The SRS spent nuclear fuel mission is to manage DOE-owned spent fuel in a cost-effective way that protects the safety of SRS workers, the public, and the environment. The goals of near-term activities are the accurate quantification and characterization of DOE-owned spent nuclear fuel, assessment of spent nuclear fuel storage facilities, elimination of current spent nuclear fuel storage vulnerabilities, and identification of technologies and requirements for interim management and ultimate disposition of spent nuclear fuel.

2.1.4 Management

The DOE Savannah River Operations Office manages the SRS; the Westinghouse Savannah River Company operates the Site under contract to DOE. Westinghouse assumed operational responsibility in April 1989 from E. I. du Pont de Nemours and Company, Inc., which had operated the Site since 1951.

2.2 Regulatory Framework

This section summarizes the framework of environmental protection regulations applicable to spent nuclear fuel management at the SRS. The framework is based on Federal and South Carolina laws and one local ordinance, as discussed below. Volume 1 (Section 7.0) of this Environmental Impact Statement (EIS) provides additional information on the major Federal environmental laws and regulations, Executive Orders, and DOE Orders that apply to spent nuclear fuel management alternatives.

2.2.1 Federal

The U.S. Environmental Protection Agency (EPA) has authorized South Carolina to implement most provisions of the Clean Air Act, Resource Conservation and Recovery Act, and Clean Water Act that apply to SRS spent nuclear fuel management. EPA Region IV has the lead responsibility for Clean Air Act standards for radionuclide emissions from DOE facilities, imposing monitoring and approval requirements on SRS spent nuclear fuel management activities that could result in radionuclide emissions.

In addition, EPA Region IV has Resource Conservation and Recovery Act authority over radioactive hazardous (mixed) waste management, affecting wastes from spent nuclear fuel processing.
EPA Region IV and the DOE Savannah River Operations Office have entered into a Federal Facility Compliance Agreement on SRS mixed waste management.

The U.S. Army Corps of Engineers District Engineer for the Charleston District implements the Clean Water Act Section 404 and the Rivers and Harbors Act permitting program for SRS spent nuclear fuel construction activities that would affect U.S. waters.

In accordance with the Endangered Species Act, the SRS would consult with the U.S. Fish and Wildlife Service, Charleston Field Office on impacts that spent nuclear fuel construction activities could have on threatened and endangered species.

2.2.2 State

The South Carolina Department of Health and Environmental Control implements the following State laws that would affect SRS spent nuclear fuel management activities:

- Pollution Control Act (nonradioactive emissions and discharges, and nonhazardous waste management)
- Hazardous Waste Management Act (nonradioactive hazardous waste management)
- Safe Drinking Water Act
- Groundwater Use Act
- Stormwater Management and Sediment Reduction Act

The U.S. Army Corps of Engineers District Engineer for the Charleston District has an agreement with the South Carolina Department of Health and Environmental Control whereby that department issues Clean Water Act Section 401 water quality certifications. The South Carolina Department of Health and Environmental Control also receives SRS reports in accordance with the Emergency Planning and Community Right-To-Know Act.

The South Carolina State Department of Archives and History includes the State Historic Preservation Office. In accordance with the National Historic Preservation Act, the SRS would consult with the State Historic Preservation Officer on impacts that construction activities could have on cultural resources.

2.2.3 Local

The only local requirement applicable to SRS spent nuclear fuel management is the Aiken County Sediment Control Ordinance, which would affect construction activities.

2.3 Spent Nuclear Fuel Management Program at the Savannah River Site

This EIS addresses the management of approximately 2,742 metric tons of heavy metal (MTHM; 3,023 tons) of spent nuclear fuel that would be stored at various locations within the DOE Complex over the next 40 years (1995-2035). At present, DOE has stored approximately 206.3 MTHM (227.4 tons), or about 8 percent of this material, at the SRS. The spent nuclear fuel currently stored at the SRS that DOE has included in the analyses in this document includes:

- 184.4 MTHM (203.3 tons) of Savannah River Defense Production [highly enriched uranium (HEU) aluminum-clad fuels], including plutonium target material, and other aluminum-clad fuels
- 4.6 MTHM (5.1 tons) of commercial spent fuel (primarily zirconium-clad)
- 11.9 MTHM (13.1 tons) of test and experimental reactor Zircaloy-clad fuel
- 5.4 MTHM (6.0 tons) of test and experimental reactor stainless steel-clad fuel

Spent nuclear fuel is currently stored in the Receiving Basin for Offsite Fuels (RBOF), in three reactor disassembly basins, and in basins in F- and H-Canyons. Table 2-2 shows the quantity of spent fuel stored at these facilities.

Table 2-2. SRS Fuel Inventory by Facility.

Facility	Quantity (MTHM)
Receiving Basin for Offsite Fuel	60.73
L-Reactor Disassembly Basin	118.11
K-Reactor Disassembly Basin	3.32
P-Reactor Disassembly Basin	1.41
F-Canyon	22.63
H-Canyon	0.07
Total	206.27

Source: Wichmann (1995).

The F- and H-Area Canyons at the SRS are among the only remaining operable chemical separations facilities of their kind in the DOE Complex. Each canyon has an associated storage basin that serves as an interim staging area where reactor fuel bundles and targets await the Chemical Separations Process. The basins currently contain 13 reactor fuel assemblies (H-Area) and aluminum-clad targets (F-Area).

DOE has stored most of the remaining aluminum-clad spent nuclear fuel from SRS reactor operations under water in concrete reactor storage basins. Three reactor disassembly basins (K-, P-, and L-Reactors) contain reactor fuel and target material. These structures were built in the 1950s and were not intended for the prolonged storage of radioactive materials. Wet (underwater) storage, while potentially viable for stainless steel-clad fuel elements, is not satisfactory for aluminum-clad elements, which are subject to corrosion and pitting.

In March 1992, chemical processing operations were suspended in the canyons to address a potential safety concern. The concern was subsequently addressed but prior to resumption of processing, the Secretary of Energy directed that defense related chemical separations activities (i.e., reprocessing) be phased out at the SRS. Since the decision, DOE has determined that further action related to the disposition of nuclear material, including spent nuclear fuel, is subject to the National Environmental Policy Act (NEPA) process. Non-safety related facility operations have remained shut down with the exception of Pu-238 processing associated with the support of NASA missions.

As a result of these shut-downs, the canyons and the basins used for storage of spent nuclear fuel and irradiated targets have a large inventory of in-process solutions and fuel and targets (respectively). Some materials stored in the L- and K-Reactor disassembly basins have corroded, releasing fissile materials to the pool water. DOE is preparing an environmental impact statement that will evaluate risks that these and other SRS materials represent to the public and workers and will assess the near-term need for the actions to stabilize these materials to ensure continued safe management (DOE 1995b). These actions would take place over the short-term (about 10 years), until DOE can make programmatic decisions on disposition.

DOE stores other spent fuel in the Receiving Basin for Offsite Fuels (RBOF) on the SRS. This basin, which is in H-Area near the center of the Site, has been operating and receiving fuels of U.S. origin since 1964. This 15,000-square-foot (1,393-square-meter) facility consists of an unloading basin, two storage basins, a repackaging basin, a disassembly basin, and an inspection basin. The basins and their interconnecting transfer canals hold about 500,000 gallons (1,893,000 liters) of water. Spent fuel elements arrive in lead-lined casks weighing from 24 to 70 tons (about 22 to 64 metric tons), which a crane lifts from a railroad car or truck trailer and places in the unloading basin. About 30 percent of the fuels in the Receiving Basin for Offsite Fuels consist of uranium clad in stainless steel or Zircaloy, which SRS facilities cannot process without modifications.

2.4 Vulnerabilities Associated with SRS Spent Nuclear Fuel

In August 1993, the Secretary of Energy commissioned a comprehensive baseline assessment of the environmental, safety, and health vulnerabilities associated with the storage of spent nuclear fuel in the DOE complex. The purpose of this assessment was to determine the inventory and condition of the Department's Reactor Irradiated Nuclear Material, which includes spent nuclear fuel and reactor irradiated target material. The assessment also evaluated the condition of the facilities that store spent fuel and identified the vulnerabilities and problems currently associated with these facilities. Vulnerabilities in nuclear facilities are conditions or weaknesses that could lead to radiation exposure to the public, unnecessary or increased exposure to workers, or release of radioactive materials to the environment. Loss of institutional controls, such as a cessation of facility funding or reductions in facility maintenance and control, could cause some vulnerabilities.

Based on this evaluation process DOE released a report to the Secretary of Energy, entitled Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and other Reactor Irradiated Nuclear Materials and Their Environmental, Safety and Health Vulnerabilities (i.e., "The Working Group Report," Volumes I, II, and III), to the public on December 7, 1993 (DOE 1993). This report identified over 100 vulnerabilities associated with spent fuel storage in the DOE complex, including 19 at the Savannah River Site. The report also determined that five facilities and three burial grounds warranted priority attention from management to avoid unnecessary increases in worker radiation exposure and cost during cleanup. The Savannah River Site L- and K-Reactor Disasssembly Basins were among these facilities. The report grouped vulnerabilities associated with each facility into three categories for management attention based on when corrective action should be initiated: less than 1 year, 1 to 5 years, and more than 5 years.

After issuing the Working Group Report, DOE developed a Plan of Action to address all vulnerabilities, taking into consideration currently available resources for implementation. The Plan of Action is a consolidation of individual action plans designed to address each spent nuclear fuel vulnerability in a manner that reflects the DOE (1) sense of urgency, (2) concern for worker protection, (3) commitment to avoid or otherwise mitigate environmental impacts, and (4) need for compatible long-term solutions.

The interim goal for the Savannah River Site reactor disassembly basins, pending completion of the removal of the stored material, is the stabilization of basin conditions to reduce corrosion and to address known vulnerabilites. The long-term goal of the action plan is a safe start of the removal of reactor-irradiated nuclear material within a 5-year period, consistent with safe and environmentally sound operations, including completion of appropriate NEPA review. These actions will lead to mitigating the identified vulnerabilities while DOE pursues other courses of action.

The 19 vulnerabilities identified for the Savannah River Site now have complete Action Plans (DOE 1994b, 1994c, 1994d). Table 2-3 lists SRS vulnerabilities by facility, tracking number, priority categorization, and Action Plan status.

DOE is currently implementing a number of the 19 Action Plans. These actions have been evaluated under the NEPA review process. The remaining corrective actions, those that will be carried out through FY99, would also undergo NEPA review prior to implementation. Only one of these outstanding actions, the construction of a dry storage facility, would likely require detailed NEPA documentation (e.g., an EIS). The construction of such a facility is addressed programmatically in this EIS as part of the Decentralization, 1992/1993 Planning Basis, Regionalization, and Centralization alternatives. Construction of new facilities would require site-specific NEPA documentation, however.

Table 2-3. SRS vulnerabilities by facility, vulnerability, tracking number, priority categorization, and Action Plan status.

Site/Facility Vulnerability Number Description	Priority Eight major facilities wit vulnerabilities	 Less than 1 year	 Greater than 1 year	Action Plan status
SRS/L-Reactor Disassembly Basin SRS-01 Potential unmonitored buildup of radionuclide or fissile materials in sand filters.	y			Complete
SRS/L-Reactor Disassembly Basin SRS-04 Lack of authorization basis in operating the sand filter cleanup system for L-Area Disassembly Basin.	y			Complete
SRS/Reactor Disassembly Basins SRS-05 Corrosion of aluminum clad fuel, targets, and components.			y	Complete
SRS/L-Reactor Disassembly Basins SRS-06 Cesium-137 activity level in L-Basin.	y			Complete
SRS/L-Reactor Disassembly Basins SRS-07 Determine whether gas bubbles release is a potential hazard above the bucket storage area at L-Reactor.	y			Complete
SRS/K-, L-, P-Reactors SRS-08 Lack of Reactor Authorization Basis.	y			Complete
SRS/K-Reactor Disassembly Basins SRS-09 Corrosion of Mark 31 A and B target slugs in K and L disassembly basins.	y			Complete
SRS/P-Reactor Disassembly Basins SRS-10 Hoist Rod Corrosion		y		Complete

SRS/L-, K-, P-Reactor Disassembly Basins	SRS-21	Inadequate seismic evaluation and potential inadequacies of structures, systems, and components to withstand a design basis event.	y			Complete

2.5 Representative Host Sites

DOE has identified two SRS areas as representative host sites for potential facilities related to the implementation of programmatic decisions on spent nuclear fuel management (Figure 2-3):

- F- and H-Areas (considered together) for the modification or expansion of existing facilities, new wet storage, and support facilities
- An undeveloped site for the construction of major new facilities, primarily an Expended Core Facility or dry storage vault.

Figure 2-3. Representative host sites on Savannah River Site. 2.5.1 F- and H-Areas

These two areas contain most of the current spent nuclear fuel facilities and operations at the SRS, including the Receiving Basin for Offsite Fuels. Therefore, DOE would focus future actions under any of the alternatives in these areas as well, for cost-effectiveness and because construction would occur in areas that had been previously disturbed.

F- and H-Areas are about 2 miles (3.2 kilometers) apart near the center of the SRS. The nearest Site boundary is approximately 7.5 miles (12 kilometers) to the west. DOE uses the land within a 5-mile (8-kilometer) radius of the two areas either for industrial purposes associated with SRS operations or as managed forest land. The closest facility to F- and H-Areas is the E-Area Solid Waste Disposal Facility, which lies between the two areas (Figure 2-3). DOE uses this facility to dispose of SRS solid low-level radioactive waste and to store TRU radioactive waste and mixed waste.

The F-Area separations facilities occupy about 420 acres (1.7 square kilometers). These facilities were designed primarily for the recovery of plutonium-239 from irradiated and unirradiated feed materials. DOE used the F-Area Canyon to dissolve target materials and produce solutions that contained the various products extracted from fission products. Further processing converted the products from solution to solid form for shipment off the Site. Large tanks in F-Area store high-level liquid radioactive waste for future stabilization and disposal through the Defense Waste Processing Facility.

H-Area facilities occupy about 395 acres (1.6 square kilometers). The H-Area Canyon processed irradiated fuel elements or target assemblies from reactors. Primary operations included the dissolution of irradiated targets and fuel tubes, chemical and physical separation, and purification of materials. DOE stores high-level liquid waste in large tanks in H-Area, as in F-Area, for future processing and disposal through the Defense Waste Processing Facility.

2.5.2 Undeveloped Representative Host Site

DOE has selected an undeveloped representative host site for the construction of new facilities that F- or H-Area could not accommodate. This site is to the south and east of H-Area, adjacent to SRS Road E and close to an existing railroad line, as shown in Figure 2-3. The SRS could make connections to existing electricity, water, and steam networks with minimal additional construction. The use of this site would have the advantage of consolidating spent nuclear fuel-related activities near F- and H-Areas and close to the center of the SRS.

This site is representative of many available areas on the SRS that could support spent nuclear fuel management activities. For example, DOE has identified a different representative site for the possible construction of the Expended Core Facility for the management of naval spent nuclear fuel (see Appendix D of Volume 1 of this Environmental Impact Statement). DOE would conduct a detailed siting analysis before implementing any programmatic decision at the SRS. DOE would assess, as necessary, the environmental consequences of the siting of any facilities as part of the site-specific NEPA documentation.

3. SPENT NUCLEAR FUEL ALTERNATIVES

This chapter describes the five management alternatives for spent nuclear fuel that the U.S. Department of Energy (DOE) has evaluated for the Savannah River Site (SRS) as part of Volume 1 of this Environmental Impact Statement. These alternatives are:

1. No Action
2. Decentralization
3. 1992/1993 Planning Basis
4. Regionalization (with 2 subalternatives for the SRS)
5. Centralization (with 2 subalternatives for the SRS)

The activities covered by the alternatives range from maintaining the current inventory of spent fuel at the SRS without receiving any more shipments (Alternative 1), through keeping the existing inventory and accepting or sending off some limited shipments (Alternatives 2 through 4), to receiving at the Site all DOE spent nuclear fuel and some from other sources (Alternative 5). DOE also examined an option for shipping all spent nuclear fuel at the SRS to another location (a variation of Alternatives 4 and 5). Table 3-1 summarizes the quantities of material that would be received, shipped out, and ultimately managed at the SRS under the various alternatives. DOE has assessed the aluminum-clad spent nuclear fuel separately from nonaluminum-clad fuel (i.e., stainless steel and Zircaloy) because the options for managing them at the Site could be different as explained in Section 3.1.

The analytical approach used in this document produces estimates of consequences that would be as large as or larger than any that could occur or be expected under the alternatives and provides a comparison of the impacts of the principal technologies for managing spent nuclear fuel at the SRS.

This chapter also provides an overview of the SRS management approach and describes the five alternatives as they relate to the SRS (Sections 3.1 and 3.2). In addition, the chapter summarizes and compares the potential environmental consequences of each alternative (Section 3.3).

