartments from the Puget Sound Naval Shipyard to the Hanford Site for burial, (b) return of cesium-137 isotope capsules to the Hanford Site, and (c) transport of uranium billets from the Hanford Site to the United Kingdom. The transport of submarine reactor compartments is an ongoing activity that is not yet completed; therefore, it was categorized as a reasonably foreseeable action. The doses for these actions are presented in Table I-61.

There are also general transportation activities that take place that are unrelated to the alternatives evaluated in this EIS or to reasonably foreseeable actions. Examples of these activities are shipments of radiopharmaceuticals to nuclear medicine laboratories and shipments of commercial low-level radioactive waste to commercial disposal facilities. The U.S. Nuclear Regulatory Commission evaluated these types of shipments based on a survey of radioactive materials transportation published in 1975 (NRC 1977). Categories of radioactive material evaluated in NRC (1977) included: (a) limited quantity shipments, (b) medical, (c) industrial, (d) fuel cycle, and (e) waste.

The U.S. Nuclear Regulatory Commission estimated that the annual collective worker dose for these shipments was 5,600 person-rem or 2.2 latent cancer fatalities. The annual collective general population dose for these shipments was estimated to be 4,200 person-rem or 2.1 latent cancer fatalities. Because comprehensive transportation doses were not available, these collective dose estimates were used to estimate transportation collective doses for 1943 through 1982 (40 years). These dose estimates included SNF and radioactive waste shipments and truck and rail shipments.

Based on the transportation dose assessments in NRC (1977), the cumulative transportation collective doses for 1943 through 1982 were 220,000 person-rem for workers and 170,000 person-rem for the general population. These collective doses correspond to 88 latent cancer fatalities for workers and 85 latent cancer fatalities for the general population.

In 1983, another survey of radioactive materials transportation in the United States was conducted

(Javitz et al. 1985). This survey included U.S. Nuclear Regulatory Commission and Agreement State licensees and the U.S. Department of Energy. Both SNF and radioactive waste shipments were included in the survey. Weiner et al. (1991a, b) used the survey by Javitz et al. (1985) to estimate collective doses from general transportation. The transportation dose assessments in Weiner et al. (1991a, b) were used to estimate transportation doses for 1983 through 2035 (53 years). The interval 1995 through 2035 corresponds to the interval of time associated with the spent nuclear fuel management activities evaluated in this EIS.

Weiner et al. (1991a) evaluated eight categories of radioactive material shipments by truck: (a) industrial, (b) radiography, (c) medical, (d) fuel cycle, (e) research and development, (f) unknown, (g) waste, and (h) other. Based on a median external exposure rate, an annual collective worker dose of 1,400 person-rem and an annual collective general population dose of 1,400 person-rem were estimated. These collective doses correspond to 0.56 and 0.70 latent cancer fatalities per year for workers and the general population, respectively. Over the 53-year time period from 1983 through 2035, the collective worker and general population doses would be 74,000 person-rem or 30 and 37 latent cancer fatalities for workers and the general population, respectively.

Weiner et al. (1991b) also evaluated six categories of radioactive material shipments by plane: (a) industrial, (b) radiography, (c) medical, (d) research and development, (e) unknown, and (f) waste. Based on a median external exposure rate, an annual collective worker dose of 290 person-rem and an annual collective general population dose of 450 person-rem were estimated. These collective doses correspond to 0.12 and 0.23 latent cancer fatalities per year for workers and the general population, respectively. Over the 53-year time period from 1983 through 2035, the collective worker dose would be 15,000 person-rem and the general population collective dose would be 24,000 person-rem or 6.0 and 12 latent cancer fatalities for workers and the general population, respectively.

Like the historical transportation dose assessments, the estimates of collective doses because of general transportation also exhibit considerable uncertainty. For example, data for 1975 were applied to general transportation activities from 1943 through 1982. This approach probably overestimates doses because the amount of radioactive material that was transported in the 1950s and 1960s was less than the amount transported in the 1970s. For example, in 1968, the shipping rate for radioactive material packages was estimated to be 300,000 packages per year (Patterson 1968); in 1975 this rate was estimated to be 2,000,000 packages per year (NRC 1977). However, because comprehensive data that would enable a more realistic transportation dose assessment are not available, the dose estimates developed by the U.S. Nuclear Regulatory Commission were used.

The total worker and general population collective doses are summarized in Table I-58. Total collective worker doses from all types of shipments (historical, the alternatives, reasonably foreseeable actions, and general transportation) were estimated to be 320,000 person-rem (130 latent cancer fatalities), for the period of time 1943 through 2035 (93 years). Total general population collective doses were also estimated to be 320,000 person-rem (160 latent cancer fatalities). The majority of the collective dose for workers and the general population was because of general transportation of radioactive material. The total number of latent cancer fatalities over the time period 1943 through 2035 was estimated to be 290. Over this same period of time (93 years), approximately 28,000,000 people would die from cancer, based on 300,000 latent cancer fatalities per year (NRC 1977). It should be noted that the estimated number of transportation-related latent cancer fatalities would be indistinguishable from other latent cancer fatalities, and the transportation-related latent cancer fatalities are 0.0010 percent of the total number of latent cancer fatalities.

I-10.2 Vehicular Accident Impacts

Fatalities involving the transport of radioactive materials were surveyed for 1971 through 1993 using the Radioactive Material Incident Report database. For 1971 through 1993, 21 vehicular accidents involving 36 fatalities occurred. These fatalities resulted from vehicular accidents and were not associated with the radioactive nature of the cargo. No radiological fatalities because of transportation accidents have ever occurred in the United States. During the same period of time, over 1,000,000 persons were killed in vehicular accidents in the United States.

For Alternatives 1 through 5, 0.047 to 1.4 vehicular accident fatalities are estimated to occur. During the 40-year time period from 1995 through 2035, approximately 1,600,000 people would be killed in vehicular accidents in the United States.

Appendix J

Spent Nuclear Fuel Management

This appendix describes a range of technologies potentially available for management of spent nuclear fuel (SNF) and the status of each technology. The identified technologies support the SNF programmatic objective to define a management path and proceed toward ultimate disposition of all U.S. Department of Energy (DOE) SNF. Included are technologies for fuel preparation, storage (stabilization) or, where appropriate, direct interim storage. The stabilization and direct storage technologies may also be applicable to ultimate disposition in some instances. The stabilization technologies selected for discussion range from the minimal to the extensive stabilization processing technologies that could be applied to prepare the SNF for extended interim storage or ultimate disposition. In addition, programmatic and institutional factors, which are considerations in the selection of technology options for application, are discussed. Also presented is a brief description of the types of DOE SNF, particularly as their characteristics apply to the technology options.

J-1 BACKGROUND

During the last 40 years, DOE and its predecessor agencies have generated, transported, received, stored, and reprocessed SNF at facilities in the nationwide DOE complex. This SNF was generated from various sources, including DOE production reactors; the Naval Nuclear Propulsion Program reactors; DOE, university, and other research and test reactors; special-case commercial power reactors; and foreign research reactors. Production reactors were constructed and operated at the Hanford and Savannah River Sites to provide special nuclear material and other radioactive isotopes for the DOE's defense programs. These production reactors are no longer operated. Naval Nuclear Propulsion Program reactors and some test and research reactors are still operating. DOE has reprocessed SNF at the Idaho National Engineering Laboratory, Hanford Site, and Savannah River Site to recover fissile materials (uranium-235 and plutonium-239) and other valuable radionuclides.

More than 100,000 metric tons of heavy metal (MTHM) of SNF was produced by DOE and its predecessor agencies since 1943. In the past, most of the SNF was chemically processed to recover the fissile materials, largely uranium-235 and plutonium-239, either for the national defense programs or reactor research and development.

With the end of the Cold War, DOE and the U.S. Department of Defense reevaluated the scale of their weapons production, nuclear propulsion, and research missions. Because of the lack of need for additional fissile materials, DOE decided in 1992 to phase out reprocessing for the recovery of fissile materials. Approximately 2,700 MTHM of SNF remains that has not been processed. Additionally, approximately 100 MTHM of DOE SNF is expected to be generated in the next 40 years. This DOE SNF, which is in a wide range of enrichments and physical conditions, is stored at various locations in the United States and overseas. This material requires management until a decision regarding its ultimate disposition is reached.

Most of the existing fuel is currently stored in 10- to 40-year-old water pools (designed for temporary storage of SNF until it could be reprocessed) at several locations at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. Smaller quantities are stored at approximately 60 locations nationwide, including 55 non-DOE United States research reactor facilities. The vulnerabilities associated with the storage of SNF are identified in a recent DOE report to the Secretary of Energy entitled, Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and Other Reactor Irradiated Nuclear Materials and Their Environment, Safety, and Health Vulnerabilities (DOE 1993). A DOE plan of action (Phases I, II, and III) to address these vulnerabilities has been issued (DOE 1994a, b, c).

J-2 SPENT NUCLEAR FUEL

Individual fuel elements and assemblies in nuclear reactors are constructed in many configurations, but they generally consist of the fuel matrix, cladding, and structural hardware. The fuel assemblies and structural hardware constitute the reactor core. Section 1.1.1 of Volume 1 of this EIS presents a summary description of SNF.

The fuel matrix contains the fissile material (typically uranium as a metal, metal alloy, or an oxide). For water-cooled reactors, the matrix form is typically plates or cylindrical pellets. Typically, for gas-cooled reactors, the matrix is particles, which are an oxide or carbide composite of the fuel material encapsulated by a ceramic coating.

Cladding materials surrounding the fuel matrix serve two principal functions: (a) protection of the fuel matrix from corrosion by the fluid that removes heat from the reactor core, and (b) containment of radioactive fission products generated within the fuel during reactor operation. The degree and rate of cladding corrosion varies with reactor design.

The structural hardware serves both to support the fuel assemblies and to maintain a fixed geometry for the fissile materials in the reactor core. For example, structural materials fix the location of the fuel elements relative to one another in a fuel assembly and also fix the location of the fuel assemblies relative to one another in the reactor core. Structural hardware also provides mechanical support for the assemblies and the core, as well as providing defined paths for cooling the core. These functions are essential to control the nuclear reactions in the reactor core and ensure that adequate cooling is provided to all heat-generating regions of the reactor core.

The characteristics of the fuel elements in a reactor are tailored to the purpose of the reactor system. Two examples, important to SNF management, are discussed below. One example is for fuel with high-integrity cladding and the other is for fuel with lesser cladding integrity. Integrity refers to the corrosion resistance of the fuel to the reactor coolant and/or to its corrosion resistance in the environment in which it is stored.

> High-Integrity Fuels Used in Naval Reactors and Nuclear Power Plants. Naval fuels use highly enriched uranium, while nuclear power plant fuels generally use low-enriched uranium. These types of reactors use water for cooling the fuel assemblies. The reactors are

operated at high coolant temperatures and pressures. The design objectives associated with commercial fuel and these reactor types are to maximize power output and minimize time spent refueling. For naval reactors, other design objectives are also critical: ability to withstand battleshock, ability to preclude release of any fission products because operating personnel must live and work in close proximity to the reactor, and ability to change reactor power levels quickly so the ship can alter speed when needed. As a result, the cladding materials are selected to be very corrosion resistant at high temperatures (a zirconium alloy is used). Long-term fuel element integrity is emphasized. From the standpoint of SNF management, such fuel element designs are well-suited for direct storage of the SNF (either wet or dry) without additional stabilization. Aggressive (concentrated) chemical and/or mechanical means are required to remove cladding if fuel processing is considered as an option for stabilization.