Table 3-1. Quantities (MTHM)a of spent nuclear fuel that would be received, shipped, and managed at the SRS under the five alternatives.b,c

Alternative	Fuel Type	Currently at SRS	Receive	Ship Out	Totals managed at SRS under this

3.1 SRS Management Approach

3.1.1 Management Options

DOE has evaluated three options for the management of spent nuclear fuel at the SRS under the five alternatives considered for this EIS. These technical management options are wet storage or dry storage of all fuels and the processing of aluminum-clad fuels. DOE could implement these options individually or in combination under any of the five alternatives. DOE would base its selection of one or more of these technical management options on additional analysis, including a separate SRS-specific National Environmental Policy Act (NEPA) review based on this programmatic EIS.

3.1.1.1 Wet Storage. As described above in Section 2.3, the SRS currently maintains its

spent nuclear fuel in wet storage in the Receiving Basin for Offsite Fuels and several reactor basins. Wet storage under the 40-year interim management plan (except under the No Action alternative) would require that DOE construct a new wet storage pool at the SRS and move all fuel to this facility. Prior to this transfer, DOE could place all the aluminum-clad fuel in stainless steel canisters to prevent further corrosion and breakdown of the fuel cladding. The stainless steel- and Zircaloy-clad fuels could also require canning. The SRS would monitor and maintain the water quality and the condition of the fuel in the storage pool throughout the interim management period.

Under this wet storage option, the spent nuclear fuel would be in an interim storage form, which could require further treatment depending on the DOE decision on its ultimate disposition.

3.1.1.2 Dry Storage. DOE currently has no dry storage facilities for spent nuclear fuel at the

Site. Dry storage of SRS aluminum-clad fuels under this management plan would require technology development prior to the construction of a dry storage facility. Although such facilities exist at other DOE sites and at commercial locations, DOE believes that the characteristics of SRS spent fuel are sufficiently different to require some research and development before the design and construction of a facility for this fuel. DOE would can all fuel before placing it into the dry storage vaults. It would also have to maintain and monitor the facility for the remainder of the 40-year management period.

As with wet storage, the dry storage option would place the spent fuel into an interim storage form that could require further treatment later depending upon DOE's decision on ultimate disposition.

3.1.1.3 Processing and Dry Storage. One method under this option would be for the SRS to process existing aluminum-clad spent nuclear fuel through the existing separations facilities in the F- and H-Area Canyons, and place the nonaluminum-clad fuels and any future receipts in dry storage. The process using existing capability would result in the generation of both separated actinides (e.g., uranium oxide), which would be stored on the site in existing facilities, and solutions of fission products that would be placed in existing waste storage facilities for later conversion to a glassified form through the Defense Waste Processing Facility (DWPF). DOE would maintain and monitor the dry storage facility containing the nonaluminum-clad spent fuel. Variations of this processing option are also possible, such as processing all the aluminum-clad fuel currently on the Site plus all that is received from elsewhere, or developing the capability at the SRS for processing for vitrification without chemical separations.

The process option selected for evaluation in this document is representative of possible processing options that might be employed, but is not necessarily the one that DOE would select. Detailed NEPA evaluations would be required to implement any spent nuclear fuel management plan at the SRS.

3.1.2 Management Plan

Figure 3-1 summarizes DOE's overall plan for the interim management of aluminum-clad and nonaluminum-clad fuels at the SRS. This flowchart shows actions for all alternatives except No Action, as explained in Section 3.2.1.

3.1.2.1 Aluminum-clad Fuels. Depending on the alternative and option selected, DOE could (within constraints of mission commitments) consolidate some aluminum-clad fuel in the Receiving Basin for Offsite Fuels to take advantage of this facility's superior water quality and then move all aluminum-clad fuel into dry storage, wet storage, or initiate processing (Figure 3-1). DOE could also process aluminum-clad fuel without any consolidation work. Before moving the fuel into dry or wet storage, DOE would place it in cans. DOE would hold the canned fuel or the stabilized products from processing in storage for the 40-year interim management period until it decided their final disposition.

DOE would place aluminum-clad fuels received by the SRS from other locations in wet or dry storage. DOE could not implement any of the options for aluminum-clad fuels, with the exception of processing using existing SRS capabilities, without a technology development effort.

3.1.2.2 Nonaluminum-clad Fuels. DOE options for the management of nonaluminum-clad fuels at the SRS are somewhat different, in that only dry or wet storage is considered (Figure 3-1). The processing of these fuels at the Site is not an option because the SRS does not currently have operational facilities capable of separating these materials. To improve aluminum-clad fuel storage, DOE could consolidate the nonaluminum-clad fuel inventory in a reactor basin where the more resistant stainless steel or Zircaloy cladding would be less susceptible to corrosion. The fuel would remain there until DOE built new dry or wet storage facilities. DOE would then can the fuel and move it into the new storage. DOE would place any nonaluminum-clad fuel received at the SRS after completion of the new facilities directly into storage. The fuel would remain in this interim storage until DOE decided its ultimate disposition.

Figure 3-1. Diagram of how SRS would manage aluminum-clad and nonaluminum-clad fuels. "Near-term Receipts" refers to the fuel that would be received before new wet or dry storage facilities are available.

3.2 Description of Alternatives

3.2.1 Overview

Table 3-2 compares actions under each of the five alternatives. These actions relate to the requirements for transportation, stabilization, facilities, and research and development that DOE would address for each alternative. Transportation would include onsite movements as well as the receipt or shipment of spent fuel. The consideration of facilities addresses not only new ones that could be required, but also the use of existing structures and capabilities such as the F- and H-Area Canyons at SRS. Finally, each alternative would involve some level of research and development on matters related to spent nuclear fuel interim management (e.g., stabilization, transportation casks) and its ultimate disposition.

Alternative 1 (No Action) addresses only the interim wet storage option, while the analysis of Alternatives 2 through 5 considers three options: dry storage, wet storage, and processing of existing aluminum-clad fuels and placing the other fuels into storage. In addition, Alternatives 4 and 5 include an option for the shipment of spent nuclear fuel off the SRS. This analytical approach shows the relative impact of viable interim storage technologies for the range of alternatives this EIS is considering for the SRS. However, this information is not sufficient to support the selection of a specific interim storage technology at the SRS because DOE has not completed site-specific research and development for dry storage and wet storage methods or an evaluation of other processing options. In addition, the specific quantities of offsite fuel that DOE would manage are subject to change. The selection of an interim storage technology will be the subject of separate NEPA documentation specific to the SRS.

Figure 3-2 is a matrix showing the types of facilities that would be required for each alternative and option. The list includes those facilities already operating at the SRS (e.g., Receiving Basin for Offsite Fuels) as well as potential facilities (e.g., fuel characterization facility). DOE considered these facilities in its evaluation of the consequences of each alternative, as described in Chapter 5.

The alternatives described below address interim storage to 2035; further treatment of the spent nuclear fuel would be necessary before DOE obtained a final disposable waste form. This EIS does not address this additional treatment. However, DOE would carry out a full NEPA documentation for any decision on final disposition of spent nuclear fuel.

Table 3-2. Actions required under each of the five alternatives at the SRS.

Alternative	Transportation	Stabilization	Facilities	Research and Development
1. No Action	No shipments to or from the Site. Limit onsite transfers to those required for safe storage.	Place aluminum-clad fuels that are badly corroded and in danger of cladding failure in containers and return them to wet storage.	Store fuels in Receiving Basin for Offsite Fuels and in an upgraded reactor basin. Requires no new facilities.	Continue existing spent nuclear fuel-related research and development.

2. Decentralization   Receive about 13.6 MTHM (15.0   Can aluminum-clad fuels and
Store fuels in Receiving Basin for   Develop technology (canning
                        tons) of aluminum-clad and   place them in wet or dry

Figure 3-2. Types of facilities required for each alternative. 3.2.2 Alternative 1 - No Action

3.2.2.1 Overview. This alternative deals only with the minimum actions that DOE would

deem necessary for the continued safe and secure management of spent nuclear fuel. It is not a status quo condition. Rather, across its complex of facilities, DOE would maintain spent nuclear fuel close to generation or current storage locations with no shipment between sites. Facility upgrades or replacements and onsite fuel transfers would occur only to support safe and secure interim storage.
DOE would continue existing and new research and development activities for spent fuel interim management. Stabilization activities would be limited only to those minimum actions required to store spent nuclear fuel safely.

3.2.2.2 SRS Alternative 1 - Wet Storage. DOE would initiate the various SRS programs

and activities necessary to obtain optimum use of existing spent nuclear fuel facilities for the extended storage of existing Site inventories totalling 206.3 metric tons (227.4 tons) of heavy metal (MTHM) in the following quantities:

- 184.4 MTHM (203.3 tons) of Savannah River Defense Production [highly enriched uranium (HEU) aluminum-clad fuels], including plutonium target material, and other aluminum-clad fuels
- 4.6 MTHM (5.1 tons) of commercial spent nuclear fuel (primarily zirconium-clad)
- 5.4 MTHM (6.0 tons) of test and experimental reactor stainless steel-clad fuel
- 11.9 MTHM (13.1 tons) of test and experimental reactor Zircaloy-clad fuel

The goal of this program would be to relocate some aluminum-clad fuels to the Receiving Basin for Offsite Fuels where precisely maintained water quality would prolong the storage life of these fuel types. In addition, DOE would relocate a portion of the stainless steel- and Zircaloy-clad fuels to a reactor basin, where their more resistant cladding would maintain fuel containment for an extended period. These actions would be accomplished within the constraints of mission requirements.

The following describes one method that could be employed to improve the storage of aluminum-clad fuel. Variations of this plan that would involve only the use of existing storage basins are also possible.

- Select a reactor basin for upgrading and for the interim storage of SNF.
- Relocate aluminum-clad fuels from the selected reactor basin to other onsite basins to enable cleaning and repair of the basin chosen for upgrade to improve water quality.
- Consolidate fuels in the Receiving Basin for Offsite Fuels to the extent possible.
- After cleaning and renovating the selected reactor basin, move a portion of the stainless steel and Zircaloy-clad fuel assemblies now at the Receiving Basin for Offsite Fuels to the renovated reactor basin.
- Move the aluminum-clad fuels temporarily stored at other locations to the Receiving Basin for Offsite Fuels or the renovated reactor basin.

DOE will continue to place heavily corroded aluminum-clad fuel elements that could be in danger of cladding failure into containers in the wet pool as required to minimize any spread of materials throughout the pool. This action would be much simpler than canning the elements, which would occur under the other alternatives.

This alternative would require no new facilities. DOE would continue existing spent nuclear fuel-related research and development.

3.2.3 Alternative 2 - Decentralization

3.2.3.1 Overview. Under this alternative, DOE would maintain existing spent nuclear fuel in

storage at the current locations, and the SRS would receive some shipments of university fuel and foreign fuel. This alternative differs from the No Action alternative by allowing significant facility development and upgrades. DOE could transport fuel on the Site for safety, fuel consideration, or research and development activities. In addition, DOE could undertake actions it deemed desirable, though not essential, for safety and could perform spent nuclear fuel processing, treatment, research, and development.

3.2.3.2 SRS Options 2a, 2b, and 2c. DOE analyzed three options specific to the SRS for

this alternative: Option 2a deals with dry storage, Option 2b deals with wet storage, and Option 2c involves processing existing SRS aluminum-clad spent nuclear fuel and storing the remaining fuel. The amount of spent fuel that the SRS would manage includes its current inventory, as described above for Alternative 1, plus:

- 11.0 MTHM (12.0 tons) of aluminum-clad fuel
- 1.1 MTHM (1.2 tons) of stainless steel-clad fuel
- 0.7 MTHM (0.8 ton) of Zircaloy-clad fuel
- 0.8 MTHM (0.9 ton) of other experimental fuel

Under this alternative, SRS would manage a total of about 219.9 MTHM (242.4 tons) of spent nuclear fuel. The SRS would receive spent fuel from research reactors as existing storage allowed and as new storage was constructed.

3.2.3.2.1 Option 2a - Dry Storage - Under this option, DOE would store existing SRS

inventories in wet pools while developing the technology and constructing the necessary facilities to examine, characterize, and can the fuels and transfer them to a new dry storage vault to await treatment for final disposition.
The SRS would proceed with the fuel rearrangement plan described above for Alternative 1 to provide acceptable storage conditions to minimize failures of the aluminum-clad material before its placement in a dry-storage container.

Placement in a dry-storage facility would require a technology development program into DOE capabilities to examine, characterize, and can aluminum-clad fuel elements before placing them in a vault. In addition, the SRS would investigate technologies for the ultimate disposition of spent nuclear fuel. In addition to a dry storage facility, the SRS would build new fuel receiving, characterization, and dry canning facilities.

3.2.3.2.2 Option 2b - Wet Storage - Under this option, DOE could rearrange existing

spent nuclear fuel as described above for Alternative 1 to provide interim wet storage capacity while constructing new facilities. SRS could also modify this rearrangement plan to accept shipments of spent fuel from offsite and place them directly into the Receiving Basin for Offsite Fuels, as circumstances warrant. The new wet storage facilities required under this option would include the capability to examine and characterize fuels and to can deteriorating fuels in a stainless steel package for placement in the new pool. DOE would move all fuel to the new storage pool once it was complete. SRS would build new fuel receiving, characterization, and wet-canning facilities as well as a new wet storage pool. SRS would investigate technologies for the ultimate disposition of spent nuclear fuel.

3.2.3.2.3 Option 2c - Processing and Storage - Under this option, SRS would

process existing aluminum-clad spent nuclear fuel to consolidate and stabilize the nuclear material for storage in vaults, and would place the stainless steel- and Zircaloy-clad fuel and new receipts of aluminum-clad fuel in dry storage. The fuel would remain in the current wet pools while awaiting processing or the construction of new dry storage facilities. DOE would use existing F- and H-Area facilities to process the aluminum-clad fuel to safe, stable, consolidated forms.

The new facilities that the SRS would require under this option would be similar to those described for dry storage (Option 2a), except they would be much smaller because the amount of fuel to be stored would be small: only about 11.0 MTHM (12.0 tons) of aluminum-clad and about 24.5 MTHM (27.0 tons) of nonaluminum-clad fuel. The SRS would investigate technologies required for the ultimate disposition of spent fuel.

3.2.4 Alternative 3 - 1992/1993 Planning Basis

3.2.4.1 Overview. This alternative assumes the continued transportation, receipt, processing,

and storage of spent nuclear fuel. Foreign and university research reactor spent nuclear fuel would be sent to the INEL and the SRS. DOE would assess the construction of new facilities required to accommodate current and projected spent nuclear fuel storage requirements. This alternative would include activities related to the treatment of spent nuclear fuel, including research and development and pilot programs to support future decisions on its ultimate disposition.

3.2.4.2 SRS Options 3a, 3b, and 3c. DOE analyzed the same three options for this

alternative as for Alternative 2: dry storage (Option 3a), wet storage (Option 3b), and the processing of existing SRS aluminum-clad fuel and storing the remaining fuel (Option 3c). The quantities of fuel would be somewhat greater than those for Alternative 2 because the options assume that the SRS would manage its present inventory (see Alternative 1) plus approximately:

- 13.7 MTHM (15.1 tons) of aluminum-clad fuel
- 1.3 MTHM (1.4 tons) of stainless steel-clad fuel
- 0.7 MTHM (0.8 ton) of Zircaloy-clad fuel
- 0.8 MTHM (0.9 ton) of other experimental fuel
- a small amount (<0.1 ton) of commercial nonaluminum-clad fuel

The total spent nuclear fuel managed would equal about 222.8 MTHM (245.6 tons). The Site would receive shipments of fuel from other locations as existing space allowed and as new facilities were completed.

3.2.4.2.1 Option 3a - Dry Storage - The Site would store current inventories in

existing wet pools while developing technology and constructing facilities necessary to examine, characterize, and can the fuels and transfer them to a new dry storage vault to await treatment for final disposition.

The actions that SRS would undertake under this option and the new facilities to be constructed would be the same as those described for Option 2a - Dry Storage under Alternative 2 (Decentralization) in Section 3.2.3.2.1.

3.2.4.2.2 Option 3b - Wet Storage - DOE could rearrange existing spent nuclear fuel

as described in Alternative 1 above to provide interim wet storage capacity while building new facilities. The Site could also accept new shipments directly into the Receiving Basin for Offsite Fuels, as required. The actions that SRS would undertake under this option, and the new facilities to be constructed, would be the same as those described for Option 2b - Wet Storage under Alternative 2 (Decentralization) in Section 3.2.3.2.2.

3.2.4.2.3 Option 3c - Processing and Storage - Under this option, the SRS would

process existing aluminum-clad spent nuclear fuel and would place the stainless steel- and Zircaloy-clad fuel and new receipts of aluminum-clad fuel in storage as described for Option 2c - Processing under Alternative 2 (Decentralization) in Section 3.2.3.2.3. The requirements for new facilities and for technology development would also be the same.

3.2.5 Alternative 4 - Regionalization

3.2.5.1 Overview. This alternative has two subalternatives. The first (Regionalization A)

would involve the distribution of existing and new spent nuclear fuel among DOE sites based primarily on the similarity of fuel type, although DOE would also consider transport distances, available processing capabilities, available storage capabilities, or a combination of these factors. Under this subalternative, SRS would receive all aluminum-clad fuel and would transfer its existing inventory of stainless steel- and Zircaloy-clad fuel to another DOE site. The SRS would manage a total of about 213.1 MTHM (234.9 tons) of spent fuel under the Regionalization A subalternative.

The second subalternative (Regionalization B) would require DOE to consolidate all existing and new spent fuel at two sites - one to the east of the Mississippi River and one to the west - depending on the location or generation site of the fuel. Under this alternative, the SRS would either receive all spent nuclear fuel in the east [approximately 256.6 MTHM (282.9 tons)] or ship its current inventory offsite to the Oak Ridge Reservation in Tennessee. An additional option if SRS becomes the Eastern Regional Site is for DOE to construct an Expended Core Facility at the SRS to manage some Naval fuel. This option is described in Appendix D of Volume 1 of this EIS.

Under either subalternative, DOE would undertake facility upgrades, replacements, and additions as appropriate. This alternative would include research and development and pilot programs to support current management and future decisions on spent fuel disposition.

3.2.5.2 SRS Options 4a, 4b, and 4c (Regionalization A). DOE analyzed three options

for the regionalization of fuels by fuel type: dry storage (Option 4a), wet storage (Option 4b) and processing of existing SRS aluminum-clad fuels and storing the remaining fuel (Option 4c). This subalternative assumes that the SRS would manage:

- Its current inventory of 184.4 MTHM (203.3 tons) of aluminum-clad fuels, plus
- Approximately 28.7 MTHM (31.6 tons) of research reactor aluminum-clad fuel from other sites

The SRS would ship to the Idaho National Engineering Laboratory approximately:

- 5.4 MTHM (6.0 tons) of stainless steel-clad fuel
- 4.6 MTHM (5.1 tons) of commercial nonaluminum-clad fuel
- 11.9 MTHM (13.1 tons) of Zircaloy-clad spent fuel

DOE would manage a total of about 213.1 MTHM (234.9 tons) of spent nuclear fuel at the SRS under this subalternative. The site would receive shipments from other locations as existing space became available and as it shipped the nonaluminum-clad fuel.

3.2.5.2.1 Option 4a - Dry Storage - The actions that the SRS would undertake under

this option, and the new facilities to be constructed, would be the same as for those described for Option 2a - Dry Storage under Alternative 2 (Decentralization) in Section 3. 2.3.2.1.

This option would require an extensive research and development program into capabilities to examine, characterize, and can the SRS aluminum-clad fuel for dry storage.

3.2.5.2.2 Option 4b - Wet Storage - The SRS would carry out the same actions and

construct the same types of facilities under this option as it would for Option 2b - Wet Storage under Alternative 2 (Decentralization) as described in Section 3. 2.3.2.2. Research and development activities would also be similar to those conducted under this Decentralization alternative, except the SRS would not perform studies on nonaluminum-clad fuels.

3.2.5.2.3 Option 4c - Processing and Storage - Under this option, the SRS would

process the existing aluminum-clad fuel as described for Option 2c - under Alternative 2 (Decentralization) and place the aluminum-clad fuel received from offsite into wet storage. The requirements for new construction would be different than in Option 2c, in that dry storage facilities would not be required because the nonaluminum-clad fuels would be shipped off the site. The small amount of aluminum-clad fuel to be received could be more readily stored in pools rather than developing new dry storage. Therefore, Option 4c would require DOE to construct a new fuel receiving, wet canning and wet storage facility to manage the fuel received after the major processing operations are completed. These facilities would be much smaller than those required for other alternatives.

3.2.5.3 SRS Options 4d, 4e, 4f, and 4g (Regionalization B). DOE analyzed the same

three options for the regionalization of spent fuel on the basis of geographic location as for the other alternatives: dry storage (Option 4d), wet storage (Option 4e), and processing of existing aluminum-clad fuel and storing the remaining fuel (Option 4f). In addition, it assessed the option of shipping all SRS inventory offsite (Option 4g).

The amount of material that the SRS would manage if all the spent fuel in the East were shipped to the Site would total about 256.6 MTHM (282.9 tons). This would include the current SRS inventory of about 206.3 MTHM (227.4 tons) as detailed in Section 3.2.2 plus:

- 19.9 MTHM (21.9 tons) of aluminum-clad fuel
- 26.7 MTHM (29.4 tons) of commercial nonaluminum-clad fuel
- 1.0 MTHM (1.1 ton) of stainless steel-clad fuel
- 1.3 MTHM (1.4 tons) of experimental Zircaloy-clad fuel
- 1.4 MTHM (1.5 tons) of other experimental fuel

The activities that DOE would have to undertake at the SRS, and the facilities that it would have to build, under the dry storage, wet storage, or processing options would be very similar to those required for the Decentralization alternative (Section 3.2.3). The difference would be that the size of the storage facilities would be somewhat greater because the amount of fuel to be managed would be larger [256.6 MTHM (282.9 tons) versus 219.9 MTHM (242.4 tons)]. In addition, DOE would conduct additional research and development on the other fuel types that SRS would manage under these options.

3.2.5.3.1 Option 4d - Dry Storage - The actions that the SRS would undertake under

this option, and the new facilities to be constructed, would be similar to those described for Option 2a - Dry Storage under Alternative 2 (Decentralization) in Section 3.2.3.2.1. This option would require an extensive research and development program into capabilities to examine, characterize, and can the SRS aluminum-clad fuel for dry storage.

3.2.5.3.2 Option 4e - Wet Storage - The SRS would carry out the same actions and

construct the same types of facilities under this option as it would for Option 2b - Wet Storage under Alternative 2 (Decentralization) as described in Section 3.2.3.2.2. Research and development activities would also be similar to those conducted under this Decentralization alternative.

3.2.5.3.3 Option 4f - Processing and Storage - Under this option, the SRS would

process the existing aluminum-clad fuel and place nonaluminum-clad fuel and aluminum-clad fuel received from offsite in dry storage as described for Option 2c - Processing with storage under Alternative 2 (Decentralization). The requirements for new facilities and for research and development would also be similar.

3.2.5.3.4 Option 4g - Shipment Off the Site - Under this option, the SRS would ship

its current inventory of about 206.3 MTHM (227.4 tons) to the Oak Ridge Reservation. The activities and facilities required for this option are the same as those described below for Option 5d of the Centralization alternative (Section 3.2.6.2.4).

3.2.6 Alternative 5 - Centralization

3.2.6.1 Overview. Under this alternative, DOE would collect all current and future spent

nuclear fuel inventories from DOE sites, the Navy, and other sources at a single location for management until final disposition. DOE would construct new facilities at the centralized site to accommodate the increased inventories. The originating sites would characterize and stabilize their spent nuclear fuel before shipping. They would then close their spent fuel facilities. This alternative would include the centralization of activities related to the treatment of spent nuclear fuel, including research and development and pilot programs to support future decisions on its disposition.

3.2.6.2 SRS Options 5a, 5b, 5c, and 5d. DOE analyzed four options for this alternative.

Three deal with shipping all DOE spent nuclear fuel to the SRS for disposition and management in dry storage (Option 5a), wet storage (Option 5b), or by processing existing aluminum-clad fuel and storing the remaining fuel (Option 5c). The fourth case involves the shipment of all SRS fuel off the Site to another location (Option 5d). Options 5a, 5b, and 5c concern the following fuels:

- 65.2 MTHM (71.7 tons) of naval fuel
- 213.1 MTHM (234.9 tons) of aluminum-clad fuel
- 2103.2 MTHM (2,318.4 tons) of Hanford defense fuel
- 27.6 MTHM (30.4 tons) of graphite fuel
- 156.5 MTHM (172.5 tons) of commercial nonaluminum-clad fuel
- 96.5 MTHM (106.4 tons) of experimental stainless steel-clad fuel
- 78.0 MTHM (86.0 tons) of Zircaloy-clad fuel
- 1.7 MTHM (1.9 tons) of other fuel types

DOE would manage a total of about 2,741.8 MTHM (3,022.3 tons) of spent nuclear fuel at the SRS under the first three options. Options 5a and 5b would involve storing all the fuel on the Site.
Option 5c would require processing the existing aluminum-clad fuel [184.4 MTHM (203.3 tons)] and placing the remaining nonaluminum-clad SRS fuels and all fuel received from other locations [2,557.4 MTHM (2,819.0 tons)] into dry storage. The SRS could accept shipments from offsite sources and place them in storage as it built new facilities and transferred the onsite inventory.

Under Option 5d, shipments leaving the Site would amount to about 206.3 MTHM (227.4 tons), which is equal to the inventory of spent nuclear fuel at the SRS under Alternative 1.

3.2.6.2.1 Option 5a - Dry Storage - The actions that the SRS would undertake under

this option would be the same as those described for Option 2a - Dry Storage under Alternative 2 (Decentralization) in Section 3.
2.3.2.1. However, the number and size of the new facilities needed to implement this centralization option would be much greater because of the larger volume of fuel that the Site would manage. In addition, DOE would have to build a new Expended Core Facility at the SRS to examine and characterize the naval fuels.

This option would require an extensive research and development program into capabilities to examine, characterize, and can SRS and other fuel types before their placement in a dry storage vault.
DOE would also carry out research and development into other aspects of the management of the spent fuels, including those related to its ultimate disposition.

3.2.6.2.2 Option 5b - Wet Storage - Under this option, DOE would undertake actions

similar to those described in Section 3.
2.3.2.2 for Option 2b - Wet Storage under Alternative 2. As with Option 5a (Dry Storage), the SRS would have to build major new facilities to manage the large volume of fuel it would receive. DOE would also have to build a new Expended Core Facility at the SRS. Research and development would be greatly expanded as well.

3.2.6.2.3 Option 5c - Processing and Storage - DOE would process the current

inventory of aluminum-clad spent fuel under this option in the same manner as described for the other alternatives.
All other fuel onsite and all fuel received from elsewhere would be canned and placed in new dry storage facilities. The SRS would shut down the F- and H-Area separations facilities after processing the existing inventory of aluminum-clad fuel. Thereafter, any aluminum-clad fuel sent

to the SRS would be placed in dry storage.

This option would require major new facilities, including a new Expended Core Facility. DOE would also conduct extensive research and development in spent fuel management.

3.2.6.2.4 Option 5d - Shipment Off the Site - DOE would consolidate and prepare

all spent nuclear fuel on the SRS for shipment to another DOE site; this would require the construction of a new fuel characterization facility. Some fuels could require canning before shipment. SRS would use existing facilities to accomplish this. DOE would then close all SRS spent nuclear fuel-related facilities.

DOE would conduct research and development into methods of stabilizing, canning, and transporting aluminum-clad fuels, particularly that which is corroded or otherwise degraded.

3.3 Comparison of Alternatives

Table 3-3 summarizes the environmental consequences of the five alternatives. Chapter 5 presents detailed descriptions of these consequences.

In general, the levels of impacts associated with Alternatives 1 through 4 would be similar because the amounts of spent nuclear fuel that DOE would manage at the SRS under these cases would be approximately the same [e.g., about 206 to 257 MTHM (227 to 283 tons)] and activities would extend throughout the full 40-year management period. The lowest level of impact at SRS would occur under Option 4g or Option 5d (Regionalization or Centralization at another site) because DOE would ship the SRS spent fuel off the Site well before the management period ended in 2035. Alternative 5, under which DOE would ship all spent nuclear fuel to the SRS, would result in the greatest onsite impacts; the Site would have to manage approximately 2,741.8 MTHM (3,022.3 tons) of spent fuel.

Table 3-3. Comparison of impacts for the five alternatives.

	ALTERNATIVE 1 - NO ACTION Option 1 Wet Storage
Land Use	No new facilities would be required.
Socioeconomics	No new operations jobs and only about 50 construction jobs would be created.
Cultural Resources	No new construction would be carried out. No impacts are anticipated.
Aesthetics and Scenic Resources	Facilities are in an existing industrial area not visible from public access roads or from off the Site. No impacts are anticipated. Emissions would not impact visibility.
Geology	No minerals of economic value are in affected area. No impacts are anticipated.
Air Resources	Emissions of criteria air pollutants and toxic air pollutants would be only a small fraction of air quality standards.
Water Resources	This option would not require use of additional surface water beyond the 75.7 billion liters (20 billion gallons) per year that the SRS withdraws at present. This option would not require withdrawals of additional groundwater beyond the 14.0 billion liters (3.7 billion gallons) per year the SRS uses. Activities related to this option currently use about 35.1 million liters (9.3 million gallons) of groundwater per year. Impacts would be minimal. No perennial streams or other surface waters would be affected. Accidental releases could contaminate shallow groundwater that is not a source for drinking water or domestic use. Releases would not affect surface streams or drinking water aquifers.
Ecological Resources	Minor disturbance of wildlife due to traffic would occur. No wetlands or threatened or endangered species would be affected.
Noise	The only noise experienced by offsite populations would

	be generated by employee traffic and by truck and rail deliveries. There would be no change in traffic noise impacts.
Traffic and Transportation	This option would not increase site traffic. Number of LCFf, normal transport: Worker: 6.0 x 10-4 Public: 7.0 x 10-5
Occupational and Public Health and Safety (Radiological)	Maximum LCFf probabilities: Worker: 4 x 10-5 Offsite population: 4 x 10-14 (air) 1 x 10-14 (water) Annual LCFf incidences: Worker: 8 x 10-5 Offsite population: 2 x 10-9

Table 3-3. (continued).

	Option 1 Wet Storage
Occupational and Public Health and Safety (Nonradiological)	Hazard index: Worker: 2 x 10-6 Maximally exposed individual: 2 x 10-7
Utilities and Energy	Minimal changes in demand for electricity, steam, domestic water and wastewater treatment would occur. Current SRS capacities are adequate for these additions. Impacts would be minimal.
Materials and Waste Management	Annual average volume of waste generated (cubic meters)b: LLW: 400 TRU: 17 HLW: 0.4 No impact on site waste management capacities.
Accidentsc	Greatest point estimate of riskd: Worker: Data not calculatede Colocated worker: 7.7 x 10-7 Maximally exposed individual: 1.6 x 10-7 Offsite population: 1.4 x 10-3

a. Not applicable.

b. LLW = low-level waste; TRU = transuranic waste; HLW = high-level waste.

c. Data is provided as adjusted point estimates of risk by receptor group to demonstrate a relative comparison of each alternative on an option-by-option basis. The adjusted values were taken from Tables 5-27 through 5-29.

d. Units for adjusted point estimates of risk are given in terms of potential fatal cancers per year.

e. The safety analysis reports from which information was extracted were written before issuance of DOE Order 5480.23; previous orders did not require the inclusion of workers.

f. LCF = latent cancer fatalities.

Table 3-3. (continued).

	ALTERNATIVE 2 - DECENTRALIZATION		
	Option 2a Dry Storage	Option 2b Wet Storage	Option 2c Processing
Land Use	Most new construction would be in parts of F- and H-Areas already dedicated to industrial use. Impacts would be minimal.	Same as Option 2a.	Same as Option 2a.
Socioeconomics	Operations jobs would be filled by current employees. A maximum of about 600 construction jobs would be created.	Same as Option 2a.	Operations jobs would be filled by current employees. A maximum of about 550 construction jobs would be created.
Cultural Resources	Same as Option 1.	Same as Option 1.	Same as Option 1.
Aesthetics and Scenic Resources	Same as Option 1.	Same as Option 1.	Same as Option 1.
Geology	Same as Option 1.	Same as Option 1.	Same as Option 1.

Air Resources	Same as Option 1.	Same as Option 1.	Same as Option 1.
Water Resources	New withdrawals of approximately 6.1 million liters (1.6 million gallons) per year of cooling water from Savannah River would be required. Impacts would be minimal.	New withdrawals of approximately 7.2 million liters (1.9 million gallons) per year of cooling water from Savannah River would be required. Impacts would be minimal.	New withdrawals of approximately 311 million liters (82.2 million gallons) per year of cooling water from Savannah River would be required. Impacts would be minimal.
	Additional groundwater withdrawals would total about 48.7 million liters (12.9 million gallons) per year. Impacts would be minimal.	Additional groundwater withdrawals would total about 50.6 million liters (13.4 million gallons) per year. Impacts would be minimal.	Same as Option 2a.
	No perennial streams or other surface waters would be affected.	No perennial streams or other surface waters would be affected.	No perennial streams or other surface waters would be affected.
	Accidental releases could contaminate shallow groundwater that is not used as a source for drinking water or domestic use. Releases would not affect surface streams or drinking water aquifers.	Accidental releases could contaminate shallow groundwater that is not used as a source for drinking water or domestic use. Releases would not affect surface streams or drinking water aquifers.	Accidental releases could contaminate shallow groundwater that is not used as a source for drinking water or domestic use. Releases would not affect surface streams or drinking water aquifers.

Table 3-3. (continued).