Savannah River Production Reactor Fuels (and targets). The Savannah River Site production reactors also used water for cooling fuel assemblies. However, the reactors were operated at relatively low temperatures and essentially at atmospheric pressure. The design of these production reactor cores was optimized for production of special nuclear materials and other valuable radioactive isotopes. Fuel irradiation times were generally on the order of a few months. Fuel element cooling times prior to reprocessing were relatively short because the fuel elements were designed for special nuclear materials production and recovery. A high degree of corrosion resistance for the cladding was not part of the design. Aluminum cladding was selected so that the fuel elements could be dissolved for processing by less highly concentrated chemical solutions than for fuel with higher integrity cladding. Therefore, this fuel type is not as suitable for long-term storage (either wet or dry) as are the higher integrity fuels.

The DOE SNF represents a broad spectrum of fuel element designs, both for the fuel matrix material and the cladding. To provide perspective, the characteristics of the principal types of DOE SNF are briefly discussed below. Inventories for the various types (current and projected), in units of MTHM, are summarized in Table J-1, along with a qualitative statement regarding fuel element enrichment and cladding integrity.

J-2.1 Category 1-Naval Fuel

This SNF type includes the fuel from the Naval Nuclear Propulsion Program, including fuel from submarines, surface vessels, and prototype reactors. Naval fuel is highly enriched and is clad with a zirconium alloy. This fuel design is structurally strong (able to withstand battleshock loads well in excess of 50 times the force of gravity), the cladding is highly corrosion-resistant (no release of fission products), and the fuel is designed to operate for more than 20 years.

J-2.2 Category 2-Aluminum-Clad Production Reactor Fuel

The principal source of DOE aluminum-clad SNF was target and driver fuel from the Savannah River Site defense production reactors. The driver fuel is highly enriched aluminum-uranium alloy clad with aluminum. Most of the targets are depleted uranium metal (containing less uranium-235 than natural uranium), also clad with aluminum. Corrosion resistance of the cladding is moderate. Aluminum cladding is susceptible to corrosion when stored in water pools with poor water quality. Also, this category is used for SNF from the Advanced Test Reactor at the Idaho National Engineering Laboratory, some domestic and foreign research reactors SNF, and some production reactor fuel at the Hanford Site. With proper water quality, this fuel has been stored for more than 20 years without cladding corrosion problems.

Table J-1. Spent nuclear fuel inventories and corrosion resistance

Some of the fuel and targets have been in storage in water pools (with poor water quality) since 1989. Fuel is showing signs of corrosion, and targets are heavily corroded.

J-2.3 Category 3-Zirconium-Clad Production Reactor Fuel

All fuel in this category is from the Hanford Site N Reactor. It consists of a low-enriched uranium alloy fuel matrix, clad with a zirconium alloy. The fuel irradiation times were such that relatively large concentrations of fissile plutonium were produced.

Some of the N-Reactor's SNF has been in storage for over 20 years and a large number of fuel elements have holes in the cladding (breached), which permits corrosion of the fuel matrix. One result is contamination of the water in the storage pools at the Hanford Site. With respect to fuel with breached cladding, it is known that the irradiated metallic uranium can undergo reactions with water to produce uranium hydrides. The hydrided, irradiated uranium can be pyrophoric (subject to spontaneous burning) if it is permitted to dry out and is exposed to air (ITAT 1994). The potential pyrophoric nature of the fuel is an important consideration as management strategies for this fuel (including stabilization and transportation) are evaluated.

J-2.4 Category 4-High-Temperature Gas-Cooled Graphite Reactor Fuel

Graphite-matrix fuel was primarily used in two gas-cooled, commercial reactors: Fort St. Vrain and Peach Bottom. This type of fuel consists of small pellets of highly enriched uranium-carbide fuel surrounded by layers of pyrolytic carbon and protective layers of other carbide compounds that serve as the primary cladding. The pellets are dispersed in much larger graphite structures that provide neutron moderation and secondary containment. The fuel has high corrosion resistance when stored dry. However, the fuel is not amenable to wet storage.

J-2.5 Category 5-Commercial Reactor Research and Development Fuel

DOE has participated in numerous commercial reactor and SNF safety investigations. These activities have resulted in accumulations by DOE of SNF elements from a number of commercial reactors. Typically, this SNF consists of zirconium-alloy-clad, low-enriched uranium oxide fuels. Many of these elements were examined in DOE analytical facilities; others were used in test reactors to study fuel behavior in simulated accidents. The damaged core from the Three Mile Island-Unit 2 reactor was investigated extensively by DOE, under cooperative research and development agreements, at several DOE sites. This damaged fuel is also included in this category.

J-2.6 Category 6-Test and Experimental Reactor Fuels

This is a category of fuels of broad description. The fuels range from low to high enrichment and encompass metal, metal alloy, and oxide fuel matrices. The fuel can be divided into three categories.

J-2.6.1 Category 6a-Stainless-Steel-Clad Fuels from Experimental Reactors

Uranium enrichments are generally high in fuels from these reactors, but low-enrichment fuels are included as well. Fuel matrices consist of uranium-zirconium hydride, uranium dioxide, plutonium oxide, plutonium alloy, uranium carbide, uranium metal, and uranium alloys. The principal sources of fuel in this category are the Experimental Breeder Reactor-II and Zero Power Physics Reactor at the Idaho National Engineering Laboratory, Hanford Fast Flux Test Facility, and the blanket assemblies from the FERMI reactor.

J-2.6.2 Category 6b-Zirconium-Alloy-Clad Spent Nuclear Fuel from Experimental Reactors

Typically, fuel in this category has a uranium dioxide fuel matrix, but there is uranium-molybdenum alloy fuel also in this inventory. Enrichment can be either high or low. Most of this SNF originated at the Shippingport Power Reactor where the light water breeder reactor concept was tested. Some thorium and uranium-233 fuels are found in this category.

J-2.6.3 Category 6c-Miscellaneous Fuel

Fuel in this miscellaneous category is derived mainly from the Molten Salt Reactor Experiment at the Oak Ridge Reservation. That fuel is now stored in the salt storage tanks beneath the reactor.

J-3 SPENT NUCLEAR FUEL INTERIM MANAGEMENT OPTIONS

In 1992, the Secretary of Energy directed the DOE to develop an integrated long-term SNF management program. The program is assessing DOE's current SNF inventory and SNF storage facilities, integrating DOE's many existing SNF activities into one program, developing an integrated decisionmaking and policy basis for SNF operations, and ensuring that all issues associated with SNF are resolved safely and cost effectively.

Until ultimate disposition is determined, it is not possible to define the SNF characteristics suitable for ultimate disposition. Pending selection of an ultimate disposition, SNF must be maintained in safe storage. Solutions to the storage questions may require changes in management strategies for these fuels, including such options as the construction of new facilities and stabilization of certain fuels.

Technologies for SNF management are required to ensure safe, environmentally sound, and economic management until ultimate disposition is implemented. There are a number of technology options available for accomplishing these objectives. Key design factors to be considered include the fuel design, structural integrity of the fuel, degree of corrosion of the cladding, fuel enrichment, and the chemical stability of the cladding and the fuel matrix. The principal technology option categories for storage are outlined in a general way on a flow chart (Figure J-1).

The options for SNF management include direct storage (high-integrity fuels) or SNF stabilization in preparation for continued storage. Technologies included under SNF stabilization are containerization, processing without separation of fissile materials, and processing in which there is separation of the fissile material. The status of technologies for each of the approaches are discussed in Section J-4. Related institutional factors associated with implementing the various management approaches are discussed in Section J-5.

Figure J-1. Technology options for preparing spent nuclear fuel for interim storage.

J-4 SUMMARY OF TECHNOLOGIES FOR SPENT NUCLEAR FUEL MANAGEMENT

In 1992, DOE had proposed to engage in research and development activities for technology development and demonstration required to ensure that SNF could be appropriately prepared for disposition in a geologic repository. Any such repository is not expected to be available until after the year 2010. Therefore, DOE has changed its focus in this effort to better define the SNF research and development program. The DOE is utilizing a system approach (a logical, structured approach to assure effective actions) to technology development for preparing SNF for safe interim storage and ultimate disposition in a geologic repository.

Figure J-1 summarizes the technology options available for preparing SNF for interim storage. Indicated under each of the four general categories on the figure is a range of representative technology options. This section describes technology options listed on Figure J-1 and discusses the following:

The option (describes what it involves)

Applicable fuel types

Maturity (demonstrated technology, early stages, or developmental)

Status of commercial and foreign applications/development that may be applicable to DOE SNF management

References that contain more detail on the technology.

When evaluating SNF management options, criticality control is an important factor, particularly for SNF with enriched uranium fuel.

Criticality considerations apply for both direct storage and stabilization. The storage system must meet applicable requirements governing nuclear criticality, which specify that the system be designed to ensure that a nuclear criticality is not possible unless at least two independent (concurrent or sequential) changes occur in the systems essential to the control of nuclear criticality.

Also important in selecting management options for SNF are the characteristics of the fuel type and the physical condition of the fuel. For specific types of fuel, characterization may be necessary to determine the extent of stabilization required and/or the most suitable stabilization process to transition the particular SNF into interim storage.

J4

J-4.1 Direct Storage

Direct storage means storing SNF in essentially the same physical form in which it is removed from the reactor (that is, little or limited stabilization of the fuel elements). Fuel that has high-integrity cladding is amenable to direct storage provided criticality issues can be adequately addressed for the planned storage interval (IAEA 1988). Specific examples are naval SNF and SNF removed from most types of commercial nuclear electric generating stations (both in the United States and foreign countries).

If a reactor that has operated at high power has fuel removed soon after shutdown (within weeks), the level of heat generation associated with fission product decay may be sufficient to damage and possibly melt the fuel if the fuel assembly is not cooled adequately. In addition, radiation levels are high from decaying fission products and radionuclides in the irradiated structural materials. Thus, both effective cooling and effective shielding of the stored SNF are essential. Common practice is to place the SNF in a water pool, for at least a period of time, following removal from the reactor. The level of heat generation and radioactive decay associated with SNF decreases with time after removal from the reactor. With the passage of time, it is possible and may be desirable to transfer SNF from a wet to a dry storage mode because, in general, the costs and potential environmental safety and health vulnerabilities associated with dry storage are less than those associated with wet storage (Lopez 1994, Taylor and Shikashio 1993). The status of wet and dry storage technologies is discussed in the following two subsections.

J-4.1.1 Wet Storage

Water pools (or water pits) are part of the design of nearly all nuclear reactor facilities. They are used to provide a storage location for SNF when it is removed from the reactor. The pools usually are designed to store the inventory of fuel removed from a reactor for a number of years. Pool depth is sufficient to provide shielding for personnel working in the region of the water pool. The water pool system normally includes a subsystem for water chemistry control with a purpose of maintaining the conditions of the water in the pool so cladding corrosion is minimized, water in the pool is clean enough that the SNF can be viewed underwater during fuel movement and fuel removal operations, and chloride content is controlled to maintain pool liner integrity. The water pools usually are of concrete construction and lined with stainless steel so as to minimize the potential accumulation of radioactivity on or under the surface of the concrete pool walls.

Wet storage systems generally have more heat removal capability than dry storage systems because heat transfer to liquids is more efficient than to gases, such as air or nitrogen.

Design, construction, and operation of water pools for SNF storage is a mature technology option for DOE and for commercial nuclear power plants (Tak-ts 1994). Wet storage system design modifications usually center around re-racking the fuel in a pool to permit more fuel to be stored in a given pool. Fuel element spacing in rack designs is carefully analyzed to ensure that there is an adequate margin relative to criticality prevention for existing or contemplated SNF to be stored in the racks in the water pool.