	Option 2a Dry Storage	Option 2b Wet Storage	Option 2c Processing
Ecological Resources	Small increase in traffic would cause slight increase in road kills and in disturbance of wildlife due to noise. Impacts would be minimal.	Same as Option 2a.	Small increases in traffic would cause small increase in road kills and in disturbance of wildlife due to noise. Impacts would be minimal.
	No wetlands or threatened or endangered species would be affected.	Same as Option 2a.	Same as Option 2a.
Noise	Only noise experienced by communities would be generated by employee traffic and by truck and rail deliveries.	Same as Option 2a.	Same as Option 2a.
	Changes in traffic levels are expected to result in only very small changes in noise impacts.		
Traffic and Transportation	This option would increase site traffic slightly.	Same as Option 2a.	This option would increase site traffic slightly.
	Number of LCFg, normal transport: Worker: 1.0 x 10-3 Public: 1.2 x 10-4		Number of LCFg, normal transport: Worker: 2.1 x 10-4 Public: 1.9 x 10-5
Occupational and Public Health and Safety (Radiologica	Maximum LCFg probabilities: Worker: 3 x 10-5 Offsite population: 4 x 10-14 (air)	Maximum LCFg probabilities: Worker: 4 x 10-5 Offsite population:	Maximum LCFg probabilities: Worker: 6 x 10-5 Offsite population:

l)	1 x 10-14 (water) Annual LCF[g] incidences: Worker: 7 x 10-5 Offsite population: 2 x 10-9	5 x 10-14 (air) 2 x 10-14 (water) Annual LCF[g] incidences: Worker: 8 x 10-5 Offsite population: 2 x 10-9	2 x 10-7 (air) 6 x 10-8 (water) Annual LCF[g] incidences: Worker: 3 x 10-2 Offsite population: 8 x 10-3
Occupational and Public Health and Safety (Nonradiological)	Same as Option 1.	Same as Option 1.	Hazard index: Worker: 6 x 10-3 Maximally exposed individual: 5 x 10-4
Utilities and Energy	Requirements would increase 3 to 7 percent above present levels. Current SRS capacities are adequate for these increases.	Same as Option 2a.	Very similar to Option 2a.
Materials and Waste Management	Annual average volume of waste generated (cubic meters)[b]: LLW: 400 TRU: 18 HLW: 0.4 No impact on site capacities.	Same as Option 2a.	Annual average volume of waste generated (cubic meters)[b]: LLW: 800 TRU: 19 HLW: 2.3[c] No impact on site capacities.

Table 3-3. (continued).

	Option 2a Dry Storage	Option 2b Wet Storage	Option 2c Processing
Accidents[d]	Greatest point estimate of risk[e]: Worker: Data not calculated[f] Colocated worker: 1.6 x 10-6 Maximally exposed individual: 3.3 x 10-7 Offsite population: 2.8 x 10-3	Greatest point estimate of risk[e]: Worker: Data not calculated[f] Colocated worker: 1.7 x 10-6 Maximally exposed individual: 3.5 x 10-7 Offsite population: 3.0 x 10-3	Greatest point estimate of risk[e]: Worker: Data not calculated[f] Colocated worker: 7.7 x 10-7 Maximally exposed individual: 1.6 x 10-7 Offsite population: 1.4 x 10-3

a. NA = not applicable.
b. LLW = low-level waste; TRU = transuranic waste; HLW = high-level waste.
c. High-level waste will be generated only during approximately the first 10 years.
d. Data is provided as adjusted point estimates of risk by receptor group to demonstrate a relative comparison of each alternative on an option-by-option basis. The adjusted values were taken from Tables 5-27 through 5-29.
e. Units for adjusted point estimates of risk are given in terms of potential fatal cancers per year.
f. The safety analysis reports from which information was extracted were written before issuance of DOE Order 5480.23; previous orders did not require the inclusion of workers.

Accidentsd	Greatest point estimate of riske: Worker: Data not calculatedf Colocated worker: 4.0 x 10-6 Maximally exposed individual: 8.4 x 10-7 Offsite population: 7.2 x 10-3	Same as Option 5a.	Greatest point estimate of riske: Worker: Data not calculatedf Colocated worker: 3.3 x 10-6 Maximally exposed individual: 6.8 x 10-7 Offsite population: 5.8 x 10-3

a. NA = not applicable.
b. LLW = low-level waste; TRU = transuranic waste; HLW = high-level waste.
c. High-level waste will be generated only during approximately the first 10 years.
d. Data is provided as adjusted point estimates of risk by receptor group to demonstrate a relative comparison of each alternative on an option-by-option basis. The adjusted values were taken from Tables 5-27 through 5-29.
e. Units for adjusted point estimates of risk are given in terms of potential fatal cancers per year.
f. The safety analysis reports from which information was extracted were written before issuance of DOE Order 5480.23; previous orders did not require the inclusion of workers.
g. LCF = latent cancer fatalities.

Table 3-3. (continued).

	ALTERNATIVE 5 - CENTRALIZATION ALTERNATIVE 4 - REGIONALIZATION B Option 4g and Option 5db Ship Out
Land Use	Same as Option 1.
Socioeconomics	No new operations jobs and only about 200 construction jobs would be created.
Cultural Resources	Same as Option 1.
Aesthetics and Scenic Resources	Same as Option 1.
Geology	Same as Option 1.
Air Resources	Same as Option 1.
Water Resources	This option would require new withdrawals of approximately 3.0 million liters (790 thousand gallons) per year of cooling water from the Savannah River. Impacts would be minimal.

	It also would require additional groundwater withdrawals of about 38.1 million liters (10.1 million gallons) per year. Impacts would be minimal. Impacts to surface water and groundwater would be similar to those from Option 1.
Ecological Resources	Same as Option 1.
Noise	Same as Option 2a.
Traffic and Transportation	NA[a]
Occupational and Public Health and Safety (Radiological)	Less than Option 1.
Occupational and Public Health and Safety (Nonradiological)	Same as Option 1.
Utilities and Energy	Requirements would increase 2 to 6 percent above current levels during first 10 years. Current SRS capacities are adequate for these increases.
Materials and Waste Management	Annual average volume of waste generated initial 10 years only (cubic meters)[c]: LLW: 400 TRU: 18 HLW: 0

Table 3-3. (continued).

	Option 4g and Option 5d[b] Ship Out
Accidents[d]	Greatest point estimate of risk[e]: Worker: Data not calculated[f] Colocated Worker: Option 4g: 8.1×10^{-7} Option 5d: 8.2×10^{-7} Maximally exposed individual: Option 4g: 1.7×10^{-7} Option 5d: 1.7×10^{-7} Offsite population: Option 4g: 1.4×10^{-3} Option 5d: 1.4×10^{-3}

a. NA = not applicable.
b. Impacts for Option 4g (Regionalization-B) are the same as for Option 5d.
c. LLW = low-level waste; TRU = transuranic waste; HLW = high-level waste.
d. Data is provided as adjusted point estimates of risk by receptor group to demonstrate a relative comparison of each alternative on an option-by-option basis. The adjusted values were taken from Tables 5-27 through 5-29.
e. Units for adjusted point estimates of risk are given in terms of potential fatal cancers per year.
f. The safety analysis reports from which information was extracted were written before issuance of DOE Order 5480.23; previous orders did not require the inclusion of workers.

4. AFFECTED ENVIRONMENT

4.1 Overview

This section describes the existing environment at the Savannah River Site (SRS) and nearby areas. Its purpose is to support the assessment of environmental consequences of the alternative actions regarding spent nuclear fuels described in Chapter 3. Chapter 5 describes the environmental consequences in detail.

4.2 Land Use

The SRS occupies an area of approximately 198,000 acres (800 square kilometers) in western South Carolina, in a generally rural area about 25 miles (40 kilometers) southeast of Augusta, Georgia. The SRS, which is bordered by the Savannah River to the southwest, includes portions of Aiken, Barnwell, and Allendale Counties (Figure 2-1).

Land use on the SRS falls into three major categories: forest/undeveloped, water/wetlands, and developed facilities. About 181,500 acres (735 square kilometers) of the SRS area are undeveloped (USDA 1991a). Approximately 90 percent of this undeveloped area is forested (Cummins et al. 1991). In 1952, an interagency agreement between the U.S. Department of Energy [DOE, which was then the Atomic Energy Commission (AEC)] and the Forest Service, U.S. Department of Agriculture, created an SRS forest management program. In 1972, the AEC designated the SRS as a National Environmental Research Park (NERP); at present, approximately 14,000 acres (57 square kilometers or 7 percent) of the SRS area are designated as "Set-Asides," areas specifically protected for environmental research activities that are coordinated either through the University of Georgia Savannah River Ecology Laboratory (SREL) or the Savannah River Technology Center (SRTC; Davis 1994). Administrative, production, and support facilities occupy approximately 5 percent of the total SRS land area.

DOE is considering decisions that could affect the long-range land use of the SRS. Programmatic decisions on the reconfiguration of the nuclear weapons complex, spent nuclear fuel interim strategies, and waste management and environmental restoration activities that could result in significant changes in the SRS mission are in the early stages of discussion. In the shorter term, however, a Land Use Technical Committee consisting of representatives from DOE, Westinghouse Savannah River Company, and various stakeholder groups is evaluating alternative land use strategies and potential future uses. These activities are consistent with the guidelines for land use plans contained in DOE Order 4320.1B, "Site Development Planning," and in the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA).

Land use bordering SRS is primarily forest and agricultural. There is also a significant amount of open water and nonforested wetlands along the Savannah River valley. Incorporated and industrial areas are the only other significant use of land in the vicinity (Figure 4-1). None of the three counties in which the SRS is located has zoned any of the Site land. The only adjacent area with any zoning is the Town of New Ellenton, which has two zoning categories for lands that bound SRS - urban development and residential development. The closest residences to the SRS boundary include several within 200 feet (61 meters) of the Site perimeter to the west, north, and northeast.

Various industrial, manufacturing, medical, and farming operations are conducted in areas surrounding the Site. Major industrial and manufacturing facilities in the area include textile mills, plants producing polystyrene foam and paper products, chemical processing plants, and a commercial nuclear power plant. Farming is diversified in the region and includes crops such as peaches, watermelon, cotton, soybeans, corn, and small grains.

There is a wide variety of public outdoor recreation facilities in the SRS region (Figure 4-2). Federal outdoor recreation facilities include portions of the Sumter National Forest [47 miles (75 kilometers) to the northwest of the Site], the Santee National Wildlife Refuge [50 miles (80 kilometers) to the east], and the Clarks Hill/Strom Thurmond Reservoir, a U.S. Army Corps of Engineers impoundment [43 miles (70 kilometers) to the northwest]. There are also a number of state, county, and local parks in the region, most notably Redcliffe Plantation, Rivers Bridge, Barnwell and Aiken County State Parks in South Carolina, and Mistletoe State Park in Georgia (HNUS 1992a).

The SRS is a controlled area with public access limited to through traffic on South Carolina Highway 125 (SRS Road A), U.S. Highway 278, SRS Road 1, and the CSX railway. The SRS does not contain any public recreation facilities. However, the SRS conducts controlled deer hunts each fall, from mid-October through mid-December; hunters can also kill feral hogs during these hunts. The intent of the hunts is to control the resident populations of these animals and to reduce animal-vehicle accidents on SRS roads.

Figure 4-1. Generalized land use at the Savannah River Site and vicinity. Figure 4-2. Federal and state forests and parks within a 2-hour drive from Savannah River Site.

No onsite areas are subject to Native American treaty rights. The SRS does not contain any prime farmland.

4.3 Socioeconomics

This section discusses baseline socioeconomic conditions within a region of influence where approximately 90 percent of the SRS workforce lived in 1992. The SRS region of influence includes Aiken, Allendale, Bamberg, and Barnwell Counties in South Carolina, and Columbia and Richmond Counties in Georgia (Figure 4-2).

4.3.1 Employment and Labor Force

The labor force living in the region of influence increased from about 150,550 to 209,000 between 1980 and 1990. In 1990, approximately 75 percent of the total labor force in the region of influence lived in Richmond and Aiken Counties. Assuming a constant unemployment rate of 5.8 percent, the regional labor force is likely to increase to approximately 257,000 by 1995 (Table 4-1).

Between 1980 and 1990, total employment in the region of influence increased from 139,504 to 199,161, an average annual growth rate of approximately 5 percent. Table 4-1 lists projected employment data for the six-county region of influence. As shown, by 1995 employment levels should increase 22 percent to approximately 242,000. The unemployment rates for 1980 and 1990 were 7.3 percent and 4.7 percent, respectively (HNUS 1992a).

In 1990, employment at the SRS was 20,230 (DOE 1993a), representing 10 percent of the employment in the region of influence. In Fiscal Year 1992, employment at the SRS increased approximately 15 percent to 23,351, with an associated payroll of more than $1.1 billion. Due to planned budget reductions, Site employment could decline by as many as 4,200 jobs (Fiori 1995). As shown in Table 4-1, this would reduce Site employment to approximately 15,800 by 1996.

Table 4-1. Forecast employment and population data for the Savannah River Site and the region of influence.

Year	Labor Force (Region)	Employment (Region)	SRS Employmentb	Population (Region)
1994	254,549	239,785	21,500	456,892
1995	256,935	242,033	20,000	461,705
1996	258,500	243,507	15,800	465,563
1997	260,680	245,561	15,800	468,665
1998	263,121	247,860	15,800	471,176
1999	265,694	250,284	15,800	473,186
2000	268,430	252,861	15,800	474,820
2001	271,265	255,532	15,800	476,179
2002	274,238	258,332	15,800	477,332
2003	277,318	261,234	15,800	478,340
2004	280,415	264,151	15,800	479,182

b. Sources: Turner (1994), Fiori (1995).

4.3.2 Personal Income

Personal income in the six-county region has doubled during the past two decades, increasing from approximately $3.4 billion in 1970 to almost $6.9 billion by 1989 (in constant 1991 dollars). Together, Richmond and Aiken Counties accounted for 75.4 percent of the personal income in the region of influence in 1989, because these two counties provide most of the employment opportunities in the region. Personal income in the region is likely to increase 3 percent to approximately $7.1 billion by 1995 and to almost $8.2 billion by 2000 (HNUS 1992a).

4.3.3 Population

Between 1980 and 1990, the population in the region of influence increased 13 percent from 376,058 to 425,607. More than 88 percent of the 1990 population lived in Aiken (28.4 percent), Columbia (15.5 percent), and Richmond (44.6 percent) Counties. Table 4-1 also lists population data for the region of influence forecast to 2004. According to census data, in 1990 the estimated average number of persons per household in the six-county region was 2.72, and the median age of the population was 31.2 years (HNUS 1992a).

4.3.4 Housing

From 1980 to 1990, the number of year-round housing units in the six-county region increased 23.2 percent from 135,866 to 167,356. In 1990, approximately 68 percent of the total housing units were single-family units, 18 percent were multifamily units, and 14 percent were mobile homes. In the same year, the region had a 4.7-percent vacancy rate with 7,818 available unoccupied housing units. Of the available unoccupied units, 29 percent (2,267) were available for sale and 71 percent (5,551) were available for rent (HNUS 1992a).

4.3.5 Community Infrastructure and Services

Public education facilities in the six-county region include 95 elementary and intermediate schools and 25 high schools. Aside from the public school systems, 42 private schools and 16 post-secondary facilities are available to residents in the region (HNUS 1992a).

Based on a combined average daily attendance for elementary and high school students in the region of influence in 1988, the average number of students per teacher was 16. The highest ratio was in Columbia County high schools where there were 19 students per teacher (1987-1988). The lowest ratio occurred in Barnwell County's District 29 high school, which had only 12 students per teacher (1988-1989) (HNUS 1992a).

The six-county region has 14 major public sewage treatment facilities with a combined design capacity of 302.2 million liters (79.8 million gallons) per day. In 1989, these systems were operating at approximately 56 percent of capacity, with an average daily flow of 170 million liters (44.9 million gallons) per day. Capacity utilization ranged from 45 percent in Aiken County to 80 percent in Barnwell County (HNUS 1992a).

There are approximately 120 public water systems in the region of influence. About 40 of these county and municipal systems are major facilities, while the remainder serve individual subdivisions, water districts, trailer parks, and miscellaneous facilities. In 1989, the 40 major facilities had a combined total capacity of 576.3 million liters (152.2 million gallons) per day. With an average daily flow rate of approximately 268.8 million liters (71 million gallons) per day, these systems were operating at 47 percent of total capacity in 1989. Facility utilization rates ranged from 13 percent in Allendale County to 84 percent in the City of Aiken (HNUS 1992a).

Eight general hospitals operate in the six-county region with a combined bed capacity in 1987 of 2,433 (5.7 beds per 1,000 population). Four of the eight general hospitals are in Richmond County; Aiken, Allendale, Bamberg, and Barnwell Counties each have one general hospital. Columbia County has no hospital. In 1989, there were approximately 1,295 physicians serving the regional population, which represents a physician-to-population ratio of 3 to 1,000. This ratio ranged from 0.8 physician per 1,000 people in Aiken and Allendale Counties to 5.4 physicians per 1,000 people in Richmond County (HNUS 1992a).

Fifty-six fire departments provide fire protection services in the region of influence. Twenty-seven of these are classified as municipal fire departments, but many provide protection to rural areas outside municipal limits. The average number of firefighters in the region in 1988 was 3.8 per 1,000 people, ranging from 1.6 per 1,000 in Richmond County to 10.2 per 1,000 in Barnwell County (HNUS 1992a).