J-4.1.2 Dry Storage Systems

In a dry storage system, cooling is provided by heat transfer to the inner wall of the storage system with eventual heat rejection to the air surrounding the storage system. Dry storage systems are mature technologies that are being applied for DOE SNF and for SNF at United States commercial and foreign nuclear electric generating systems (Schneider et al. 1992).

Dry storage system options generally are of three types: (a) stand-alone modular casks, (b) modular vault arrays, and (c) multiple-unit vault storage systems. Hot cells are also employed but are not generally considered cost efficient for storing significant quantities of SNF. Multiple examples of each of these three types have been built and are storing SNF at the present time in DOE, commercial, and foreign applications.

Stand-Alone Modular Casks. A number of large stand-alone casks are available in the DOE system and in commercial applications. The casks are top- or end-loading, made from a variety of materials, and have been developed primarily in North America and Europe (Monthey and Bergsman 1994). Some cask designs are licensed for offsite transport of SNF and others are used principally for onsite fuel movement.

There are also a variety of smaller stand-alone casks that are designed primarily for onsite transportation and storage of specific irradiated fuels and other materials. The safety basis documentation for these casks can be found in accompanying safety analysis reports (for example, Saito 1992).

Modular Vault Arrays. A second type of dry storage system uses a basic concrete housing with an arrangement of openings in the concrete. Canisters containing fuel are placed in the openings. The concrete housing provides supplementary shielding and prohibits unauthorized access to the SNF. Depending on the design, fuel can be stored either vertically or horizontally in canisters.

Multiple-Unit Vault Storage Systems. Multiple-unit vault systems tend to be large facilities that contain cask unloading stations, fuel handling cells, ventilation systems, and office space (Carter 1994). In the main storage area array, fuel assemblies or fuel assemblies in canisters are stored vertically in floor wells topped with shielded plugs. Insertion or removal of a canister containing the fueled component is accomplished using a shielded, floor-supported machine or a wall-mounted, unshielded bridge crane.

J-4.2 Containerization

Some SNF has deteriorated because of past storage conditions, fuel damage during operation or destructive tests, or use of cladding materials that are quite susceptible to deterioration if placed in prolonged wet storage without adequate protection. To provide adequate protection for the public, environment, and facility workers, containerization technologies have been employed to (a) add additional containment to the SNF, (b) provide a passivating environment for the spent fuel (a passivating environment is one where corrosion is minimized), or (c) place the spent fuel into an inert atmosphere to retard or eliminate the fuel-element deterioration process. These technologies are described below.

J-4.2.1 Canning

Canning is the technology whereby the SNF is placed into an engineered metal canister, which then is usually sealed. This technology (commonly called overpacking) is usually done in a water pool. Overpacking is used as a temporary corrective action if the SNF is releasing fission products. Further refinements include blowing the water out of the overpack canister while it is still underwater and then evacuating the canister (vacuum) to evaporate the remaining water. An inert gas, such as helium or nitrogen, can also be added. Another refinement to this technology involves adding a chemical for passivation to the water inside the canister to retard the corrosion of the SNF by the water. This approach has been attempted at the K-West Basin at the Hanford Site; however, its effectiveness is unknown because the fuel has not been inspected since it was canned. Small vents in the lid of the can, which allow release of gases generated by radiolysis or corrosion, have also been used.

Canning can also be carried out in a shielded, dry cell having remote-handling capabilities. The SNF is brought into the remote cell and dried, either by normal drip-drying or employing heating ovens to expedite the drying process. The SNF can be visually inspected in the remote cell and then placed into a metal canister that is welded closed. Inert gas can be added; high quality inspection of the closed canister is also possible.

This technology has been used extensively throughout DOE and foreign countries for research fuels. The commercial industry has not done a significant amount of direct canning because the commercial nuclear fuels have been designed for high integrity and so rarely require an overpack.

J-4.2.2 Passivation

The passivation approach is applicable to SNF that may contain regions that could undergo adverse chemical reactions if exposed to air or moisture during dry storage. Passivation increases the stability of the fuel by reducing its reaction rate with air or other oxidants. Consequently, if the fuel were inadvertently exposed to air during dry storage, the heat generated would be less than the minimum heat dissipation rate, thus minimizing the chances of a fuel fire or rapid adverse chemical reactions. This process potentially could be used to stabilize metallic fuel with damaged cladding, such as Hanford Site N-Reactor fuel.

Passivation could also include preparatory steps such as SNF cleaning, drying, and heating in a controlled environment to remove any bound water or to potentially remove or oxidize uranium hydride. A typical process first involves fuel cleaning. When cleaning is completed, a flow of dry inert gas is introduced around the fuel, which is maintained at the predetermined elevated temperature. A small concentration of oxidant is introduced into the flowing inert gas. Reactive regions of the fuel matrix react with the small amount of oxidant at the elevated temperature to oxidize them and make them nonreactive. When process instrumentation indicates that the reaction rate between the oxidant and the fuel (in the controlled environment) is sufficiently low, the fuel is cooled down and appropriately packaged. The fuel packaging must restrain the fuel from excessive movement to prevent the formation or exposure of new highly reactive fuel regions.

A passivation process has been used on metallic fuel in a laboratory setting by the British, who considered it to be a potentially viable method to transition their SNF from wet to dry storage. Passivation is being investigated for use on N-Reactor fuel at the Hanford Site.

J-4.2.3 Coating

Coating is a technology whereby the SNF is placed into a metal container, dried to remove any water, and then heated to the casting temperature for particular materials such as lead, copper, or an epoxy. The fuel element is covered with the molten material. The intent is to provide monolithic containment around the fuel element to ensure that the SNF will not release any fission products, nor encounter an atmosphere that causes the fuel to degenerate further. To date, this technology has been investigated primarily as an approach for preparing SNF for disposal. Pressing copper around SNF at high pressures has been studied by the Swedish government.

J-4.3 Processing

For over 40 years, DOE has employed aqueous reprocessing. The purpose for reprocessing was to separate plutonium and residual uranium materials in the SNF from the radioactive fission products and structural material, including fuel element cladding.

Some of the SNF that is currently in storage at the Savannah River Site, Hanford Site, and Idaho National Engineering Laboratory shows signs of degraded cladding. Aqueous processing may be a way of preventing safety and environmental problems with fuels that have questionable cladding integrity (DOE 1994a). From the standpoint of SNF stabilization, processing is a technology for which DOE facilities exist and where there are still capable technical and facility operating personnel to staff and support facility operations. By removing part of the SNF inventory from the present wet storage environments, processing affords an additional level of stability for the inventory of stored SNF.

Processing of SNF with separation of fissile materials has a long history of operations. The technology is mature and well understood. The primary process used for fissile materials separation for DOE SNF, commercial fuels, and foreign separations processing has been the PUREX (Plutonium URanium EXtraction) process or variations of this process. Facilities for PUREX-type processing have been built in the United States, a number of European countries, Russia, and Japan. In the United States, all of the recently operating facilities are owned and operated by DOE. With the end of the cold war, DOE and the U.S. Department of Defense reevaluated the need for additional fissile materials and decided in 1992 to phase out processing for recovery of fissile materials. DOE's processing facilities at the Hanford Site and Idaho National Engineering Laboratory are now shut down. One processing facility at the Savannah River Site has recently been restarted to stabilize aqueous solutions of uranium.

While chemical separation is the only technology currently available, there are other technologies that could accomplish fuel processing. The following technologies are intended to provide representative examples of technologies that could be employed for various types of SNF subject to the appropriate National Environmental Policy Act documentation. All technologies are not applicable to all types of fuel.

Several processes have been proposed and studied to stabilize SNF that do not involve separation of uranium and/or plutonium from the other highly radioactive contaminants. These processes involve changing the SNF physical and chemical form to make the volume smaller, material less reactive, or the material more homogeneous. Materials to assist in preventing nuclear criticality (nuclear poison) may also be introduced into the process. Because none of these methods remove fissile material, the possibility of a nuclear criticality exists for DOE SNF with a fuel matrix of highly enriched uranium-235, unless the uranium-235 is diluted with uranium-238 or a nuclear poison is added to assist in preventing nuclear criticality.

J-4.3.1 Oxidation

An oxidation process can be used for two purposes. It can be used to (a) separate the fuel from the cladding, minimize the volume of material to be stored, or prepare the fuel matrix to be more easily dissolved, or (b) convert fuel matrix or graphite fuel elements into a stable oxide form. The decladding options include

AIROX-Holes are drilled into the fuel matrix. Uranium dioxide (UO_2) is oxidized to U_3O_8 by injecting oxygen gas at 400C (750F). There is an increase in fuel matrix volume of about 70 percent. The uranium then is reduced back to UO_2 using hydrogen gas. The process is repeated several times until the cladding breaks apart. This process is in the developmental stages.

RAHYD-Holes are drilled into the fuel matrix. Uranium metal is reduced with hydrogen gas at 225C (435F) to produce uranium trihydride. There is about a 70 percent volume increase. The fuel matrix is then converted back to uranium metal by heating to 780C (1400F). The process is repeated several times until the cladding breaks apart. This process is in the developmental stages.

CARBOX-Holes are drilled into the fuel matrix. Oxygen is injected into uranium carbide fuel at 400 to 700C (750 to 1300F) to form U_3O_8. There is about an 85 percent volume increase. This process is in the developmental stages.

After the fuel is declad, the fuel matrix material can be consolidated and packaged for storage.

Development work was performed on decladding technologies in the late 1950s and early 1960s in connection with dry SNF reprocessing research at Atomics International.

The fuel elements can also be oxidized to convert the cladding and/or the fuel matrix into oxide form. One example is the burning of the graphite and metal fuels. The oxidized fuel and any ash would contain the uranium, plutonium, and most of the fission products, which then would be consolidated and packaged for storage. Technology for burning graphite fuels is well developed and has been used at the Idaho National Engineering Laboratory (WINCO 1992).

J-4.3.2 Chemical Dissolution

The fuel is dissolved chemically by a highly concentrated acid or base solution. If necessary, a nuclear poison can be added to assist in criticality control. Separation of the fissile material from the fission products and cladding material does not occur. The resultant product is converted into an SNF interim storage form, such as a glass, oxide, or ceramic, with improved characteristics relative to criticality control. This process applies to all DOE fuel types except graphite fuel. The dissolution technology is well developed (Long 1978) and has been used throughout the DOE complex and in several foreign countries.

J-4.3.3 Mechanical

Several mechanical processes, such as shredding, chopping, grinding, and disassembly, have been proposed to change the configuration of the fuel. The resultant product can be mixed with other material, such as glass formers or depleted uranium, for safe interim storage. All DOE fuel can be treated by this method. Choppers have been used at several DOE facilities, and shredders have been evaluated at the Idaho National Engineering Laboratory for graphite fuel (WINCO 1992).

J-4.3.4 Aqueous Processing

The primary aqueous extraction processing approach used is called PUREX. Aqueous processing consists of chemically dissolving the fuel in an acid, adjusting the solution pH for stability and uranium extraction, and contacting (mixing) the acid solution with an organic phase, such as kerosene or n-dodecane, usually with tributyl phosphate added (Long 1978, Benedict 1981). The organic compound forms a complex with the uranyl ion that is extracted into the organic phase, thus separating the uranium from other dissolved constituents of the fuel. Depending on the fuel type, the entire fuel element may be dissolved, or the cladding can be breached by chopping the element to enable the acid to leach the fuel matrix. For the chop-leach approach, there remains undissolved cladding hulls. The acid solutions used in the process are tailored to the fuel type. By adjusting the valence of plutonium, it can be separated from the uranium and/or fission products by a series of water-solution-to-organic-phase extraction steps. The PUREX process is applicable to almost all fuel types, if there is a suitable fuel matrix dissolution (headend) process. A process variation called TRUEX, developed at Argonne National Laboratory, can be used to recover the transuranic elements other than uranium or plutonium.

Aqueous processing of SNF utilizing the basic PUREX separation approach is a mature technology and is used world-wide (Leigh 1992). The United States has used PUREX aqueous processing for separating fissile materials from irradiated defense fuels since the 1950s at the Savannah River Site, Hanford Site, and Idaho National Engineering Laboratory. The West Valley Plant in New York, constructed for fissile material extraction from commercial light water reactor fuels, used a PUREX-type process. The United Kingdom, France, Russia, and Japan use large-scale aqueous PUREX processing to recover fissile materials from spent fuels.

J-4.3.5 Electrometallurgical Processing

Electrometallurgical processing employs rapid anhydrous (or water-free) chemical reactions at high temperature for the extraction of metal from mixtures or concentrates and for refining metallic elements and compounds. The process is based on passing an electrical current through fused salts. It involves three steps. First, a basket of chopped fuel is made anodic with respect to the electrorefiner crucible, which promotes rapid dissolution of the fuel into the electrolyte salts. These salts float on a pool of liquid cadmium metal. Second, a metallic cathode is introduced into the salts and much of the uranium is deposited on the metallic cathode (which is removed for uranium recovery). Third, a liquid cadmium cathode is then used to collect the remaining uranium, plutonium, and fission products. Zirconium and noble metals remain in the molten electrorefiner cadmium pool. Most fission products remain in the electrolyte salts. Cadmium in the liquid cadmium cathode can be distilled, leaving the fissile materials and uranium/plutonium for further disposition, as appropriate. The process is being developed at Argonne National Laboratory-West and being demonstrated on a near-commercial pilot-plant scale in the Fuel Cycle Facility at the Idaho National Engineering Laboratory using sodium-bonded metallic fuel. In principle, other metallic fuel can be processed electrometallurgically. This developmental process is unique to DOE with no foreign or commercial counterparts at the present time.

J-4.3.6 Halide Volatility

A dry chloride volatility process is being developed for separation of the nonradioactive bulk cladding material (e.g., zirconium), fissile uranium, and other fissile or nonfissile transuranic products in SNF. This process is in the conceptual stage (Christian 1994). The process involves complete volatilization of a SNF element. Fuel is exposed to chlorine gas at high temperature [greater than 1200-C (2200-F)]. All of the fuel constituents form volatile chlorides. The chloride compounds are separated by scrubbing the gases through a molten zinc chloride bath to remove the fission products and transuranic radionuclides. The fission products and transuranic radionuclides are recovered by evaporating away the zinc chloride. The remaining chloride gases are fractionally condensed to separate and recover nonradioactive constituents, uranium, iodine, and krypton. The process produces a single waste form (e.g., glass) for ultimate disposition. A significant reduction in volume can be achieved. The process can be applied to fuels with almost any of the existing claddings (such as zirconium alloys, aluminum, and stainless steel).

J-4.4 Capabilities of Existing Facilities for Processing Each of the Fuel Types

The current DOE SNF inventory was characterized into six categories as discussed previously in Section J-2 and Table J-1. Table J-2 summarizes the locations for each category of SNF as well as the processing capabilities that might be brought to bear on them. The information in the tables is expanded on below.

Table J-2. Capabilities of existing facilities for processing each type of spent nuclear fuel (SNF).

SNF category	Description	Source	Conditioning and stabilization needs for interim storage	Processing technology status	Existing applicable facilities
1	Metallic fuel with zirconium-alloy cladding	Naval fuel	Excellent condition; minimal stabilization required	Proven on a production scale	Existing Idaho National Engineering Laboratory facilities using second generation dissolution facilities (fluorinel dissolution process cell) and extraction via CPP-601 facility
2	Highly enriched metallic fuel with aluminum clad	Fuel from the Savannah River Site production reactors; Idaho National Engineering Laboratory	Condition varies; stabilization is a near-term issue; fuel in wet storage will degrade further during interim period; long-term dry storage has unresolved questions	Proven on a production scale	Existing Savannah River Site facilities for Savannah River fuel; other research and development SNF can be processed at either the Savannah River Site or Idaho National Engineering

		Advanced Test Reactor driver fuel; some domestic and foreign research reactor fuels			Laboratory
3	Low enrichment, metallic fuel with zircaloy-clad	Hanford Site N-Reactor fuel	Poor condition and degrading; about half of the SNF has breached cladding with fuel leaching; stabilization is a near-term issue	Proven on a production scale	Existing Savannah River Site or Idaho National Engineering Laboratory facilities with new chop-leach head-end; certain foreign facilities exist that have the capability to process N-Reactor SNF
4	Uranium carbide in graphite matrix within a graphite structure UO2 fuel with zirconium	Gas-cooled commercial reactors at Fort St. Vrain and Peachbottom	Excellent condition; minimal stabilization necessary	Proven on a production scale for ROVER SNF; proven on a prototype scale for other graphite fuels	Idaho National Engineering Laboratory or Savannah River Site facilities could be used with a new head-end facility
5	Zircaloy-clad rods typically with low-enrichment UO2 pellets	DOE tests of commercial reactor fuel; damaged Three-Mile Island core debris	Condition excellent with the exception of Three-Mile Island core debris; minimal stabilization necessary	Proven on a production scale	Existing Idaho National Engineering Laboratory or Savannah River Site facilities perhaps with new head-end facility

Table J-2. (cont.)

6a	Various stainless-steel clad fuels with either high or low enrichment	Idaho National Engineering Laboratory and Hanford Site test reactors	Various and sometimes unknown fuel condition. Degradation of some fuels expected because of long storage times	Proven on a production scale for steel-clad high-enriched uranium SNF; prototype demonstrations are needed for other types	Existing Idaho National Engineering Laboratory or Savannah River Site facilities with new or modified head-end
6b	Zircaloy-clad UO2 or U-Mo alloy of high or low enrichment	Shippingport power reactor and various experiment reactors	Various and sometimes unknown fuel condition; degradation of some fuels expected because of long	Proven for some fuel types; others may require further work	Existing Idaho National Engineering Laboratory or Savannah River

			storage times		Site facilities with an upgraded dissolution facility
6c	Liquid uranium-235 in a salt solution, no cladding	Molten salt reactor experiment at Oak Ridge National Laboratory	Unknown; corrosive nature of fuel raises questions regarding present conditions; evidence of corrosion of storage container exists; stabilization will be required	Processing technology yet not identified	None at present

J-5 SPENT NUCLEAR FUEL INSTITUTIONAL CONSIDERATIONS

This section, in a general way, summarizes potential impacts of institutional considerations on SNF management. The institutional factors include availability of an infrastructure of personnel with knowledge and training in SNF management; facility capacity for SNF operations; and availability of equipment, facilities, railheads, and roadways for transport of SNF. These factors are important considerations in evaluating and selecting technology options for SNF management.

J-5.1 Availability of Technical Personnel Trained in Spent Nuclear Fuel Management

The management of SNF requires personnel qualified and experienced in a number of appropriate skill areas and operations. The skill areas include proficiency in the design, fabrication, and use of special tooling; specific training in safety and radiation protection; specific understanding of criticality controls; an understanding of SNF and SNF handling and shipping operations; and emergency preparedness capabilities. Most operations involving SNF must be performed remotely in hot cells.

The disciplines specific to SNF management include mechanical and structural engineering, construction engineering, radiation protection, nuclear safety, industrial safety, chemistry, and nuclear physics.

J-5.2 Availability of Facilities for Spent Nuclear Fuel Management Operations

Important facilities factors to be considered in SNF management include availability and adequacy of existing facilities for storing and stabilizing of SNF and the design requirements for new facilities. Important factors when evaluating existing facilities include fuel type to be handled, fuel integrity, type of storage (for example, wet or dry), stabilization requirements, capacity and condition of dry storage facilities, and any conditioning or processing that could be required for ultimate disposition.

J-5.3 Transport of Spent Nuclear Fuel

Important factors relating to transport of SNF include fuel reactivity or stability, availability of shielded casks, availability of cask-handling cranes with adequate capacity, status of licenses and permits for a particular site, availability of transport equipment and loading and unloading facilities, availability of qualified roadways and/or railheads, and vehicle tracking and communications capabilities.

J-5.4 Safeguards and Security

The management of SNF typically requires rigorous safeguards and security controls to protect the fissile material within the SNF from diversion. In addition, protection of personnel, the public, and environment must be maintained. These requirements result in specific safeguards and security criteria that include access control to areas where SNF is handled, stored, and processed and the maintenance of controlled databases to account for fuels and their inventory of fissile materials.

J-5.5 Current Federal and State Agreements

DOE has entered into agreements with state governments that apply to SNF sites. The DOE agreement with the State of New York provides that the SNF will be removed from the West Valley Site to another DOE site. An agreement among the DOE, Navy, and State of Idaho regarding the Idaho National Engineering Laboratory provides for removal of SNF from underwater storage in the north and middle basins of Building CPP-603 by the end of 1996 and from the south basin of this facility by the end of 2000. There is also an agreement among the DOE, U.S. Environmental Protection Agency, and State of Washington regarding the Hanford Site that requires the removal of SNF and pool sludge from the Building 105-K basins.

J-5.6 Maintaining Flexibility Until Ultimate Disposition is Available

Some stabilization technologies for storage may be undesirable if they could potentially make a later conversion to an acceptable form for ultimate disposition very difficult. For example, SNF stabilized for interim storage could be precluded from ultimate disposition by certain possible acceptance criteria.

APPENDIX K Environmental Consequences Data

Appendix K

Environmental Consequences Data

This appendix presents data that were used to discuss environmental consequences and to generate the graphics used in comparing environmental consequences among alternatives (in Chapter 3) and among alternatives and sites (in Chapter 5). These data are taken from Volume 1 Appendices A through F and converted as required to different units or time periods. To understand the technical basis and context for each of the reported data elements, refer to the appropriate site appendix:

Hanford Site	Appendix A
Idaho National Engineering Laboratory	Appendix B
Savannah River Site	Appendix C
Naval Nuclear Propulsion Program	Appendix D
Other Generator/Storage Locations	Appendix E
Nevada Test Site and Oak Ridge Reservation	Appendix F

The appendix contains (a) a key to alternatives, (b) a summary of data by alternative, and (c) a summary of data by alternative and site. The key to alternatives defines the site combinations represented by the subalternatives and options and relates these to the columns in Tables K-1 and K-2. The summary of data by alternative in Table K-1 presents the summed (or maximum) impacts across all sites involved in that alternative, subalternative, and option. The summary of data by alternative and site in Table K-2 presents data for each site that is affected by that alternative, subalternative, and option. Those sites not affected by a particular option are not shown.

Ten categories of data, numbered in the first column of the attached tables, were used to develop the discussions and graphs in Chapter 5 and are summarized by discipline below.

1. Land Use-The value presented is an estimate of the amount of additional acreage that would be disturbed if a particular alternative was implemented. Minimum and maximum values were provided for options within each alternative where available. The maximum percent of the total site area that would be dedicated to spent nuclear fuel (SNF) management activities was also calculated. Land use impacts are discussed in Section 5.2.1 of Volume 1. A detailed discussion on land use is provided in Appendices A through F.