The county sheriff departments and municipal police departments provide most law enforcement services in the region of influence. In addition, state law enforcement agents and state troopers assigned to each county provide protection and assist county and municipal law enforcement officers. In 1988, the average ratio in the region of full-time police officers employed by state, county, and local agencies per 1,000 population was 2.0. This ratio ranged from 1.4 per 1,000 in Columbia County to 2.5 per 1,000 in Richmond County (HNUS 1992a).

4.3.6 Government Fiscal Structure

This section discusses the fiscal structure of Aiken and Barnwell Counties because these two counties would have the greatest potential for fiscal impacts from changes at SRS.

Public services provided by Aiken County are funded principally through the county's general fund. In Fiscal Year 1988, revenues and expenditures of this fund were $15.5 million and $18 million, respectively. The current property tax rate is 55.8 mills for county operations and 8.0 mills for debt service. Long-term general obligation bond indebtedness was $9.3 million at the end of Fiscal Year 1988, and reserve general obligation bond indebtedness was $5.5 million. The assessed value of property in the county was $182.5 million in Fiscal Year 1988 (HNUS 1992a).

Assuming revenues and expenditures increase in proportion to projected growth in the employment and population, estimated revenues and expenditures for Aiken County over the period from Fiscal Year 1990 to Fiscal Year 2000 will be $15.6 million to $17.0 million (in constant 1988 dollars) (HNUS 1992a).

Public services provided by Barnwell County also are funded principally through the county's general fund. In Fiscal Year 1988, revenues and expenditures of this fund were $4.0 million and $4.9 million, respectively. The property tax rate is 23.9 mills of assessed valuation. Budgeted Fiscal Year 1990 revenues were approximately $4.5 million (HNUS 1992a).

4.4 Cultural Resources

4.4.1 Archeological Sites and Historic Structures

Field studies conducted under an ongoing program over the past two decades by the South Carolina Institute of Archeology of the University of South Carolina, under contract to DOE and in consultation with the South Carolina State Historic Preservation Officer, have provided considerable information about the distribution and content of archeological and historic resources on the SRS. By the end of Fiscal Year 1992, approximately 60 percent of the Site had been examined, and 858 archeological (historic and prehistoric) sites had been identified; these include 706 prehistoric and 350 historic components, some of which are mixed (i.e., contain elements of both). Of the 858 sites, 53 have been determined to be eligible for the National Register of Historic Places; 650 have not been evaluated. Approximately 21 of the 53 (40 percent) are historic sites, such as building foundations; none are standing structures. These sites provide knowledge of the area's history before 1820. The remainder are primarily prehistoric sites and some are mixed (historic and prehistoric). No SRS facilities have been nominated for eligibility to the National Register for Historic Places and there are no plans for such a nomination at this time (Brooks 1993; Brooks 1994). The existing SRS nuclear production facilities are not likely to be eligible for the National Register, either because they might lack architectural integrity, might not represent a particular architectural style, or might not contribute to the broad historic theme of the Manhattan Project and initial nuclear materials production (DOE 1993a).

Archeologists have divided areas of the SRS into three sensitivity zones related to their potential for containing sites with multiple archeological components or dense or diverse artifacts, and their potential for eligibility to the National Register of Historic Places (SRARP 1989).

- Zone 1 is the zone of the highest archeological site density with a high probability of encountering large archeological sites with dense and diverse artifacts, and high potential for nomination to the National Register of Historic Places.
- Zone 2 covers areas of moderate archeological site density that should contain sites of similar composition. Activities in this zone have a moderate probability of encountering archeological sites, but a low probability of encountering large sites with more than three prehistoric components. All areas within the zone are conducive to site preservation. The zone has moderate potential for encountering sites that would be eligible for nomination to the National Register of Historic Places.
- Zone 3 covers areas of low archeological site density. Activities in this zone have a low probability of encountering archeological sites and virtually no chance of encountering large sites with more than three prehistoric components; potential for site preservation is low. Some exceptions to this definition have been discovered in Zone 3, so some sites in the

zone could be considered eligible for nomination to the National Register of Historic Places.

4.4.2 Native American Cultural Resources

In conjunction with 1991 studies related to a proposed New Production Reactor, DOE conducted an investigation of Native American concerns over religious rights in the Central Savannah River Valley. During this study three Native American groups - the Yuchi Tribal Organization, the National Council of Muskogee Creek, and the Indian People's Muskogee Tribal Town Confederacy - expressed concerns over sites and items of religious significance on the SRS. DOE has included these organizations on its environmental mailing list and sends them documents about SRS environmental activities (NUS 1991a).

Native American resources in the region include villages or townsites, ceremonial lodges, burial sites, cemeteries, and areas containing traditional plants for certain rituals. Villages or townsites might contain a variety of sensitive features associated with different ceremonies and rituals. The Yuchi and Muskogee Creek tribes have expressed concerns that the area might contain several plants traditionally used in tribal ceremonies (DOE 1993a).

4.4.3 Paleontological Resources

Invertebrate fossil remains occur within the McBean, Barnwell, and Congaree formations of the Eocene Age (54 million to 39 million years ago) on the SRS. Relatively large quantities of marine invertebrate fossils have been recorded for the McBean and Barnwell Formations. Relative assessment of fossil localities is difficult because the South Carolina Geological Survey has not established criteria for, or registry of, important paleontological locations (DOE 1991b).

4.5 Aesthetics and Scenic Resources

The dominant aesthetic setting in the vicinity of the SRS consists mainly of agricultural land and forest, with some limited residential and industrial areas. Because of the distance to the Site boundary, the rolling terrain, normally hazy atmospheric conditions, and heavy vegetation, SRS facilities are not generally visible from off the Site. The few locations that have views of some of the SRS structures are quite distant from the facility [5 miles (8 kilometers) or more].

SRS land is heavily wooded, and developed areas occupy only approximately 5 percent of the total land area. The facilities are scattered across the SRS and are brightly lit at night. Typically, the reactors and principal processing facilities are large concrete structures as much as 100 feet (30 meters) high and usually colocated with lower administrative and support buildings and parking lots. The facilities are visible in the direct line-of-sight when approaching them from SRS access roads. A 500-foot cooling tower is located in K-Area. Otherwise, heavily wooded areas that border the SRS road system and public highways that cross the Site limit views of the facilities.

4.6 Geology

The SRS is on the Upper Atlantic Coastal Plain of South Carolina, which consists of 213 to 366 meters (700 to 1,200 feet) of sands, clays, and limestones of Tertiary and Cretaceous age. These sediments are underlain by sandstones of Triassic age and older metamorphic and igneous rocks (Arnett et al. 1993). There are no known capable faults on the SRS or volcanic activities within 800 kilometers (500 miles) of the Site.

4.6.1 General Geology

The SRS is in the Coastal Plain physiographic province of western South Carolina, approximately 32 kilometers (20 miles) southeast of the Fall Line, which separates the Piedmont and Coastal Plain provinces (Figure 4-3). The Coastal Plain province is underlain by a wedge of seaward-dipping and thickening unconsolidated and semiconsolidated sediments that extend from the Fall Line to the Continental Shelf (Figure 4-4).

In South Carolina, the Coastal Plain province is divided into the Upper Coastal Plain and the Lower Coastal Plain. Subdivisions of the Coastal Plain in the State include the Aiken Plateau and the Congaree Sand Hills in the Upper Coastal Plain, and the Coastal Terraces in the Lower Coastal Plain. The Congaree Sand Hills trend along the Fall Line northeast and north of the Aiken Plateau. The Savannah and Congaree Rivers bound the Aiken Plateau, on which the SRS is located; the plateau extends from the Fall Line to the Coastal Terraces. The surface of the plateau is highly dissected and characterized by broad interfluvial areas with narrow steep-sided valleys. The plateau is generally well drained, although poorly drained depressions (Carolina bays) do exist (DOE 1991b). Because of the proximity of the SRS to the Piedmont province, it has more relief than areas that are nearer to the coast, with onsite elevations ranging from 27 to 128 meters (89 to 420 feet) above mean sea level.

The sediments of the Atlantic Coastal Plain of South Carolina overlie a basement complex composed of Paleozoic crystalline and Triassic sedimentary rocks. These sediments dip gently seaward from the Fall Line and range in age from Late Cretaceous to Recent. The sedimentary sequence thickens from essentially zero at the Fall Line to more than 1,219 meters (4,000 feet) at the coast. Regional dip is to the southeast. Coastal Plain sediments underlying the SRS consist of sandy clays and clayey sands, although occasional beds of clean sand, gravel, clay, or carbonate occur (Figure 4-5). Two clastic limestone zones occur within the Tertiary age sequence. These calcareous zones vary in thickness from about 0.6 meter (2 feet) to approximately 24 meters (80 feet). Most of the clastic sediments are unconsolidated, but thin semiconsolidated beds also occur (DOE 1991b). Underlying sediments are dense crystalline igneous and metamorphic rock or younger consolidated sediments of the Triassic Period. The Triassic formations and older igneous and metamorphic rocks are separated hydrologically from the overlying Coastal Plain sediments by a regional aquitard, the Appleton Confining System (Arnett et al. 1993). Section 4.8.2 contains a detailed discussion of hydrogeology on the SRS.

Figure 4-3. Location of the Savannah River Site in the southern United States. **Figure 4-4. Generalized subsurface cross-section.** **Figure 4-5. Stratigraphy of the SRS region.**

4.6.2 Geologic Resources

SRS construction activities have used clay, sand, and gravel to a limited extent. These materials are not of major economic value due to their abundance throughout the region. The SRS historically has been a major user of groundwater in the region, withdrawing about 33 million liters (9 million gallons) per day. Section 4.8.2 describes the groundwater resources at the SRS.

4.6.3 Seismic and Volcanic Hazards

The closest offsite fault system of significance is the Augusta Fault Zone, approximately 40 kilometers (25 miles) from the SRS. In this fault zone, the Belair Fault has experienced the most recent movement, but it is not considered capable of generating major earthquakes (DOE 1987a). There is no conclusive evidence of recent displacement along any fault within 320 kilometers (200 miles) of the SRS, with the possible exception of the buried faults in the epicentral area of the 1886 earthquake at Charleston, South Carolina, approximately 145 kilometers (90 miles) away (DOE 1991b). Faulting in the subsurface Coastal Plain sediments in the Charleston vicinity has been suggested, based on structure contour mapping of the Eocene-Oligocene unconformity, which lies at a depth of about 30 to 61 meters (100 to 200 feet) below ground surface (WSRC 1994a). However, because it is not known if these faults offset sediments younger than Eocene-Oligocene, these shallow faults cannot be related to modern earthquakes that occur at depths greater than about 1.9

kilometers (1.2 miles). Figure 4-6 shows the geologic structures within 150 kilometers (95 miles) from the SRS, some of which are discussed above.

Several Triassic-Jurassic basins, 140 to 230 million years old, have been identified in the Coastal Plain province of South Carolina and Georgia. The Dunbarton Triassic basin, which underlies a portion of the SRS, was formed by fault movement resulting from extensional forces operating during the formation of the Atlantic Ocean. After the erosion of basin margins and infilling of the basin with Triassic age sediments, possible movement of an opposite sense to that during basin formation occurred along the fault during the Late Cretaceous age. Geophysical data indicate minimal movement on faults at the basement-Coastal Plain interface, with the exception of possible reverse fault motion along the Pen Branch Fault up into the Tertiary (WSRC 1994a).

Figure 4-6. Geologic structures within 150 km of SRS (Source: DOE 1991b).

Researchers have mapped the Pen Branch Fault for at least 24 kilometers (15 miles) across the central portion of the SRS (Snipes et al. 1993). This fault is probably a continuation of the northern boundary fault of the Triassic age Dunbarton basin and is interpreted as being at least a Cretaceous/Tertiary (144-1.6 million years) reactivation of that fault (WSRC 1994a). Observed displacements of the Coastal Plain sediments range from about 26 meters (85 feet) at the Basement/Cretaceous contact to about 9 meters (30 feet) in the shallower sediments (WSRC 1994a). Based on the available data, there is no evidence to indicate that the Pen Branch is a "capable fault" as defined by the U.S. Nuclear Regulatory Commission (NRC). Under the NRC definition, a fault is capable if it has moved within the last 35,000 years, has had recurring movement within the last 500,000 years, is related to any earthquake activity, or is associated with another capable fault. A recent study (Snipes et al. 1993) examined a Quaternary light tan soil horizon in SRS railroad cuts. The soil horizon, which has a thickness of 3 to 6 meters (10 to 20 feet), revealed no detectable offset, indicating that there has been no recent Pen Branch Fault activity. Figure 4-7 shows the locations of the Pen Branch Fault and other known or suspected faults within the Paleozoic and Triassic Basement (DOE 1991b).

Seismicity in the Coastal Plain of South Carolina occurs in three distinct seismic zones near the Charleston area (WSRC 1994a): Middleton Place-Summerville, about 19 kilometers (12 miles) northwest of Charleston; Bowman, about 59 kilometers (37 miles) northwest of the Middleton Place-Summerville; and Adams Run, about 30 kilometers (19 miles) southwest of the Middleton Place-Summerville (WSRC 1994a). Of the distinct seismic zones within the Coastal Plain province, the Charleston area has been and remains the most seismically active. The Charleston area is also the most significant source of seismicity affecting the SRS, both in terms of maximum historic site intensity and the number of earthquakes felt in the area (WSRC 1994a).

Tables 4-2 and 4-3 summarize the historic information on earthquakes that have occurred in the SRS region. Two notable earthquakes have occurred within 320 kilometers (200 miles) of the SRS. The first was a major earthquake in 1886 centered in the Charleston area about 145 kilometers (90 miles) from the Site; it had an estimated Richter magnitude of 6.8. DOE estimates that the SRS would have felt a tremor with an estimated Modified Mercalli Intensity (MMI) of VI to VII and an estimated peak horizontal acceleration of 10 percent of gravity, or 0.10g, due to that earthquake (WSRC 1994a). The second earthquake was the Union County, South Carolina, earthquake of 1913, which had an estimated Richter magnitude of 6.0 and occurred about 160 kilometers (100 miles) from the SRS (WSRC 1994a). This earthquake, which is the closest significant event to the SRS other than

Figure 4-7. Geologic faults of the Savannah River Site.

the Charleston-area earthquake, produced an estimated intensity of II to III (MMI) in the City of Aiken, which is approximately 19 kilometers (12 miles) north of the Site (DOE 1991b; WSRC 1994a).

Two earthquakes have occurred on the SRS during recent years (see Figure 4-7). On June 8, 1985, onsite instruments recorded an earthquake with a Richter magnitude of 2.6 and a focal depth of about 1.0 kilometer (0.6 mile) (WSRC 1994a). The epicenter was just west of the C- and K-Areas. The ground acceleration from this event did not activate instrumentation in the reactor areas (detection limits of 0.002g). On August 5, 1988, an earthquake with a Richter magnitude of 2.0 and a focal depth of approximately 2.7 kilometers (1.7 miles) occurred (Stephenson 1988); earthquakes of Richter magnitude 2.0 are normally detected only by specialized instrumentation. The epicenter for this event was just northeast of K-Area. Although this event was not felt by workers on the SRS, it was recorded by sensors within 96 kilometers (60 miles) of the Site. A report on the August 1988 earthquake (Stephenson 1988) also reviewed the latest earthquake history for the region. This report predicts recurrence period of 1 year for a magnitude 2.0 event for the southeast Coastal Plain. However, the report notes that historic data to calculate recurrence rates accurately are sparse. SRS workers did feel the effects of two other events that occurred in the area within the past 7 years. A Richter magnitude 2.6 earthquake occurred in the City of Aiken, approximately 19 kilometers (12 miles) north of the SRS on February 17, 1988. Reports indicate that this event was felt in the Aiken area and on the SRS (DOE 1991b). Most recently, a Richter magnitude 3.2 earthquake occurred on August 8, 1993, approximately 16 kilometers (10 miles) east of the City of Aiken near Couchton, South Carolina. Residents reported feeling this earthquake in Aiken, New Ellenton (immediately north of the SRS), North Augusta (approximately 40 kilometers [25 miles] northwest of the SRS), and the Site.

Based on seismic activity information in the past 300 years, this analysis does not project earthquakes greater than a Richter magnitude 6.0, which corresponds to a Modified Mercalli Intensity of VII, to occur on the SRS. The design-basis earthquake for the SRS is a Modified Mercalli Intensity VIII event, which corresponds to a horizontal peak ground acceleration of 0.2g. Based on current technology, as applied in various probabilistic evaluations of the seismic hazard in the SRS region, the 0.2g peak ground acceleration can be associated with a 2 x 10-4 annual probability of exceedance (5,000-year return period). DOE Standards 1020 (DOE 1994a) and 1024 (DOE 1992) summarize the results of recent seismic analyses at DOE sites and show that maximum horizontal ground accelerations for the Savannah River Site for 500 year, 1,000 year, 2,000 year, and 5,000 year seismic events are 0.10g, 0.13g, 0.18g, and 0.19g respectively. The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility-specific basis consistent with DOE Orders and standards and site-specific standards.