2. Employment Related to SNF Management-The values presented are the projected 10-year average changes in site employment related to proposed SNF management activities for the period from 1995 to 2005. Minimum and maximum values were calculated where data were available. Baseline site employment refers to the sitewide employment at June 1995, inclusive of those employed in SNF management activities. The maximum percent of baseline site employment represents the maximum incremental change in sitewide employment that might occur because of the proposed SNF management activities. SNF-related employment is discussed by alternative in Section 5.1, Chapter 5, Volume 1. A detailed analysis of socioeconomic impacts is provided in Appendices A through F.

3. Population Collective Dose-The radiation dose that would be received by the population within 80 kilometers (50 miles) of each site per year from normal operations. It is derived from data in the site appendices and represents the dose for the maximum option within each alternative. Because of the differences in methods used to generate the data, the estimated SNF management doses are

sometimes higher than total site doses. The SNF management doses were developed by modeling releases from existing and proposed facilities, and sitewide doses were determined by a combination of modeling of existing facilities and monitoring data. The monitoring data are more accurate, while the modeling approach overestimates expected dose, making the expected dose higher than would probably be realized. Population collective doses are described by alternative in Section 5.1, Chapter 5, Volume 1.

4. Maximally Exposed Individual (MEI)-The MEI is a hypothetical person located downwind at the site boundary closest to the facilities that might have radiation releases. The MEI doses are calculated by modeling releases from existing and proposed facilities from normal operations. Data on the MEI doses can be found in Appendices A through F and represent the dose for the maximum option within each alternative.

5. Worker Dose-The dose that would be received by workers at facilities, based on expected radiation levels at those facilities for normal operations. Sitewide worker doses are based on historical monitoring of workers. These values are not particularly useful in comparing among sites or alternatives as worker doses are controlled by limiting worker involvement in activities that could result in exposures to radiation. Both individual doses and collective doses to workers are taken from Appendices A through F.

6. Water Use-The values represent an estimate of the change in annual consumption of water (in millions of gallons) that may result from the proposed SNF management activities for a given alternative. Minimum and maximum values are provided where available. The baseline water use is the annual water consumption for a site for all operations. The maximum percent of baseline site water represents the annual maximum incremental change in water use that would occur because of the proposed SNF management activities. Water impacts are discussed in Section 5.2.6, Chapter 5, Volume 1. A detailed discussion of water use and related consequences is provided in Appendices A through F.

7. Electricity Use-The values represent an estimate of the change in annual power consumption (in megawatt-hours per year) that would result from the proposed SNF management activities for a given alternative. Minimum and maximum values are provided where available. The baseline site electricity use is the annual power consumption for a site for all operations. The maximum percent of site electricity use represents the annual maximum incremental change in power consumption that would occur because of the proposed SNF management activities. Electricity use is discussed by alternative in Section 5.1, Chapter 5, Volume 1. A detailed discussion of electricity use is provided in Appendices A through F.

8. Sewage-The values represent an estimate of the change in annual rate of wastewater generation (in millions of gallons) that would result from the proposed SNF management activities for a given alternative. Minimum and maximum values are provided where available. The baseline site sewage value represents the annual volume of wastewater generated from total site operations. The maximum percent of baseline site sewage represents the annual maximum incremental change in wastewater generation that would occur because of the proposed SNF management activities. Wastewater generation is discussed in Section 5.2.9 of Volume 1. A detailed discussion of wastewater generation is provided in Appendices A through F.

9. Waste Volume Estimates (high-level, transuranic, mixed, and low-level waste)-The annual generation rate of these waste types (in cubic meters per year) from the proposed SNF management activities is provided. These values represent 10-year cumulative generation rates divided by ten.

Minimum and maximum values are provided where available. The waste volumes are discussed by alternative in Section 5.1 of Volume 1. A detailed discussion of the waste-generating activities at each site is provided in Appendices A through F.

10. Facility Accidents-For accidents, the individual and collective dose values in the tables represent the consequences for the accident having the highest radiological risk (dose times frequency, not necessarily the highest dose) to the public or to workers. The accidents selected for reporting are not necessarily the same for workers and the general population. In each category, the accident with the highest risk was selected, which may be different for workers and the general population. Doses and risks in Table K-2 are the maximum values from each alternative in Table K-1. Accident analyses reported in this summary are based on SNF management-related activities only and are found in the site appendices. Doses from accidents are described by alternative in Section 5.1 of Volume 1. The Savannah River Site did not quantify the worker dose for the maximum risk accident because the safety analysis reports from which accident information was extracted were prepared before the issuance of DOE Order 5480.23 (DOE 1992). Before 1992, applicable DOE orders did not require the inclusion of worker doses in safety analysis reports. Appendix C to Volume 1 of this EIS provides a co-located worker dose rather than a worker dose for the maximum risk accident.

11. Transportation-For incident-free transportation, the values in Table K-2 represent the total annual average fatalities from shipments of SNF for each alternative. Total fatalities are the sum of radiation-related latent cancer fatalities for transportation workers and the general population, plus nonradiological fatalities from vehicular emissions. These data are an aggregate of the data presented in Appendices A, B, C, D, and I. For transportation accident risks, two sets of data are presented in Table K-2 for each alternative. The estimated risks of cancer fatalities represent the radiological risk from transportation accidents. The estimated risk of traffic fatalities represent the nonradiological risk from traffic accidents. Both quantities are on an annual average basis. These data are an aggregate of the data presented in Appendices D and I.

The data in Table K-1 have been rounded to two significant figures, the greatest number of significant figures that can be justified with this analysis. Zero values indicate no impact for that parameter. In the summary table by alternatives, however, missing site data are treated as zeroes, so the impacts for given alternatives can be understated. Missing data are indicated by blanks. Missing values exist only where impacts are expected to be very small or trivial, so the magnitude of underestimation is probably also small.

Table K-1 shows the magnitude of differences between alternatives is very low. To understand observed differences between alternatives, Chapter 5 of this EIS should be consulted. Differences between sites within an alternative require examination of the site-specific appendices for the reasons noted above.

Key to Alternatives and Sites

No Action: Very limited SNF shipments, limited upgrades to facilities, limited stabilization.

Decentralization: Non-DOE sites (except Navy) transport to DOE sites, some upgrades to facilities, stabilization.

- Option A: No examination of naval SNF
- Option B: Limited examination of naval SNF at Puget Sound Naval Shipyard
- Option C: Full examination of naval SNF at Idaho National Engineering Laboratory; SNF returned to Navy sites for storage

1992/1993 Planning Basis: New SNF transported to Idaho National Engineering Laboratory or Savannah River Site, facility upgrades and expansion, stabilization.

Regionalization: SNF transported to regional sites, facility upgrades and expansion, stabilization.

4A: SNF to Idaho National Engineering Laboratory or Savannah River Site depending on fuel type

4B: SNF to Western or Eastern Regional Site depending on geography

Option	Western Regional Site	Eastern Regional Site	Expended Core Facility location
1E	Hanford Site	Savannah River Site	Savannah River Site
1W	Hanford Site	Savannah River Site	Hanford Site
2W	Idaho National Engineering Laboratory	Savannah River Site	Idaho National Engineering Laboratory
3E	Nevada Test Site	Savannah River Site	Savannah River Site
3W	Nevada Test Site	Savannah River Site	Nevada Test Site
4E	Hanford Site	Oak Ridge Reservation	Oak Ridge Reservation
4W	Hanford Site	Oak Ridge Reservation	Hanford Site
5W	Idaho National Engineering Laboratory	Oak Ridge Reservation	Idaho National Engineering Laboratory
6E	Nevada Test Site	Oak Ridge Reservation	Oak Ridge Reservation
6W	Nevada Test Site	Oak Ridge Reservation	Nevada Test Site

Centralization: SNF transported to central site, facility upgrades and expansion, stabilization.

Option A: Hanford Site is the central site
Option B: Idaho National Engineering Laboratory is the central site
Option C: Savannah River Site is the central site
Option D: Oak Ridge Reservation is the central site
Option E: Nevada Test Site is the central site

Hanford	Hanford Site
INEL	Idaho National Engineering Laboratory
SRS	Savannah River Site
ORR	Oak Ridge Reservation
NTS	Nevada Test Site
Navy	Navy shipyards and prototype locations
Other	Small DOE, other government, and university research reactor sites

Appendix L

Environmental Justice

L-1 INTRODUCTION

in Minority Populations and Low-Income Populations (FR 1994), was released to Federal agencies. This order directs Federal agencies to incorporate environmental justice as part of their missions. As such, Federal agencies are specifically directed to identify and address as appropriate disproportionately high and adverse human health or environmental effects of their programs, policies, and activities on minority populations and low-income populations. In addition to describing environmental justice goals, Executive Order 12898 directs the Administrator of the Environmental Protection Agency to convene an interagency Federal Working Group on Environmental Justice (referred to below as the Working Group). The Working Group is directed to provide guidance to Federal agencies on criteria for identifying disproportionately high and adverse human health or environmental effects on minority populations and low-income populations. The Working Group is also directed to coordinate with each Federal agency to develop an environmental justice strategy, if a strategy is required by the proposed activities. At the time of this analysis, the Working Group had not issued final guidance on the approach to be used in analyzing environmental justice, as directed by the Executive Order.

The Working Group has issued draft definitions of terms in the Draft Guidance for Federal Agencies on Terms in Executive Order 12898, dated November 28, 1994. These definitions, with slight modifications, were used in the following analysis. Further, in coordination with the Working Group, DOE is developing internal guidance for the implementation of the Executive Order, which has not yet been adopted. Because both DOE and the Working Group are still in the process of developing guidance, the approach used in this analysis might depart somewhat from whatever guidance is eventually issued.

This section provides an assessment of the areas surrounding the 10 sites under consideration for the management of SNF under all programmatic alternatives considered in this volume. It is divided into two sections: (a) the five sites considered for the management of DOE naval SNF only (under the No Action and Decentralization alternatives, and (b) the five DOE sites being considered for the management of all types of DOE SNF under all alternatives. The five sites considered for the management of naval SNF only are the Norfolk Naval Shipyard, Portsmouth, Virginia; Portsmouth Naval Shipyard, Kittery, Maine; Pearl Harbor Naval Shipyard, Honolulu, Hawaii; Puget Sound Naval Shipyard, Bremerton, Washington; and Kesselring Site, West Milton, New York. The five DOE sites considered for the management of some portion or all DOE SNF are the Savannah River Site, Aiken, South Carolina; Oak Ridge Reservation, Oak Ridge, Tennessee; Idaho National Engineering Laboratory, Idaho Falls, Idaho; Hanford Site, Richland, Washington; and Nevada Test Site, Mercury, Nevada.

This assessment includes potential adverse impacts resulting from both onsite activities and associated transportation of materials. Based on this assessment, it is concluded that none of the alternatives analyzed results in disproportionately high and adverse effects on minority populations or low-income communities surrounding any of the sites under consideration for the management of SNF or associated offsite transportation routes.

L-2 PUBLIC COMMENT RECEIVED ON THE DRAFT ENVIRONMENTAL IMPACT STATEMENT

Public comment received on the Draft EIS is addressed in Volume 3, "Response to Public Comment," of this Final EIS. Overall comment indicated a widespread concern about past and present DOE activities on human health and the environment. A small number of comments were received related to environmental justice; these indicated the need for an expanded analysis in the Final EIS, which was previously committed to in the Draft EIS. The most specific comments were received from the U.S. Environmental Protection Agency's Office of Enforcement and Compliance Assurance and the Shoshone-Bannock Tribes on the Fort Hall Indian Reservation. Environmental justice comments pertaining to Volume 1 of this EIS were in essence:

> Although the Draft EIS includes discussions on socioeconomic impacts, it does not state whether the alternatives would affect minority communities and low-income communities (Sanderson 1994).

> The DOE should pay particular attention to any environmental impacts that may affect the Cattaraugus Reservation of the Seneca Nation of Indians, located downstream on Cattaraugus Creek from the DOE's West Valley Site in New York State. Tribal residents engage in subsistence fishing on the river and should be given a full opportunity to participate in the National Environmental Protection Agency process (Sanderson 1994).

> The DOE must meet the requirements of Executive Order 12898 on environmental justice and fully consider the comments of the Shoshone-Bannock Tribes on the Draft EIS and consider the impacts of its proposed actions on the Tribes, the Fort Hall Indian Reservation, and on other disadvantaged populations living in proximity to the Idaho National Engineering Laboratory. It was stated that the Indian Tribes are not just another "minority population," but are governments that have a special relationship to the Federal Government

and its agencies and have certain authorities to regulate others including the United States Government (Tinno 1994, Wolfley 1994).

Pertinent public comments on the topic of environmental justice have been considered in this assessment, which has been expanded over the discussions in the Draft EIS. Consultations have taken place with the Shoshone-Bannock Tribes on the Fort Hall Indian Reservation and the Seneca Nation of Indians on the Cattaraugus Reservation. As a result of consultations with the Seneca Nation of Indians, DOE and the Navy have received a request by this tribe for notification of impending SNF shipments across the Cattaraugus Reservation. Consultations with the Shoshone-Bannock Tribes on the Fort Hall Indian Reservation are specifically addressed in Section 5.20, Volume 2 of this EIS.

L-3 COMMUNITY CHARACTERISTICS

Demographic information obtained from the U.S. Bureau of Census was used to identify minority populations and low-income communities in the zone of potential impact surrounding each of the sites under consideration. This zone is within a circle that has an 80-kilometer (50-mile) radius. This 80-kilometer (50-mile) radius was selected because it was judged to encompass all of the impacts that may occur. This radius also is based on air impact modeling and socioeconomic impact analysis used throughout this EIS. Transportation impacts are assessed within 800 meters (0.5 miles) of transportation routes for incident-free transportation because impacts beyond this distance are negligible. For transportation accidents, an 80-kilometer (50-mile) radius was used.

L-3.1 Methodology

Demographic maps were prepared using 1990 census data available from the U.S. Bureau of the Census. Figures L-1 through L-10 and Figures L-11 through L-20 illustrate census tract distributions for both minority populations and low-income populations for areas surrounding the five naval SNF-specific and five DOE sites being considered for the management of all or some portion of all DOE SNF respectively. These maps are based on an analysis of 1990 United States Bureau of the Census Tiger Line files, which contain political boundaries and geographical features, and Summary Tape Files 3A (as processed by the U.S. Environmental Protection Agency), which contain demographic information (USBC 1992). Data were resolved to the census tract (see definition in Section 3.2) group level.

An 80-kilometer (50-mile) radius circle appears on each map, defining a zone of potential impact. As discussed above, this zone of potential impact for low-income and minority communities is the same as that used for analysis performed in the EIS. The circle has been indexed to the center location of hypothetical or existing major SNF management facilities at each site or a conservative location to identify the maximum number of minority populations and low-income populations.

L-3.2 Definitions

Definitions used to develop community characteristics are as follows:

Census tract: An area defined for the purpose of monitoring census data that is usually comprised of between 2,500 and 8,000 persons, with 4000 persons being ideal. When first delineated, census tracts are designed to be homogenous with respect to population characteristics, economic status, and living conditions. Census tracts do not cross county boundaries. The spatial size of census tracts varies widely depending on the density of settlement. Census tract boundaries are delineated with the intention of being maintained over a long period of time so that statistical comparisons can be made from census to census.

Minority population: A group of people and/or community experiencing common conditions of exposure or impact that consists of persons of the United States classified by the U. S. Bureau of the Census as Negro/Black/African-American, Hispanic, Asian and Pacific Islander, American Indian, Eskimo, Aleut, and other nonwhite persons, based on self-classification by the people according to the race with which they most closely identify. For the purposes of analysis, minority populations are defined as those census tracts within the zone of impact for which the percent minority population exceeds the average of all census tracts within the zone of impact or where the percent minority population exceeds 50 percent of the spacial area for any given census tract. In the case of migrant or dispersed populations, a minority population consists of a group that is greater than 50 percent minority.

Low-income population: A group of people and/or community experiencing common conditions of exposure or impact in which 25 percent or more of the population is characterized as living in poverty (FR 1993) The U.S. Bureau of Census characterizes persons in poverty as those whose income is less than a "statistical poverty threshold." Table L-1 presents the U.S. Census poverty thresholds (USBC 1992) used in this analysis. This threshold is a weighted average based on family size and the age of the persons in the family. For instance, the 1990 census threshold for a family of four was a 1989 income of $12,674 .

Population Base: For the purpose of this analysis, census tracts were included in the analysis if 50 percent of the tract fell within the 80-kilometer (50-mile) radius.

Table L-1. Poverty thresholds in 1989 by size of family and number of related children under 18 years.

Size of family unit	Weighted average threshold ($)	Related children under 18 years								
		None ($)	One ($)	Two ($)	Three ($)	Four ($)	Five ($)	Six ($)	Seven ($)	Eight or more ($)
One person (unrelated individual)	6,310									
Under 65 years	6,451	6,451								
65 years and over	5,947	5,947								
Two persons	8,076									
Household under 65 years	8,343	8,303	8,547							
Household 65 years and over	7,501	7,495	8,515							
Three persons	9,885	9,699	9,981	9,990						
Four persons	12,674	12,790	12,999	12,575	12,619					
Five persons	14,990	15,424	15,648	15,169	14,796	14,572				
Six persons	16,921	17,740	17,811	17,444	17,092	16,569	16,259			
Seven persons	19,162	20,412	20,540	20,101	19,794	19,224	18,558	17,828		

Eight persons	21,328	22,830	23,031	22,617	22,253	21,738	21,084	20,403	20,230	
Nine or more persons	25,480	27,463	27,596	27,229	26,921	26,415	25,719	25,089	24,933	23,973

L-3.3 Distribution of Minority Populations Near Candidate Sites

The minority population characteristics within the 80-kilometer (50-mile) radius of candidate sites for the SNF and INEL EIS are presented in Tables L-2 and L-3. Table L-2 lists the number of minority individuals residing near the candidate sites for the management of DOE naval SNF. Table L-3 lists the number of minority individuals residing near the candidate sites for the management of all or some portion of DOE SNF.

The racial and ethnic composition of the minority population residing near the candidate naval sites is predominantly African-American, with the exception of Pearl Harbor where the main ethnic population is Asian and Native Hawaiian.

The racial and ethnic composition of the minority population residing near the candidate sites for the management of all or some portion of DOE SNF is predominantly African-American at the Oak Ridge Reservation and Savannah River Site; Hispanic, American Indian, and Asian at the Idaho National Engineering Laboratory; Hispanic and American Indian at the Hanford Site; and Hispanic and African-American at the Nevada Test Site.

Table L-2. Minority individuals residing near the candidate sites for the management of DOE naval spent nuclear fuel only per the 1990 census.

Candidate Site	Number of census tracts considered	Number of individuals residing within 80 km of site	Number of minority individuals within 80 km of site	Percent of individuals that are minority	See figure
Kesselring Site	304	1,148,924	65,590	6	L-1
Norfolk Naval Shipyard	386	1,631,671	534,585	33	L-2
Puget Sound Naval Shipyard	643	2,960,229	379,461	13	L-3
Portsmouth Naval Shipyard	522	2,412,691	121,516	5	L-4
Pearl Harbor Naval Shipyard	200	836,465	571,482	68	L-5

Table L-3. Minority individuals residing near the candidate sites for the management of all or some portion of DOE spent nuclear fuel per the 1990 census.

Candidate Site	Number of census tracts considered	Number of individuals residing within 80 km of site	Number of minority individuals within 80 km of site	Percent of individuals that are minority	See figure
Savannah River Site	147	619,959	233,955	38	L-6
Oak Ridge Reservation	211	867,231	49,742	6	L-7
Idaho National	37	172,366	11,722	7	L-8

Engineering Laboratory					
Hanford Site	79	370,807	75,381	20	L-9
Nevada Test Site	4	11,918	759	6	L-10

The spatial distribution by census tract of the minority population within 80 kilometers (50 miles) of each candidate site is shown in Figures L-1 through L-10. As indicated in the legend of each figure, census tracts have been shaded according to the percentage of minority individuals within the area. It should be noted that Bureau of Census tracts often extend into oceans, bays, and lakes to allow for the inclusion of individuals who reside on boats or offshore houses. This is especially noticeable in locations considered only for the management of DOE naval SNF, with the exception of the inland Kesselring Site. Census tract lines have been removed from Puget Sound proper in Figures L-3 and L-13 to improve clarity.

L-3.4 Distribution of Low-Income Individuals Near the Candidate Sites

The low-income population characteristics within the 80-kilometer (50-mile) radius of candidate sites for the SNF and Idaho National Engineering Laboratory EIS are presented in Tables L-4 and L-5. Table L-4 lists the number of low-income individuals residing near the candidate sites

Table L-4. Low-income individuals residing near the candidate sites for the management of naval spent nuclear fuel only per the 1990 census.

Candidate site	Number of census tracts considered	Number of individuals within 80 km of site	Number of low-income individuals within 80 km of site	Percent of individuals that are low-income	See figure
Kesselring Site	304	1,148,924	101,424	9	L-11
Norfolk Naval Shipyard	386	1,631,671	179,336	11	L-12

Figure L-9. Minority population distribution within 80 kilometers (50 miles) of the Hanford Site. Figure L-10. Minority population distribution within 80 kilometers (50 miles) of the Nevada Test Site.for the management of naval SNF. Table L-5 lists the number of low-income individuals residing near the candidate sites for the management of all or some portion of DOE SNF.

The spatial distribution by census tract of low-income individuals residing within 80-kilometers (50 miles) of each candidate site are shown in Figures L-11 to L-20. As indicated in the legend of each figure, census tracts have been shaded according to the percentage of low-income population within the area.

L-3.5 Limitations of Demographic Data

As discussed in Section 5.8 of Volume 1 of this EIS, characterization of minority and low-income populations residing within a geographical area is sensitive to the basic definitions and assumptions used in conducting the analysis to identify them. Both the Interagency Working Group and DOE are in the process of preparing final guidelines for use in the evaluation of environmental justice. In the absence of final guidance, the definitions and approaches being used by and within Federal agencies could vary. For example, this EIS and the Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor SNF (Draft FRR SNF EIS) present demographic characterizations obtained from the same U.S. Census Bureau database, but use different definitions and assumptions.

The differences in the definitions and assumptions between this EIS and the Draft FRR SNF EIS are as follows:

1. Although both these EISs use the same 1990 U.S. Census Bureau database, this EIS uses data aggregated at the census tract level (2,500 to 8,000 persons), while the Draft FRR SNF EIS uses data aggregated at the block group level (250 to 550 housing units).

2. In some cases, census blocks or tracts lie partly within the area being analyzed; that is, within the 80-kilometer (50-mile) radius around a potential SNF management site. Because the exact distribution of the populations within such blocks or tracts is not available, the data are insufficient to allow a precise count. To address this situation, this EIS includes a low-income or minority population in its analyses if 50 percent or more of the tract falls within an 80 kilometer (50 mile) radius around the site being considered. In similar situations, the Draft FRR SNF EIS assumes that the general population and the minority population are distributed uniformly throughout a block group, and includes the fraction of the low-income or minority population that corresponds to the fraction of the census block group area that falls within the 80-kilometer (50-mile) radius.