Historically, DOE has generally selected the more conservative 0.20g as the peak ground acceleration for the 5,000 year seismic event when preparing safety analysis reports and environmental impact statements for the SRS. For consistency with these existing analyses, this environmental impact statement assumes 0.20g to be the peak horizontal ground acceleration that would result from the 5,000 year seismic event. Figure 4-8 shows seismic hazard curves for the SRS.

A number of paleoliquefaction sites have been identified in Beaufort County, South Carolina, some 50 miles (80 kilometers) southeast of the SRS, indicating a likelihood of prehistoric seismic events outside of the currently-active Charleston seismic zone (Rajendran and Talwani 1993). There is no evidence to suggest that seismically-induced liquefaction of soils represents a hazard at SRS, however. Weak subsurface zones are encountered occasionally during drilling. These zones are associated with carbonate materials and appear to be related to dissolution of these materials.

Engineering investigations have been conducted on granular soils underlying the Defense Waste Processing Facility [in S-Area just north of H-Area (see Figure 2-3)] to evaluate the cyclic mobility (liquefaction under cyclic stresses) of these soils (WSRC 1992b). These investigations determined that the sands and clayey sands throughout the subgrade will not experience liquefaction (strength loss leading to bearing capacity failures) and will not develop cyclic mobility (significant cyclic or accumulate deformations) under the safe shutdown earthquake with a peak horizontal ground surface acceleration of 0.20g (9.8 meters/second2 or 32.1 feet/second2).

4.7 Air Resources

4.7.1 Meteorology and Climatology

The SRS collects wind data from instruments mounted on seven onsite 61-meter (200-foot) meteorological towers. Figure 4-9 shows a wind rose that represents annual wind direction frequencies and wind speeds for the SRS from 1987 through 1991. The maximum wind directional frequencies are from the northeast and west-southwest. The average wind speed for this 5-year period was 3.8 meters per second (8.5 miles per hour). Calm winds (less than 1 meter per second or 2.2

miles per hour) occurred less than 10 percent of the time during the 5-year period. Seasonally, wind speeds were greatest during the winter at 4.1 meters per second (9.5 miles per hour) and lowest during the summer at 3.4 meters per second (7.6 miles per hour) (WSRC 1994a).

Figure 4-8. Seismic hazard curves for the SRS. Figure 4-9. Wind Rose.

The annual average temperature at the SRS is 18 degrees C (64 degrees F); monthly averages range from a low of 7 degrees C (45 degrees F) in January to a high of 27 degrees C (81 degrees F) in July. Relative humidity readings taken four times each day range from 36 percent in April to 98 percent in August (DOE 1991a).

The average annual precipitation at the SRS is approximately 122 centimeters (48 inches). Precipitation distribution is fairly even throughout the year, with the highest precipitation in the summer [36.1 centimeters (14.2 inches)] and the lowest in autumn [22.4 centimeters (8.8 inches)]. Snowfall has occurred in the months of October through March, with the average annual snowfall at 3.0 centimeters (1.2 inches). Large snowfalls are rare (DOE 1991a).

Winter storms in the SRS area occasionally bring strong and gusty surface winds with speeds as high as 32 meters per second (72 miles per hour). Thunderstorms can generate winds with speeds as high as 18 meters per second (40 miles per hour) and even stronger gusts. The fastest 1-minute wind speed recorded at Augusta between 1950 and 1986 was 37 meters per second (83 miles per hour) (DOE 1991a).

4.7.1.1 Occurrence of Violent Weather. The SRS area experiences an average of 56 thunderstorm days per year. From 1954 to 1983, 37 tornadoes were reported for a 1-degree square of latitude and longitude that includes the SRS (DOE 1991a). This frequency of occurrence is equivalent to an average of about one tornado per year. The estimated probability of a tornado striking a point on the SRS is 7 x 10-5 per year (DOE 1991a). Since operations began at the SRS in 1953, nine confirmed tornadoes have occurred on or near the Site. They caused nothing more than light damage, with the exception of a tornado in October 1989 that caused considerable damage to forest resources in an undeveloped southeastern sector of the SRS (WSRC 1994a).

From 1700 to 1992, 36 hurricanes occurred in South Carolina, resulting in an average frequency of about one hurricane every 8 years. Three hurricanes were classified as major. Because SRS is about 160 kilometers (100 miles) inland, the winds associated with hurricanes have usually diminished below hurricane force [i.e., equal to or greater than a sustained wind speed of 33.5 meters per second (75 miles per hour)] before reaching the SRS. Winds exceeding hurricane force have been observed only once at SRS (Hurricane Gracie in 1959) (WSRC 1994a).

4.7.1.2 Atmospheric Stability. Based on measurements at onsite meteorological stations, the atmosphere in the SRS region is unstable approximately 56 percent of the time, neutral 23 percent of the time, and stable about 21 percent of the time. On an annual basis, inversion conditions occur 21 percent of the time at the SRS (WSRC 1994a).

4.7.2 Nonradiological Air Quality

4.7.2.1 Background Air Quality. The SRS is in the Augusta (Georgia) - Aiken (South Carolina) Interstate Air Quality Control Region (AQCR). This Air Quality Control Region, which is designated as a Class II area, is in compliance with National Ambient Air Quality Standards (NAAQS) for criteria pollutants. The criteria pollutants include sulfur dioxide, nitrogen oxides reported as nitrogen dioxide, particulate matter (less than or equal to 10 microns), carbon monoxide, ozone, and lead (CFR 1993a). The closest nonattainment area to the SRS is the Atlanta, Georgia, air quality region, 233 kilometers (145 miles) to the west, which is in nonattainment of the standard for ozone.

The SRS will have to comply with Prevention of Significant Deterioration (PSD) Class II requirements if there is a significant increase in emissions of criteria air pollutants due to a modification at the Site (CFR 1993b). Development at the SRS has not yet triggered Prevention of Significant Deterioration permitting requirements. If a permit were required, the SRS would have to address several requirements, including impacts on the air quality of Class I areas within 10 kilometers (6.2 miles) of the Site (CFR 1993b). The nearest Class I area to the SRS is the Congaree Swamp National Monument in South Carolina, approximately 73 kilometers (45 miles) to the east-northeast of the Site. Therefore, a Prevention of Significant Deterioration permit, if required for the SRS, would not have to address Class I areas.

4.7.2.2 Air Pollutant Source Emissions. The SRS utilized the 1990 comprehensive

emissions inventory data to establish the baseline year for showing compliance with State and Federal air quality standards - calculating both maximum potential and actual emission rates. The air quality compliance demonstration also included sources forecast for construction or operation in this decade (for which the SRS had obtained air quality construction permits through December 1992). The SRS based its calculated emission rates for the sources on process knowledge, source testing, permitted operating capacity, material balance, and U.S. Environmental Protection Agency (EPA) Air Pollution Emission Factors (AP-42; EPA 1985).

4.7.2.3 Ambient Air Monitoring. At present, the SRS performs no onsite ambient air quality

monitoring. State agencies operate ambient air quality monitoring sites in Barnwell, Aiken, and Richmond Counties. These areas, which include the SRS, are in attainment with National Ambient Air Quality Standards for sulfur dioxide, nitrogen oxides, carbon monoxide, particulate matter, ozone, and lead (CFR 1993a).

4.7.2.4 Atmospheric Dispersion Modeling. The SRS has performed atmospheric

dispersion modeling for criteria and toxic air pollutants for both maximum potential and actual emissions for the base year 1990, using the EPA Industrial Source Complex Short Term No. 2 Model. The SRS used 1991 meteorological data collected at the Site meteorological stations for input to the model.

4.7.2.5 Summary of Nonradiological Air Quality. The SRS is in compliance with

National Ambient Air Quality Standards and with the gaseous fluoride and total suspended particulate standards required by South Carolina Department of Health and Environmental Control (SCDHEC) Regulation R.61-62.5, Standard 2, "Ambient Air Quality Standards" (AAQS) (see Table 4-4).

The SCDHEC has non-radiological air quality regulatory authority over the SRS. The Department determines SRS ambient air quality compliance based on SRS air pollutant emissions modeled at the Site perimeter (excluding SC Highway 125, which crosses the southwestern quadrant of the SRS).

The SRS is in compliance with SCDHEC Regulation R.61-62.5, Standard 8, "Toxic Air Pollutants," which regulates the emission of 257 toxic substances. The SRS has identified emission sources for 139 of the 257 regulated substances; the modeled results indicate that the Site is within applicable Department of Health and Environmental Control standards (WSRC 1993a). Table 4-5 lists

SRS emissions of toxic air pollutants of concern related to the SRS spent nuclear fuel alternatives, based on 1990 baseline data and the potential sources of air pollution permitted for construction or operation in December 1992.

4.7.3 Radiological Air Quality

4.7.3.1 Background and Baseline Radiological Conditions. In the SRS region, airborne

radionuclides originate from natural resources (terrestrial or cosmic), worldwide fallout, and Site operations. The SRS maintains a network of air monitoring stations on and around the Site to

4.8 Water Resources

4.8.1 Surface Water

The Savannah River bounds the SRS on its southwestern border for about 20 miles (32 kilometers), approximately 160 river miles (260 kilometers) from the Atlantic Ocean. At the SRS, river flow averages about 10,000 cubic feet (283 cubic meters) per second. River flows range from 3,960 cubic feet (112 cubic meters) per second to 71,700 cubic feet (2,030 cubic meters) per second.

Five upstream reservoirs - Jocassee, Keowee, Hartwell, Richard B. Russell, and Strom Thurmond - minimize the effects of droughts and the impacts of low flow on downstream water quality and fish and wildlife resources in the river.

At the SRS, a swamp occupies the floodplain along the Savannah River for a distance of approximately 10 miles (17 kilometers); the swamp is about 1.5 miles (2.5 kilometers) wide. A natural levee separates the river from the swampy floodplain. Figure 4-10 shows the 100-year floodplain of the Savannah River in the vicinity of the SRS as well as the floodplains of major tributaries draining the SRS. A 500-year floodplain map of the SRS has not been completed, but would be required prior to the siting of any spent nuclear fuel management facilities, in compliance with DOE regulations (CFR 1979). These regulations require DOE to evaluate the potential effects of flooding to proposed "critical actions" (for example, the storage of highly toxic or water-reactive materials), which it defines as those for which even a slight chance of flooding would be unacceptable.

The five principal tributaries to the river on the SRS are Upper Three Runs Creek, Fourmile Branch, Pen Branch, Steel Creek, and Lower Three Runs Creek (Figure 4-10). These tributaries drain almost all of the SRS. Each of these streams originates on the Aiken Plateau in the Coastal Plain and descends 50 to 200 feet (15 to 60 meters) before discharging into the river. The streams, which historically have received varying amounts of effluent from various SRS operations, are not commercial sources of water. The natural flow of SRS streams ranges from less than 10 cubic feet (l cubic meter) per second in smaller streams such as Pen Branch to 240 cubic feet (6.8 cubic meters) per second in Upper Three Runs Creek.

Figure 4-10. Savannah River Site, showing major stream systems and facilities.

4.8.1.1 SRS Streams.

This section describes the pertinent physical and hydrologic properties of Upper Three Runs Creek and Fourmile Branch, which are the streams closest to most SRS spent nuclear fuel management locations (Figure 4-10). These two streams are among the largest on the SRS, and they border the areas where DOE is most likely to locate new spent nuclear fuel facilities.

Upper Three Runs Creek is a large, cool [annual maximum temperature of 26.1 degrees C

(79 degrees F)] blackwater stream in the northern part of the SRS. It drains an area of approximately 210 square miles (545 square kilometers), and has an average discharge of 330 cubic feet (9.3 cubic meters) per second at the mouth of the creek. Upper Three Runs Creek is approximately 25 miles (40 kilometers) long, with its lower 17 miles (28 kilometers) inside the boundaries of the SRS. This creek receives more water from underground sources than the other SRS streams and, therefore, has low conductivity, hardness, and pH values. Upper Three Runs Creek is the only major tributary on the SRS that has never received thermal discharges.

Fourmile Branch is about 15 miles (24 kilometers) long and drains an area of approximately 34 square miles (89 square kilometers). In its headwaters, Fourmile Branch is a small blackwater stream that receives relatively few impacts from SRS operations. The water chemistry in the headwater area of the creek is very similar to that of Upper Three Runs Creek, with the exception of nitrate concentrations, which are an order of magnitude higher than those in Upper Three Runs Creek (WSRC 1994a). These elevated nitrate concentrations are probably the result of groundwater transport and outcropping from the F- and H-Area seepage basins. In its lower reaches, Fourmile Branch broadens and flows through a delta formed by the deposition of sediments. Although most of the flow through the delta is in one main channel, the delta has many standing dead trees, logs, stumps, and cypress trees that provide structure and reduce the water velocity in some areas. Downstream of the delta, the creek flows in one main channel and most of the flow discharges into the Savannah River at River Mile 152 (kilometer 245), while a small portion of the creek flows west and enters Beaver Dam Creek, a small onsite tributary.

4.8.1.2 Surface Water Quality. The Savannah River, which forms the boundary between the States of Georgia and South Carolina, supplies potable water to several users. Upstream of the SRS, the river supplies domestic and industrial water needs for Augusta, Georgia, and North Augusta, South Carolina. The river also receives sewage treatment plant effluent from Augusta, Georgia; North Augusta, Aiken, and Horse Creek Valley, South Carolina; and as described above from a variety of SRS operations via onsite stream discharges. Approximately 130 river-miles (210 kilometers) downstream of the SRS, the river supplies domestic and industrial water needs for Savannah, Georgia, and Beaufort and Jasper Counties in South Carolina through intakes located at about River Mile 29 and River Mile 39. In addition, Georgia Power's Vogtle Electric Generating Plant withdraws an average of 1.3 cubic meters per second (46 cubic feet per second) for cooling and returns an average of 0.35 cubic meters per second (12 cubic feet per second) of cooling tower blowdown. Also, the Urquhart Steam Generating Station at Beech Island, South Carolina withdraws approximately 7.5 cubic meters per second (265 cubic feet per second) for once-through cooling water.

The South Carolina Department of Health and Environmental Control regulates the physical properties and concentrations of chemicals and metals in SRS effluents under the National Pollutant Discharge Elimination System (NPDES) program. This agency also regulates chemical and biological water quality standards for SRS waters. On April 24, 1992, the agency changed the classification of the Savannah River and SRS streams from "Class B waters" to "Freshwaters." The definitions of Class B waters and Freshwaters are the same, but the Freshwaters classification imposes a more stringent set of water quality standards (Arnett et al. 1993). Tables 4-10 and 4-11 list the characteristics of SRS surface-water quality upstream and downstream, respectively, due to contributions from SRS and possibly other sources. A comparison of these results indicates that influences from SRS or other sources are not seriously degrading Savannah River water quality.

4.8.2 Groundwater Resources

4.8.2.1 Hydrostratigraphic Units. There are two hydrogeologic provinces in the subsurface beneath SRS (WSRC 1994a). The first, referred to as the Piedmont hydrogeologic province (Figure 4-11), includes Paleozoic metamorphic and igneous basement rocks and Triassic-aged lithified mudstone, sandstone, and conglomerate contained within the Dunbarton Basin. The second, referred to as the Southeastern Coastal Plain hydrogeologic province, represents the major aquifer systems and consists of a wedge of unconsolidated Coastal Plain sediments of Late Cretaceous and Tertiary age (Figure 4-11). These two units are overlain by the vadose or unsaturated zone, which extends from

Figure 4-11. Comparison of lithostratigraphy and hydrostratigraphy for the SRS region (not to scale). the ground surface to the water table. The unsaturated zone is a heterogeneous unit of clean, clayey, or silty sand through which recharge takes place.

The sediments that make up the Southeastern Coastal Plain hydrogeologic province in west-central South Carolina are grouped into three major aquifer systems divided by two major confining systems, all of which are underlain by the Appleton confining system (Figure 4-11). The Appleton system separates the Southeastern Coastal Plain hydrogeologic province from the underlying Piedmont hydrogeologic province. Locally, each of the major aquifer systems contains individual aquifer and confining units. Figure 4-11 shows the regional lithostratigraphy of the geologic province with the attendant primary hydrostratigraphic subdivision of the province. The complexly interbedded strata that form the three aquifer systems consist primarily of fine- to coarse-grained sand and local gravel and limestone deposited under relatively high energy conditions in fluvial to shallow marine environments (WSRC 1994a).

Figure 4-11 shows the current aquifer/aquitard terminology at the SRS. Aquifers, in ascending order, include the McQueen Branch, the Crouch Branch, and the Steed Pond. For comparison, the figure also includes the corresponding aquifer terminology used on the Georgia side of the Savannah River. These include the Midville, Dublin, and Floridan aquifer systems. In addition, the three aquifers are separated by confining layers which include, in ascending order, the Appleton, Allendale, and Meyers Branch confining systems (WSRC 1994a).

4.8.2.2 Groundwater Flow. Excellent quality groundwater is abundant in this region of

South Carolina from many local aquifer units. As a result, the South Carolina Department of Health and Environmental Control has classified all aquifers in the state as Class GB (South Carolina 1976), or U.S. Environmental Protection Agency (EPA) Class II, meaning that the aquifers can provide resource-quality water, but are not the sole source of supply (South Carolina Class GA or EPA Class I aquifers) (DOE 1991b).

The main source of recharge to the vadose zone is rainfall. The annual precipitation at the SRS is 48 inches (121.9 centimeters), with an estimated 16 inches (41 centimeters) designated as surface recharge at the center of the SRS, in bare and grass-covered areas (WSRC 1994a). The direction of groundwater flow in the vadose zone is predominantly downward. However, given the lenses of silt and clay that exist, there is significant lateral spread in some areas. In general, the vadose zone thickness ranges from approximately 130 feet (40 meters) in the northernmost portion of the SRS to 0 feet where the water table intersects wetlands, streams, or creeks.

The following discussion of groundwater flow in the Coastal Plain hydrogeologic province begins with the deepest aquifers at the SRS and proceeds to shallower units. It does not address flow in the confining units because few hydraulic head measurements are available for these units and, to a good approximation, flow in aquitards is limited predominantly to vertical flow between aquifer units.

The Midville or McQueen Branch aquifer (which has also been called the Middendorf, the Lower Cretaceous, the Tuscaloosa, and Aquifer IA) is highly transmissive and, therefore, serves in part as the production aquifer for much of the SRS. This aquifer flows horizontally, predominantly toward the Savannah River. In the past, groundwater production wells at the SRS were screened in both the Midville (McQueen Branch) and Dublin (Crouch Branch) aquifers. In 1985 DOE committed to the South Carolina Department of Health and Environmental Control to complete production wells only in the McQueen Branch aquifer to minimize the potential for contamination to reach such wells and spread in the deeper aquifers.

Flow in the Dublin or Crouch Branch aquifer (which has also been called the Black Creek, the Tuscaloosa, the Upper Cretaceous, and Aquifer IB) is more complicated than flow in the deeper McQueen Branch aquifer because of the apparent communication with Upper Three Runs Creek on the SRS. Nonetheless, horizontal flow in the Dublin (Crouch Branch) aquifer is predominantly toward the Savannah River. However, there is an upward vertical flow component near the river and Upper Three Runs Creek. Recharge to the Dublin-Midville aquifer system occurs in areas exposed at the ground surface near the Fall Line (see Figure 4-3).

Horizontal flow in the Gordon aquifer (previously called the Congaree, the Tertiary, and Aquifer II) is toward Upper Three Runs Creek and the Savannah River, depending on the area of the SRS. Both the river and Upper Three Runs Creek intercept this aquifer. The Gordon aquifer receives most of its recharge from groundwater that originates on the SRS.

Previous SRS studies have called the Upper Three Runs aquifer the "water table aquifer"; others have defined it as both the Barnwell/McBean and water table aquifers in the central portion of the SRS where those aquifers were thought to be separated by a "tan clay." The Upper Three Runs aquifer is the shallowest aquifer at the SRS. The horizontal groundwater flow is generally toward the nearest surface-water feature that is in communication with the water table. Most SRS streams, except Tims Branch in the northeastern part of the Site, are in communication with the water table. Tims Branch is a "losing stream," meaning it provides, or "loses," water to the Upper Three Runs aquifer. However, the Upper Three Runs aquifer receives most of its recharge from precipitation. The Upper Three Runs aquifer is not a source of domestic or production water on the SRS because the lower aquifers provide a more abundant supply of higher quality water (WSRC 1994a).

4.8.2.3 Groundwater Quality. The quality of groundwater in the principal hydrologic systems beneath the SRS depends on both the source of the water and the inorganic and biochemical reactions that take place along its flowpath. Quality is strongly influenced by the chemical composition and mineralogy of the enclosing geologic materials (WSRC 1994a).

In general, the quality of the groundwater in the Coastal Plain sediments at the SRS and the surrounding areas is suitable for most domestic and industrial purposes. The waters have low concentrations of total dissolved solids (TDS), ranging from less than 10 milligrams per liter to about 150 to 200 milligrams per liter. The pH values range from 4.9 to 7.7 (where the groundwater is in contact with limestone). Much of the groundwater is corrosive to metal surfaces due to its low solids content and frequently low pH values. High dissolved iron concentrations can also be of concern in some groundwater units. The SRS uses degasification and filtration processes to raise the pH and remove iron in domestic water supplies where necessary (WSRC 1994a).

Table 4-12 summarizes groundwater quality data from 85 existing waste sites on the SRS compared to drinking water standards; Table 4-13 lists similar information for selected radiological constituents. The data in these tables are from ongoing monitoring programs on the Site. EPA-accepted methods and guidelines for sampling and analysis are an integral part of this monitoring program. Several of the facilities discussed below have state-approved sampling and analysis plans.

The shallow aquifers beneath 5 to 10 percent of the SRS have been contaminated by industrial solvents, metals, tritium, or other constituents used or generated on the Site. Figure 4-12 shows the locations of facilities where the SRS monitors groundwater and areas with constituents that exceeded drinking water standards in 1992; the concentrations shown on Figure 4-12 represent the maximum data from one monitoring well on at least one occasion at a given area. Contamination is limited to the shallow aquifers, with one exception (see next paragraph). Most contaminated groundwater at the SRS is beneath a few facilities; contaminants reflect the operations and chemical processes those facilities perform. For example, contaminants in the groundwater beneath A- and M-Areas include chlorinated volatile organics, radionuclides, metals, and nitrate. At F- and H-Areas, contaminants in the groundwater include tritium and other radionuclides, metals, nitrate, chlorinated volatile organics at values much smaller than those found at A- and M-Areas, and sulfate. The groundwater beneath the Sanitary Landfill contains chlorinated volatile organics, radionuclides, and metals. The groundwater

beneath all the reactor areas except R-Area contains tritium, other nuclides, metals, and chlorinated volatile organics. At R-Area, groundwater contaminants include radionuclides and cadmium. The groundwater beneath D-Area contains metals, radionuclides, sulfate, and chlorinated volatile organics. At TNX-Area, the groundwater contains chlorinated volatile organics, radionuclides, and nitrate (Arnett et al. 1993). None of these cases indicated the presence of groundwater contamination beyond Site boundaries. With the ongoing and expanding "pump and treat" system at the A-/M-Area (Figure 4-12), concentrations in the volatile organic compound plume are likely to decrease with time.

Contamination of groundwater in a drinking water aquifer has been found in only one relatively-small area north of A-Area, in the northwest portion of the site. In the early 1980s, SRS monitors found low concentrations of trichloroethylene (11.7 microgram per liter) in water from one production well (53A) completed to the Dublin-Midville Aquifer System (formerly called the Tuscaloosa Formation) in M-Area. The monitors found the contamination only at 430 and 480 feet (131 and 146 meters) in this well, which is 670 feet (204 meters) deep. The well is screened intermittently from 387 feet (118 meters) to the bottom. DOE concluded that the contamination is probably migrating down the outside well casing from soils near the surface that are contaminated with trichloroethylene. This contaminated water enters the well through screens set in the Dublin-Midville System (Du Pont 1983). In addition, in 1992 trichloroethylene and tetrachloroethylene were detected above Primary Drinking Water Standards in cretaceous zone (Dublin-Midville) well MSB 55TA, which is approximately 3,500 feet west of well 53A and 1,500 feet north of A-Area (Arnett et al. 1993).

Figure 4-12. Groundwater contamination at the Savannah River Site.

4.8.2.4 Groundwater Use. The McQueen Branch aquifer, which becomes shallower toward the Fall Line, forms the base for most municipal and industrial water supplies in Aiken County. Toward the coast, in Allendale and Barnwell Counties, this aquifer exists at increasingly greater depths. As a consequence, the shallower Gordon aquifer supplies some municipal, industrial, and agricultural users (Arnett et al. 1993).

DOE has identified 56 major municipal, industrial, and agricultural groundwater users within 20 miles (32 kilometers) of the center of the SRS (DOE 1987a). The total pumpage for these users is about 49 billion liters (13 billion gallons) per year. The SRS withdraws approximately 14.0 billion liters (3.7 billion gallons) of groundwater per year for domestic and industrial uses (DOE 1990).

4.9 Ecological Resources

The U.S. Government acquired the SRS in 1951. At that time, the Site was approximately two-thirds forested and one-third cropland and pasture (Dukes 1984). At present, more than 90 percent of the SRS is forested. An extensive forest management program conducted by the Savannah River Forest Station, which is operated by the U.S. Forest Service, has converted many pastures and croplands to pine plantations. With the exception of the SRS production and support areas, natural succession has reclaimed previously disturbed areas. Table 4-14 lists SRS land cover, other than the land used for nuclear reactors and support facilities.

The SRS is important to maintaining the biodiversity of the region. Satellite imagery of the Site shows a circle of wooded habitat within a matrix of cleared uplands and narrow forested riparian corridors. The SRS provides more than 734 square kilometers (181,000 acres) of contiguous forested cover broken only by unpaved secondary roads, transmission line corridors in various stages of succession, and a few paved primary roads. Carolina bays, the Savannah River swamp, and several relatively intact longleaf pine-wiregrass communities provide important contributions to the biodiversity of the SRS and of the entire region.

Table 4-14. Land cover of undeveloped areas on the Savannah River Site.

Land cover types	Square kilometer	Percent of total
Longleaf pine	150	20
Loblolly pine	258	35
Slash pine	117	16
Mixed pine/hardwood	23	3
Upland hardwood	20	3
Bottomland hardwood	117	16
Savannah River swamp	49	7

Total	734	100.0

a. Source: USDA (1991a).
b. To convert square kilometers to acres, multiply by 247.1.

F- and H-Areas, located near the center of the SRS and approximately 1.6 kilometers (1 mile) southeast of Upper Three Runs Creek, are heavily industrialized with little natural vegetation remaining inside the fenced areas. These areas are dominated by buildings, paved parking lots, gravelled construction areas, and laydown yards. While some grassed areas occur around the administration buildings and some vegetation is present along the ditches that drain the area, the majority of the site contains no vegetation. Wildlife is absent except for occasional crows (Corvus brachyrhynchos) and nesting barn swallows (Hirundo rustica) around the buildings.

Figure 2-3 shows the location of a representative host site at the SRS for potential spent nuclear fuel activities. F- and H-Areas (and developed areas immediately adjacent to them) would house most spent nuclear fuel management facilities, while the undeveloped area south and east of H-Area would be used for the construction of new facilities that F- and H-Areas could not accommodate. The undeveloped area, which was 98 percent cleared fields in 1951, is now almost completely forested, for the most part with 5- to 40-year-old upland pine stands that are actively managed by the Savannah River Forest Station. Most of these stands are loblolly pine (Pinus taeda), but there are small stands of slash pine (P. elliottii), upland hardwoods (predominantly oaks and hickories), and bottomland hardwoods (most commonly sweetgum, Liquidambar styraciflua, and yellow poplar, Liriodendron tulipifera) associated with two small Carolina bays located south of H-Area. The area south of H-Area lies in the Fourmile Branch watershed, while the area east of H-Area is in the McQueen Branch (a tributary of Upper Three Runs Creek) watershed. Neither area is likely to contain any threatened or endangered species or their habitats.

The general area of the representative host site contains suitable habitat for white-tailed deer and feral hogs as well as other faunal species common to the mixed pine/hardwood forests of South Carolina. Additional wildlife species found in the area include gray squirrel (Sciurus carolinensis), fox squirrel (S. niger), wild turkey (Meleagris gallopovo), cottontail rabbit (Sylvilagus floridanus), raccoon (Procyon lotor), bobcat (Felix rufus), and gray fox (Urocyon cinereoargenteus).

4.9.1 Terrestrial Ecology

The SRS is near the transition area between the oak-hickory-pine forest and the southern mixed forest. As a consequence, species typical of both associations occur (Dukes 1984). In addition, farming, fire, soil features, and topography have strongly influenced existing SRS vegetation patterns.

A variety of vascular plant communities occurs in the upland areas (Dukes 1984). Typically, scrub oak communities occur on the drier, sandier areas. Longleaf pine (Pinus palustrus), turkey oak (Quercus laevis), bluejack oak (Q. incana), blackjack oak (Q. marilandica), and dwarf post oak (Q. margaretta) dominate these communities, which typically have understories of wire grass (Aristida stricta) and huckleberry (Vaccinium sp.). Oak-hickory communities occur on more fertile, dry uplands; characteristic species are white oak (Q. alba), post oak (Q. stellata), southern red oak (Q. falcata), mockernut hickory (Carya tomentosa), pignut hickory (C. glabra), and loblolly pine, with an understory of sparkleberry (Vaccinium arboreum), holly (Ilex sp.), greenbriar (Smilax sp.), and poison ivy (Rhus radicans).

The removal of human residents in 1951 and the subsequent restoration of forest cover has provided the wildlife of the SRS with excellent habitat. Furbearers such as gray fox, raccoon, opossum (Didelphis virginiana), bobcat, beaver (Castor canadensis), and otter (Lutra canadensis) are relatively common throughout the Site. Game species such as gray squirrel and fox squirrel, white-tailed deer (Odocoileus virginianus), cottontail rabbit, and wild turkey are also common. The Savannah River Ecology Laboratory has conducted numerous studies of reptile and amphibian use of the wetlands and adjacent uplands of the SRS.

DOE allows carefully regulated public hunting for white-tailed deer and feral hogs (Sus scrofa) on most of the SRS to reduce the incidence of animal/vehicle collisions and maintain healthy populations within the carrying capacity of the range. SRS personnel monitor all animals removed from the Site for contamination before releasing them to the hunters (WSRC 1992a).

Before releasing any animal to a hunter, SRS technicians perform field analyses for cesium-

137 at the hunt site. In 1992, hunters collected 1,519 deer and 168 hogs. The maximum 1992 cesium-137 field measurement for deer was 22.4 picocuries per gram; the average was 6.4 picocuries per gram (Arnett et al. 1993). For hogs, the maximum value was 22.9 picocuries per gram and the average was 3.5 picocuries per gram. The field technicians determine estimated doses from consumption of the venison and pork and make this information available to the hunters.

In 1992, the estimated maximum dose received by a hunter was 49 millirem per year. The basis for this unique hypothetical maximum dose, which was for a hunter who harvested eight deer and one hog, is the assumption that the hunter consumed the entire edible portion of each animal. An additional hypothetical model involved a hunter whose total meat consumption for the year consisted of SRS deer [81 kilograms (179 pounds) per year] (Arnett et al. 1993). Based on these low-probability assumptions and on the average concentration of cesium-137 (6.4 picocuries in deer harvested on the SRS), the estimated potential maximum dose from this pathway is 26 millirem; this is 26 percent of the annual 100-millirem DOE Derived Concentration Guide. Although a large percentage of this hypothetical dose is probably due to cesium-137 from worldwide fallout, the estimated total contains this background cesium-137 for conservatism.

4.9.2 Wetlands

The SRS has extensive, widely distributed wetlands, most of which are associated with floodplains, creeks, and impoundments. In addition, approximately 200 Carolina bays occur on the Site (Shields et al. 1982; Schalles et al. 1989).

The southwestern SRS boundary adjoins the Savannah River for approximately 32 kilometers (20 miles). The river floodplain supports an extensive swamp, covering about 49 square kilometers (12,148 acres) of the Site; a natural levee separates the swamp from the river. Timber was cut in the swamp in the late 1800s. At present, the swamp forest consists of second-growth bald cypress (Taxodium distichum), black gum (Nyssa sylvatica), and other hardwood species (Workman and McLeod 1990; USDA 1991a).

Five major streams drain the SRS and eventually flow into the Savannah River. Each stream has floodplains characterized by bottomland hardwood forests or scrub-shrub wetlands in varying stages of succession. Dominant species include red maple (Acer rubrum), box elder (A. negundo), bald cypress, water tupelo (Nyssa aquatica), sweetgum, and black willow (Salix nigra) (Workman and McLeod 1990).

Carolina bays are unique wetland features of the southeastern United States. They are islands of wetland habitat dispersed throughout the uplands of the SRS. The approximately 200 bays on the Site exhibit extremely variable hydrology and a range of plant communities from herbaceous marsh to forested wetland (Shields et al. 1982; Schalles et al. 1989). SRS scientists have studied Carolina bay ecology extensively, particularly in relation to the construction of the Defense Waste Processing Facility (DWPF; SREL 1980).

4.9.3 Aquatic Ecology

The aquatic resources of the SRS have been the subject of intensive study for more than 30 years. Research has focused on the flora and fauna of the Savannah River and the five tributaries of the river that drain the Site. Section 4.8.1.1 describes those portions of the aquatic systems that spent nuclear fuel management activities could affect. In addition, several monographs (Patrick et al. 1967; Dahlberg and Scott 1971; Bennett and McFarlane 1983), the eight-volume Comprehensive Cooling Water Study (Du Pont 1987), and three EISs (DOE 1984; DOE 1987b; DOE 1990) that evaluated operations of SRS production reactors describe the aquatic biota and aquatic systems of the SRS.

4.9.4 Threatened and Endangered Species

Threatened, Endangered, and Candidate Plant and Animal Species of the Savannah River Site (HNUS 1992b) describes threatened, endangered, and candidate plant and animal species that are known to occur or that might occur on the SRS. Table 4-15 lists these species.