Figure L-11. Low-income population distribution within 80 kilometers (50 miles) of the Kesselring Site. Figure L-12. Low-income population distribution within 80 kilometers (50 miles) of the Norfolk Naval Shipyard.

Figure L-13. Low-income population distribution within 80 kilometers (50 miles) of the Puget Sound Naval Shipyard.

Figure L-14. Low-income population distribution within 80 kilometers (50 miles) of the Portsmouth Naval Shipyard.

Figure L-15. Low-income population distribution within 80 kilometers (50 miles) of the Pearl Harbor Naval Shipyard.

Figure L-16. Low-income population distribution within 80 kilometers (50 miles) of the Savannah River Site.

Figure L-17. Low-income population distribution within 80 kilometers (50 miles) of the Oak Ridge Reservation.

Figure L-18. Low-income population distribution within 80 kilometers (50 miles) of the Idaho National Engineering Laboratory.

Figure L-19. Low-income population distribution within 80 kilometers (50 miles) of the Hanford Site.

Figure L-20. Low-income population distribution within 80 kilometers (50 meters) of the Nevada Test Site.

3. This EIS defines low-income populations as those in a poverty status as determined annually by the U.S. Census Bureau, based on the Consumer Price Index, and aggregated by the thresholds set forth by the U.S. Census Bureau (that is, a group of people and/or a community experiencing common conditions of exposure or impact, in which 25 percent or more of the population is characterized as living in poverty), a method used by the U.S. Environmental Protection Agency. The Draft FRR SNF EIS uses the definition of low-income community, established by the U. S. Department of Housing and Urban Development, as an area for which the median household income is 80 percent or below the median household income for the metropolitan statistical area (urban) or county (rural). Both definitions are permitted under the draft guidance developed by the Interagency Working Group.

These different definitions and assumptions have resulted in differences in the characterization of low-income and minority populations. The two sets of data are summarized in Tables L-6 and L-7, and the most significant differences are discussed below.

The minority populations identified are reasonably consistent between this EIS and the Draft FRR SNF EIS, except for results obtained at the Nevada Test Site (the largest proportional difference) and the Hanford Site (the largest difference in numbers of individuals), as shown in Table L-6. The range in results for both locations is due to the different aggregations of the demographic data used (census tracts vs. blocks), and the differences in the methods used to account for the populations of tracts or groups lying only partly within the area being analyzed, as discussed above. For example, both sites are located in rural or sparsely populated regions so that census tracts surrounding the sites are relatively large in geographical area. In addition, the outskirts of Las Vegas, Nevada, begin approximately 80 kilometers (50 miles) from the Nevada Test Site, making the analysis particularly sensitive to differences in treatment of census tracts or block groups that lie partly within a circle of 80-kilometer (50-mile) radius centered at that site. Most areas within the zone of impact of the Nevada Test Site are restricted access and unpopulated lands.

As a result of the different definitions used for the identification of low-income populations, the results of these analyses are markedly different, as shown in Table L-7. Both sets of data are correct. They reflect the fact that different definitions and assumptions can result in different characterizations of low-income populations.

Table L-6. Comparison of the DOE Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement (SNF & INEL EIS) and the Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel (Draft FRR SNF EIS) minority characterization results.

L-4 ENVIRONMENTAL JUSTICE ASSESSMENT

This assessment of potential environmental justice impacts addresses activities associated with the programmatic management of DOE SNF discussed in this EIS.

L-4.1 Methodology and Definitions

Analysis of environmental justice concerns was based on a qualitative assessment of the impacts reported in Section 5 of Volume 1 of the EIS regarding the proposed action and its alternatives. This analysis was performed to identify any disproportionately high and adverse human health or environmental impacts on minority populations or low-income populations surrounding each of the 10 candidate sites.

For this assessment, the following definitions were used:

Disproportionately high and adverse human health effects: Adverse health effects are measured in risks and rates that could result in latent cancer fatalities, as well as other fatal or nonfatal adverse impacts to human health. Disproportionately high and adverse human health effects occur when the risk or rate for a minority population or low-income population from exposure to an environmental hazard significantly exceeds the risk or rate to the general population and, where available, to another appropriate comparison group.

Disproportionately high and adverse environmental impacts: An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. In assessing cultural and aesthetic environmental impacts, account shall be taken of impacts that uniquely affect geographically dislocated or dispersed low-income or minority populations.

In this assessment, DOE reviewed the human health effects and environmental impacts associated with the siting of the alternatives analyzed in Volume 1 of this EIS. This review included potential impacts arising under each of the major disciplines evaluated for the alternatives, including land use, socioeconomics, water resources, air resources, ecology, health and safety, facility operations, cultural resources, and transportation, which are the sciences pertinent to the identification of environmental impacts in the EIS. Regarding health effects, both normal facility operations and accident conditions were examined, with accident scenarios evaluated in terms of the risk to the public. Likewise, the examination of transportation included both normal and potential accident conditions for both truck and rail transportation of DOE SNF. Special exposure pathways were evaluated with respect to subsistence consumption of fish, game, or native plants.

L-4.2 Results

Potential radiological impacts because of both facility operations and reasonably foreseeable accident conditions are small for all management alternatives and potential sites considered in this EIS. Likewise, the number of potential fatalities due to both radiological and nonradiological exposures to truck or rail transportation are small. There is also little probability of adverse impacts because of subsistence consumption of fish, game, or native plants.

L-4.2.1 Results of Environmental Justice Assessment Near the Alternative Sites

Considered for the Management of Naval Spent Nuclear Fuel Only

The five sites evaluated for the management of naval SNF only are specifically addressed in Appendix D to Volume 1 of the EIS. Additional environmental justice matters pertaining to the naval sites are included in Appendix D. It should be noted that, with one exception, these five alternative sites are only considered for storage of naval SNF under the No Action and Decentralization alternatives. The one exception is the partial examination of naval SNF at the Puget Sound Naval Shipyard under Decentralization alternative 2B. Under all other alternatives, these five sites would transport naval SNF to one or several of the larger five DOE sites analyzed in this EIS, and evaluated from an environmental justice perspective in Section L-4.2.2.

L-4.2.1.1 Incident-Free Human Health Effects and Environmental Impacts. As

discussed in Appendix D to Volume 1 of this EIS, the impacts on human health or the environment resulting from operations associated with the management of naval SNF at any of the five locations limited to the storage of naval SNF would be small under any of the alternatives considered. This includes the impacts of incident-free transportation. For example, it is unlikely that a single fatal cancer would occur as a result of naval SNF management activities under any alternative at any one of the five sites. Also, it is unlikely that a single fatal cancer would occur as a result of activities associated with naval SNF examination under any alternative considered in the EIS. In fact, naval SNF could be managed at any of the five sites for between 7,100 and 43,500 years (depending on the site) before a single fatal cancer would be expected. Because the impacts as a result of incident-free operations present no significant risk and do not constitute a reasonably foreseeable adverse impact to the surrounding population, no disproportionately high and adverse effects would be expected for any particular segment of the population, minority populations and low-income populations included (see Tables L-2 and L-4).

L-4.2.1.2 Human Health Effects and Environmental Impacts Because of Accidents.

As discussed in Appendix D, the impacts on human health and the environment resulting from the risk of facility or transportation accidents at any of the five locations limited to the storage of naval SNF would be small under any of the alternatives considered. As explained in the EIS, the risk to the public is defined as the potential consequence of an accident multiplied by its probability of occurrence. This risk calculation represents the expected impact to members of the public. Based on this risk calculation, it is unlikely that a single fatal cancer would occur from reasonably foreseeable facility or transportation accidents related to naval SNF management activities under any of the alternatives. Because the potential impacts as a result of an accident for any of the alternatives considered would present no significant risk and do not constitute a reasonably foreseeable adverse impact to the surrounding population, no disproportionately high and adverse effects would be expected for any particular segment of the population, minority populations and low-income populations included (see Tables L-2 and L-4).

L-4.2.1.3 Effects of Natural Motive Forces. Impact analysis indicates that there would not be

disproportionately high and adverse impacts on human health and the environment resulting from the prevailing winds or the direction of surface or subsurface water flow. This is true for site operations because the effects of routine operations on air and water quality are so small. It is also true for accident conditions because the consequences of any accident, however unlikely its chance of occurrence, would depend on the random conditions at the time it occurred. The wind conditions at the Pearl Harbor Naval Shipyard are variable, but the predominant wind direction is toward the southwest, away from land and residential areas. The wind directions at the other four sites are highly variable with no strongly dominant direction.

L-4.2.1.4 Effects on Subsistence Consumption of Fish and Wildlife. Available data do

not show potential for disproportionately high and adverse impacts to minority and low-income communities related to subsistence consumption of fish and wildlife in the vicinity of these five sites under any alternative. Environmental monitoring in the vicinity of these relatively small and restricted sites has shown no detectable difference in the amounts of radionuclides present in the environment from levels in similar parts of their respective regions.

L-4.2.2 Results of Environmental Justice Assessment Near the Alternative Sites

Considered for the Management of All or Some Portion of DOE Spent Nuclear Fuel

The five sites evaluated for the management of all or some portion of DOE SNF are specifically addressed in Appendices A (Hanford Site), B (Idaho National Engineering Laboratory), C (Savannah River Site), and F (Nevada Test Site and the Oak Ridge Reservation) to Volume 1 of the EIS. It should be noted that these five alternative sites are considered for the management of DOE SNF under all alternatives analyzed in this EIS. The one exception is the Nevada Test Site, which is not considered in the No Action, Decentralization, and 1992/1993 Planning Basis alternatives because no SNF is currently managed at that site.

L-4.2.2.1 Facility Operations. This EIS considers the impacts from the operations of both

existing and new facilities on a site-by-site basis as appropriate for programmatic decisionmaking. Site-specific implementation of the programmatic strategy for the management of SNF for the 40-year interim period between 1995 and 2035 will be subject to additional National Environmental Policy Act review, as appropriate on a case-by-case basis. Both incident-free operations and reasonably foreseeable accidents were analyzed in terms of risk to both workers and the public. The potential impacts calculated for both incident-free operations and the risk of reasonably foreseeable accidents present no significant risk and do not constitute a reasonably foreseeable adverse impact to the surrounding population as discussed below. Therefore, no disproportionately high and adverse effects would be expected for any particular segment of the population, minority populations and low-income populations included.

L-4.2.2.1.1 Incident-Free Operations-In Table K-2 of Volume 1 of this EIS, it is

shown that under all the alternatives, the estimated number of latent cancer fatalities from the normal operation of DOE SNF management facilities would range from approximately zero to about two latent cancer fatalities over the 40 year period, or about 0.05 latent cancer fatalities per year. Therefore, no disproportionately high and adverse effects would be expected for any particular segment of the population, minority populations and low-income populations included (see Tables L-3 and L-5).

L-4.2.2.1.2 Reasonably Foreseeable Accidents-As explained in Section 5.1.1.4 of

this EIS, the risk to the public is defined as the potential consequence multiplied by the probability of occurrence. This risk calculation represents the expected impact to members of the public. The calculated risk of latent cancer fatalities associated with reasonably foreseeable facility accidents is small for all alternatives. The evaluated facility accident with the highest risk (breach of a fuel assembly for the Centralization alternative at the Savannah River Site) would result in an estimated 0.0072 latent cancer fatality per year, which equates to one fatal cancer in 140 years of operation. Impacts from high-consequence, low-probability accident scenarios would be adverse should they occur; however, the impacts to specific population locations would be subject to meteorological conditions on the day of the accident. Whether or not such impacts would have disproportionately high and adverse effects with respect to any particular segment of the population, minority and low-income populations included, would be subject to natural motive forces, including random meteorological factors (see Tables L-3 and L-5).

L-4.2.2.1.3 Natural Motive Forces-Offsite health effect impacts from operations and

reasonably foreseeable accidents are propagated by natural motive forces such as meteorological conditions and water pathways, both surface and subsurface. Impacts because of incident-free operations are dominated by prevailing patterns in these natural motive forces, whereas the impacts of an accident, should one occur, would be random based on the meteorological conditions at the time of and following occurrence. The following conditions are prevalent at each of the five large DOE sites under consideration:

Prevailing winds for the Idaho National Engineering Laboratory are primarily from the southwest, although winds at the Test Area North are frequently from the north and west-northeast. Local rivers and streams drain mountain watersheds to the north and west of the Idaho National Engineering Laboratory, but most surface water is diverted for irrigation before it reaches the site boundaries. Groundwater in the underlying Snake River Plain Aquifer generally flows to the south and southwest (see Figures L-8 and L-18).

Prevailing wind conditions at the Savannah River Site are from the northeast and west-southwest. Both onsite surface streams and groundwater aquifers generally drain in a southwesterly direction, toward the Savannah River, which flows southeast to Savannah, Georgia (see Figures L-6 and L-16).

The prevailing wind direction at the Oak Ridge Reservation is from the southwest, with a secondary pattern from the northeast during the winter, spring, and summer months. The situation is reversed in the fall. Surface and shallow subsurface water in an area susceptible to the potential siting of SNF management facilities would flow south into Grassy Creek and then to the Clinch River. The Clinch River flows southwest and west around the reservation and subsequently to the Tennessee River. Deeper groundwater tends to remain relatively stationary because of high retention times (see Figures L-7 and L-17).

Prevailing winds at the Nevada Test Site are from the south during the summer and the north during the winter. Surface topography usually results in a wind reversal from the south in the day to the north during the night. Almost all surface water is transient and short-lived in nature. In an area susceptible to the siting of SNF management facilities, surface water would flow east towards Frenchman Lake, where it would be lost by evaporation or recharge to the local groundwater system which discharges to the southwest. Water discharged beneath the site would likely either evaporate or remain indefinitely because of the great depth of the groundwater at the site (see Figures L-10 and L-20).

Prevailing winds at the area of interest on the Hanford Site are from the northeast in all months of the year, with the second predominant pattern occurring from the southwest, primarily during the spring and fall. Roughly two-thirds of any surface water runoff would drain to the Columbia River, with the rest draining to the Yakima River and joining the Colombia River below the Hanford Site. Groundwater systems underlying the Hanford Site tend to flow toward the Columbia River in a southeast and northeast direction (see Figures L-9 and L-19).

As indicated in Appendix K of this EIS, the risk of impacts from incident-free routine operations and from reasonably foreseeable accidents is so small that the propagation by motive forces is essentially of no consequence.

L-4.2.2.2 Transportation. Transportation corridors associated with shipment of SNF

management by either truck or rail can be classified as roughly 80 percent rural, 17 percent suburban, and 3 percent urban. Specific details of mileage and percentages by route are contained in Table I-1 of Appendix I to Volume 1 of the EIS.

L-4.2.2.2.1 Incident-Free Transportation-For incident-free transportation, the total

number of potential fatalities would be the sum of the health effects because of exposure to radiation and vehicular emissions. The total number of shipments over the 40-year period would vary from about 200 during the transition period for naval SNF under the No Action alternative to about 7,400 shipments if all of DOE's SNF were managed at the Nevada Test Site under the Centralization alternative. The DOE's preferred alternative would result in a total of approximately 3,700 shipments among the sites. The estimated total latent cancer fatalities resulting from incident-free transportation is less than two under the maximum shipment (Centralization) alternative, while the preferred alternative results in less than one fatality.

L-4.2.2.2.2 Transportation Accidents-It is worth noting that the risk of fatalities

associated with vehicular accidents during the transport of SNF is higher than the risk of cancer caused by radiation exposure because of such accidents, although both are very small. Also, the risks associated with radiation because of transportation accidents is even less than the small risk associated with facility accidents. The reasonably foreseeable transportation accident scenario with the largest consequences (SNF rail shipment accident occurring in an suburban area) would lead to 55 latent cancer fatalities; however, the probability of this scenario occurring is about 1 in 10 million. The overall risk (probability multiplied by consequence) of all accidents analyzed, including the above scenario, over the total 40-year timeframe analyzed is much less than one fatality. Over this 40-year timeframe, up to two fatalities could result from vehicular traffic accidents themselves without any radiological releases. When and where an accident occurred, if one in fact occurred, would be completely random with respect to the immediate and surrounding population, as well as the motive forces that could propagate the impacts during the timeframe of occurrence. Although adverse impacts could occur in the unlikely event of a high-consequence accident, any potential disproportionality with respect to any population, minority and low-income populations included, is subject to the randomness of the combination of factors that can produce such impacts.

L-4.2.2.3 Subsistence Consumption of Fish, Wildlife, or Native Plants. The

calculations in this EIS estimate dose and risk from ingestion of radioactive materials based on site-specific agricultural data and assume a typical dietary pattern. Subsistence consumption of fish, wildlife, and native plant species is not explicitly addressed in these analyses. However, the calculations in this EIS include several conservative assumptions that bound the potential for ingestion of radioactivity through these special exposure pathways. In particular, these calculations assume that a very high proportion of the diet is based on locally grown produce and locally grazed livestock, both of which are produced at locations representing the highest calculated concentrations of radioactivity. Nevertheless, there may be some differences between the uptakes of grazed livestock and free-ranging game. No human populations in the immediate vicinity of the any of the five DOE sites are known to subsist entirely on locally harvested fish or wildlife. Fishing is not usually allowed on DOE sites, but some hunting is allowed under controlled conditions.

Game species, locally grazed livestock, fish, locally grown foodstuffs, and native plants around DOE sites are routinely sampled for radionuclides. Concentrations of radionuclides in samples have generally been small, and are seldom elevated above those observed at locations distant from these sites where the principal source of non-natural radionuclides is very small amounts of residual global fallout from past nuclear weapons tests. Data from monitoring programs are reported annually in site-specific environmental reports.

If SNF management activities were to increase wildlife losses because of vehicle collisions with game, there might be a disproportionate impact to minority or low-income communities that rely primarily on hunted game. However, the maximum potential increases in shipments of SNF would be small additions to current rail and highway traffic, so the overall impact to wildlife would be small. Potential mitigation measures for any resulting adverse impact to low-income or minority populations include distributing the deceased animals to hunters in the vicinity known to partially subsist on game, controlling subsequent hunts, or relocating game if necessary.

L-4.2.2.4 Other Considerations. In addition to the above, reviews of other technical disciplines

pursuant to the methodology in Section 4.1 did not indicate any significant adverse impacts because of land use, socioeconomics, water and air resources, ecology, cultural resources, or cumulative impacts. Therefore, no disproportionately high and adverse impacts were identified for any segment of the population. Of particular interest are the following:

L-4.2.2.4.1 Socioeconomics-Depending upon the various alternative evaluated, the

total labor force involved in SNF management could decrease by up to 180 jobs or increase by more than 2,100 jobs averaged over the 10-year implementation period between 1995 and 2005. Affirmative action programs would distribute such effects proportionately among workers, whereas coordination of planning activities with local communities would be intended to avoid placing undue burdens on local community resources. DOE may also provide support to local agencies if necessary to mitigate localized impacts.

L-4.2.2.4.2 Land Use, Ecology, and Cultural Resources-None of the alternatives

would have a significant adverse impact on land use, ecology, and cultural resources because of the limited amount of previously undisturbed land which would be needed for use onsite (no offsite lands are involved) and mitigative programs already in place. These programs include working closely under agreements with State Historical Preservation Officers and Tribal governments regarding preservation of historic and cultural resources. Consultations with Tribal governments have expanded the DOE's awareness of Tribal interests and values with respect to nature, religion, and the land, and are designed to avoid or relocate these resources as possible. If avoidance were not possible, data recovery (such as archiving artifacts) or other mitigation measures may be developed in consultation with affected Tribes and the respective State Historical Preservation Officer, as appropriate. Similarly, the DOE is aware of sensitive ecological resources, and avoids wetlands and endangered plant or animal specie habitats. Disturbance of certain ecological resources (which are not federally listed as threatened or endangered) is possible, but not likely. The reasonably foreseen environmental impacts, if any, to land use, ecological resources, or cultural resources are expected to be small under any of the alternatives.

L-4.2.2.4.3 Cumulative Impacts-Based on the analysis of the impacts for each of the

disciplines analyzed in this EIS, along with the impact of other past, present, and reasonably foreseeable future activities at each of the alternative sites, no reasonably foreseeable cumulative adverse impacts are expected to the surrounding populations, minority populations and low-income populations included (see Tables L-2 through L-5).

L-4.2.2.5 Impacts Because of Perception. Potential adverse impacts may result from the

public's perception of risk associated with nuclear industry activities in general and DOE's activities in particular. For example, a SNF management facility has the potential to increase awareness of the nuclear industry, leading to concerns of potential adverse effects to the conduct of local commerce, whether it be tourism, agriculture, or the like. From both a National Environmental Policy Act and an environmental justice perspective, both the character and substance of these potential impacts is not discernable. Therefore, it is not possible to identify any quantifiably adverse or disproportionately high distribution of any impacts of such perceived risk.

In order to better understand and help mitigate unfounded perceptions, the DOE is working to enhance the general population's understanding of the potential impacts of DOE programs in general and the proposed action in particular, with emphasis on minority populations, low-income groups, and Tribal governments.

L-4.2.3 Perspective

To place the impacts in perspective with respect to risks encountered in everyday life, in 1990, there were approximately 510,000 cancer deaths in the United States population, of which about 64,000 were among the nonwhite population. This equates to an average of roughly 1,132 cancer fatalities (of which 142 would affect minority populations) in an area comparable to that included in the 80 kilometer (50 mile) radius around any of the sites considered in this EIS. Additionally, in 1992, there were about 40,000 traffic fatalities in the United States, of which about 7,400 were among the non-white population. This equates to an average of roughly 89 traffic fatalities (of which 16 would affect minority populations) in an area comparable to that included in the 80-kilometer (50-mile) radius around any of these sites. Based on the risk of additional fatalities provided in Sections L-4.2.1, L-4.2.2.1.2, and L-4.2.2.2.2, the risk to the surrounding population because of DOE SNF management activities would not appreciably increase this total, even if all impacts were associated with minority or low-income populations.

L-5 CONCLUSIONS

The overall review indicated that the potential impacts calculated for each discipline under each of the alternative sites considered for the management of all or some portion of DOE SNF (or naval SNF only) present no significant risk and do not constitute a reasonably foreseeable adverse impact to the surrounding population. Therefore, the impacts of the programmatic management of DOE SNF under all alternatives evaluated in this EIS do not constitute a disproportionately high and adverse impact on any particular segment of the population, minorities or low-income communities included, and thus do not present an environmental justice concern.

The approach to evaluating environmental justice used in this EIS may differ from future guidance issued by the Interagency Working Group or the DOE. Nevertheless, as demonstrated by the different approaches discussed in Section L-3.5, the conclusions are not expected to change because the impacts resulting from the proposed action under all alternatives present no significant risk to the potentially affected populations. As a result, no disproportionately high and adverse effects would be expected for any particular segment of the populations, including minority populations and low-income populations.