The following Federally listed endangered animals are known to occur on the SRS or in the Savannah River adjacent to the Site: the red-cockaded woodpecker (Picoides borealis), the southern bald eagle (Haliaeetus leucocephalus), the wood stork (Mycteria americana), and the shortnose sturgeon (Acipenser brevirostrum) (HNUS 1992b). Researchers have found one Federally listed endangered plant species, the smooth coneflower (Echinacea laevigata), on the Site, several Federally listed Category 2 species, and several state listed species (Knox and Sharitz 1990). At present, the SRS is implementing strategies for the protection of these species.

Table 4-15. Threatened, endangered, and candidate plant and animal species of the SRS.

Common Name (Scientific Name)	Status
Animals	
Rafinesques (= Southeastern) big-eared bat (Plecotus rafinesquii)	FC2
Loggerhead Shrike (Lanius ludovicianus)	FC2
Bachman's sparrow (Aimophila aestivalis)	FC2
Carolina crawfish (= Gopher) frog (Rana areolata capito)	FC2
Southern hognose snake (Heterodon simus)	FC2
Northern pine snake (Pituophis melanoleucus melanoleucus)	FC2
Bald eagle (Haliaeetus leucocephalus)	E
Wood stork (Mycteria americana)	E
Red-cockaded woodpecker (Picoides borealis)	E
American alligator (Alligator mississippiensis)	T/SA
Shortnose sturgeon (Accipenser brevirostrum)	E
Plants	
Smooth coneflower (Echinacea laevigata)	E
Bog spice bush (Lindera subcoriacea)	FC2
Boykin's lobelia (Lobelia boykinii)	FC2
Loose watermilfoil (Myriophyllum laxum)	FC2
Nestronia (Nestronia umbellula)	FC2
Awned meadowbeauty (Rhexia aristosa)	FC2

Key: E = Federal endangered species.
T/SA = Threatened due to Similarity of Appearance.
FC2 = Under review (a candidate species) for listing by the Federal government.

F- and H-Areas and the representative host site contain no habitat suitable for any of the Federally listed threatened or endangered species found on the SRS. The Southern bald eagle and the wood stork feed and nest near wetlands, streams, and reservoirs, and thus would not be attracted to the host site, a densely forested upland area. Shortnose sturgeon, typically residents of large coastal rivers and estuaries, have never been collected in Fourmile Branch or any of the tributaries of the Savannah River that drain the SRS.

Red-cockaded woodpeckers prefer open pine forests with mature trees (older than 80 years) for foraging and nesting. The pines of the undeveloped host site are 5 to 40 years old, thus red-cockaded woodpeckers probably would not forage or nest in the area.

The Red-cockaded Woodpecker Management Standards and Guidelines, Savannah River Site (USDA 1991b) describes the SRS management strategy for the red-cockaded woodpecker. The most significant element of this management strategy is the conversion of slash (and some loblolly) pine in a designated red-cockaded woodpecker management area to longleaf pine, with a harvest rotation of 120 years.

4.10 Noise

The major noise sources at the SRS occur primarily in developed operational areas and include various facilities, equipment, and machines (e.g., cooling towers, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles). Major noise sources outside the operational areas consist primarily of vehicles and railroad operations.

Previous studies have assessed noise impacts of existing SRS operational activities (NUS 1991b; DOE 1991b; DOE 1990; DOE 1993a). These studies concluded that, because of the remote locations of the SRS operational areas, there are no known conditions associated with existing onsite noise sources that adversely affect individuals at offsite locations. Some disturbance of wildlife activities might occur on the SRS as a result of operational and construction activities.

Existing SRS-related noise sources of importance to the public are those resulting from the transportation of people and materials to and from the Site. These sources include trucks, private vehicles, helicopters, and freight trains. In addition, a portion of the air cargo and business travel using commercial air transport through the airports at Augusta, Georgia, and Columbia, South Carolina, are attributable to SRS operations.

The States of Georgia and South Carolina and the counties in which the SRS is located have not established any regulations that specify acceptable community noise levels with the exception of Aiken County. A provision of the Aiken County Nuisance Ordinance limits daytime and nighttime noise by frequency band (Aiken County 1991).

During a normal week in 1995, about 20,000 employees are likely to travel to the SRS each day in private vehicles from surrounding communities. Both government-owned and private trucks pick up and deliver materials at the Site. Most private vehicles and trucks traveling to and from the Site each day use South Carolina Highways (SC) 125 and 19. The contribution of SRS operations to traffic volumes along SC 125 and SC 19, especially during peak traffic periods, affects noise levels through the towns of New Ellenton and Jackson and the City of Aiken.

Noise measurements taken during 1989 and 1990 along SC 125 in the Town of Jackson at a point about 15 meters (50 feet) from the roadway indicate that the 1-hour equivalent sound level from traffic ranged from 48 to 72 decibels (A-weighted). The estimated day/night average sound level along this route was 66 decibels for summer and 69 decibels for winter. Similarly, noise measurements along SC 19 in the town of New Ellenton at a point about 15 meters (50 feet) from the roadway indicate that the 1-hour equivalent sound level from traffic ranged from 53 to 71 decibels. The estimated day/night average sound level along this route was 68 decibels for summer and 67 decibels for winter (NUS 1990). Employment at the SRS has increased slightly since 1989, potentially causing small increases in traffic noise, especially during peak traffic periods (approximately between 6:30 and 8:30 a.m. and between 3:30 and 5:30 p.m., corresponding to the major shift changes). Because some residences and at least two schools are within 100 to 200 feet of these routes, some annoyance to members of the public residing along these highways might occur based on the relationship between the day/night average sound level and the "percent highly annoyed" (Schultz 1978; Fidell et al. 1989; FICON 1992).

Noise sources from rail transport include diesel engines, wheel-track contact, and whistle-warnings at rail crossings.

4.11 Traffic and Transportation

4.11.1 Regional Infrastructure

The SRS is surrounded by a system of Interstate highways, U.S. highways, state highways, and railroads. The regional transportation networks service the four South Carolina counties (Aiken, Allendale, Bamberg, and Barnwell) and two Georgia counties (Columbia and Richmond) that generate about 90 percent of SRS commuter traffic (HNUS 1992a). Two major railroads - CSX Transportation and Norfolk Southern Corporation - also serve the SRS vicinity. Although barge traffic is possible on the Savannah River, neither the SRS nor commercial shippers normally use barges. Figure 4-13 shows the regional transportation infrastructure.

4.11.1.1 Regional Roads. Two Interstate highways serve the SRS area. Interstate 20 (I-20)

provides a primary east-west corridor and I-520 links I-20 with parts of Augusta, Georgia. U.S. Highways 1 and 25 are principal north-south routes and U.S. 78 provides east-west connections. Several other highways - U.S. 221, U.S. 301, U.S. 321, and U.S. 601 - provide additional transport routes in the region.

Several state routes provide direct access to the SRS. Running northwest/southeast is SC 125. Access to the Site is provided from the north by SC 19, from the northeast by SC 39, and from the east by SC 64.

U.S. 278 bisects the northern part of the SRS and is available to public access without restriction. The SRS maintains barricades at site entries and exits on SC 125 to control public access if necessary, although it is generally open to unrestricted public travel. The public also has direct access to Site Road 1. All other site roads have restricted access.

4.11.1.2 Regional Railroads. Norfolk Southern serves Augusta and Savannah, Georgia, as

well as Columbia and Charleston, South Carolina. CSX serves the same locations and the SRS.

4.11.2 SRS Infrastructure

The SRS transportation infrastructure consists of more than 143 miles (230 kilometers) of primary roads, 1,200 miles (1,931 kilometers) of unpaved secondary roads, and 103 kilometers (64 miles) of railroad track (WSRC 1993b). These roads and railroads provide connections among the various SRS facilities and to offsite transportation linkages. Figure 4-14 shows the SRS network of primary roadways and access points. Figure 4-15 shows the SRS railway system.

4.11.2.1 SRS Roads. Two major public highways traverse the Site: SC 125 and U.S. 278.

SC 125 connects Allendale, South Carolina, to Augusta, Georgia, by crossing the Site in a northwest-to-southeast direction. U.S. 278 also connects Augusta and Allendale, but its route approximately follows the northern and eastern SRS boundaries.

Figure 4-13. Regional transportation infrastructure. Figure 4-14. Major SRS road and access points. Figure 4-15. SRS railroads lines.

Ten barricades around the Site limit access from public roads. Five barricades limit SRS access from SC 125; three limit access from SC 19, SC 39, and SC 64; and two limit access from the public areas of the administrative complex near the northern SRS boundary (A-Area).

In general, the primary SRS roadways are in good condition and are smooth and free from potholes. Typically, wide, firm shoulders border roads that are either straight or have wide gradual turns. Intersections are well marked for both traffic and safety identification and are sufficiently cleared of trees and brush that might obstruct a driver's view of oncoming traffic. Railings along the side of the roadways offer protection at appropriate locations from dropoffs or other hazards. In general, the roadways are lighted only at gate areas and near major facilities. The SRS has two overpasses, one at the cloverleaf intersection of Roads 2 and C, and the other where SC 125 overpasses the CSX railroad tracks in the southern part of the Site. The 60 bridges on the Site have been inspected and evaluated for safe loading, with some bridges rated as high as 200 tons (181 metric tons) under controlled conditions. The steepest roadway gradient is on Road C at the east bank of Upper Three Runs Creek, where the road drops more than 100 feet (30 meters) in about 0.25 miles (0.4 kilometer). At the base of the dropoff is a bridge over the creek and an immediate turn in the road. This area presents a relatively hazardous roadway condition.

In general, heavy traffic occurs early in the morning and late in the afternoon when workers from surrounding communities commute to and from the Site. During working hours, official vehicles and logging trucks constitute most of the traffic. At any time, as many as 60 logging trucks, which can impede traffic, might be operating on the Site, with an annual average of about 25 trucks per day. Table 4-16 provides data on traffic counts for various roads and access points around the SRS.

4.11.2.2 SRS Railroads. Railroads on the Site include both CSX tracks and SRS rolling

stock and tracks. Two routes of the CSX distribution system run through the Site: a line between Florence, South Carolina, and Augusta, Georgia, and a line between Yemassee, South Carolina, and Augusta, Georgia. The two lines join on the Site just south of L-Lake (Figure 4-15). Early in 1989

CSX discontinued service on the line from the SRS junction to Florence.

The 64 miles (103 kilometers) of SRS railroads are well maintained. The rails and crossties are in good condition, and the track lines are clear of vegetation and debris. Significant clear areas border the tracks on both sides. Intersections of railroads and roadways are marked by railroad crossing signs with lights where appropriate.

Table 4-16. SRS traffic counts - major roads.

Measurement point	Date	Direction	Day Total	Peak[b]	Peak time[c]	Average speed (mph)[d]
Road 2 between Roads C and D	2-23-93	East	3,031	800	1530	47

c. Start of peak hour.
d. mph = miles per hour; to convert to kilometers per hour multiply by 1.6093.
e. NA = data not available.

The SRS rail classification yard is east of P-Reactor. This eight-track facility sorts and redirects rail cars. Deliveries of SRS shipments occur at two onsite rail stations at the former towns of Ellenton and Dunbarton. From these stations, an SRS engine moves the railcars to the appropriate receiving facility. The Ellenton station, which is on the main Augusta-Yemassee line, is the preferred delivery point. The Dunbarton station, which is on the discontinued portion of the Augusta-Florence line, receives less use.

4.12 Occupational and Public Radiological Health and Safety

The sources of radiation exposure to individuals consist of natural background radiation from cosmic, terrestrial, and internal body sources; radiation from medical diagnostic and therapeutic practices; and radiation from manmade sources, including consumer and industrial products, nuclear facilities, and weapons test fallout.

All radiation doses discussed in this document are effective dose equivalents (i.e., organ dose equivalents weighted for biological effect and summed to yield a whole-body dose equivalent with the same risk as irradiation of individual organs) as defined by the International Commission on Radiological Protection, Publication 26 (ICRP 1977), unless specifically identified otherwise (e.g., thyroid dose, bone dose).

Natural background radiation contributes about 83 percent of the annual dose of 380 millirem received by an average member of the population within 50 miles (80 kilometers) of the Site. Based on national averages, medical exposure accounts for 14 percent of the annual dose, and the combined doses from weapons test fallout, consumer and industrial products, and air travel account for approximately 3 percent (Arnett et al. 1993).

4.12.1 Occupational Health and Safety

SRS maintains a network of air monitoring stations on and around the Site to determine the concentrations of radioactive particulates and aerosols in the air (Arnett et al. 1993). Table

4-17 lists average and maximum radionuclide particulate concentrations found in 1992 in air at the F- and H-Areas, SRS boundary, and background [100-mile (160-kilometer) radius] monitoring locations. Table 4-18 lists average and maximum concentrations of tritium in atmospheric moisture during 1992 for the F- and H-Areas, SRS boundary, and background monitoring locations.

Gamma radiation levels measured by thermoluminescent dosimeters in 1992 at the F- and H-Area **fences averaged 70 and 74 millirem per year, respectively.** Gamma radiation levels, including natural background (terrestrial and cosmic) radiation, measured at the Site perimeter in 1992 yielded an average dose of 35 millirem per year (Arnett et al. 1993).

Table 4-17. Radioactivity in air at the Savannah River Site and vicinity (pCi/m3).

Location	Gross Alpha	Nonvolatile Beta	SR-89,90b	Pu-238b	Pu-239b

a. Arnett (1993).

Soil samples from uncultivated areas provide a measure of the quantity of particulate radioactivity deposited from the atmosphere. Table 4-19 lists maximum measurements of radionuclides in the soil for 1992 at F- and H-Areas, SRS boundary, and background [100-mile (160-kilometer)-radius] monitoring locations. The SRS measured elevated concentrations of plutonium-238 and plutonium-239 around F- and H-Areas, reflecting releases from these areas. From 1955 through 1992, total atmospheric plutonium releases from the F- and H-Areas were approximately 0.7 curie of plutonium-238 and 3 curies of plutonium-239 (Arnett et al. 1992; 1993).

Table 4-19. Maximum radioactivity concentrations in soil at the Savannah River Site (pCi/g).

Location	Sr-90	Cs-137	Pu-238	Pu-239
F-Area	2.16x10-2	7.19x10-1	4.03x10-1	5.31x10-1

a. Arnett et al. (1992).
b. None detected.

The SRS workers investigated for purposes of assessing occupational radiation exposures belong to the group of involved workers assigned to F- and H-Area facilities. The investigation selected these facilities because they process materials with radiological characteristics similar to the materials being analyzed in this EIS. The dosimetry results for these two involved worker groups are most useful because they depict occupational impacts that are directly relevant to each alternative. The investigation selected two dosimetry periods of record for this analysis: 1983 - 1987 and 1993. The earlier 5-year period included times when materials processing was occurring at a rate that was accelerated in comparison with recent years. The later period includes processing rates that better reflect near-term DOE mission initiatives.

Tables 4-20 and 4-21 list the involved worker dosimetry data for 1983 - 1987 and 1993, respectively. This analysis adapted these data from monitoring data statistics (Matheny 1994a; Matheny 1994b) for operations, maintenance, laboratory, and health protection personnel assigned to the F- and H-Area Canyons and the associated B-Line facilities. The calculated incidences of excess fatal cancer attributable to each facility's collective worker dose are approximately 0.11 and 0.037 for the earlier and later time periods, respectively. Similarly, the highest calculated excess fatal cancer probabilities attributable to average individual worker doses are approximately 0.0003 and 0.0001, respectively. The analysis estimated these health effects using risk coefficients adopted by DOE (DOE 1993).

4.12.2 Public Health and Safety

Table 4-22 summarizes the major sources of exposure for the population within 50 miles (80 kilometers) of the SRS and for the Savannah River water-consuming population in Beaufort and Jasper Counties, South Carolina, and Port Wentworth, Georgia. Most of the sources, such as natural background dose and medical dose, are independent of the presence of the SRS.

Table 4-20. Annual involved worker doses, 1983 - 1987.

Facility	Average Worker Dose (rem)	Total Collective Worker Dose (person-rem)
H-Canyon	0.41	36.28
HB-Line	0.49	21.84
F-Canyon	0.48	87.25
FB-Line	0.74	124.68
Facilities Average	0.53	NA
Facilities Total	NA	270.05

NA = Not applicable.

Table 4-21. Annual involved worker doses, 1993.

Facility	Average Worker Dose (rem)	Total Collective Worker Dose (person-rem)
H-Canyon	0.17	11.07
HB-Line	0.24	21.97
F-Canyon	0.22	9.16
FB-Line	0.24	51.16
Facilities Average	0.22	NA
Facilities Total	NA	93.36

NA = Not applicable.

Table 4-22. Major sources of radiation exposure to the public in the vicinity of the Savannah River Site.

Source of Exposure	Dose to average individual (mrem/yr)	Percentage of exposure
Natural background radiation	315	83
Medical radiation	54	14
Consumer and industrial products, fallout, air travel	10	3
Savannah River Site operations	0.22	0.06
Grand Total	380	100

a. Arnett et al. (1993).

Atmospheric releases of radioactive material to the environment from SRS operations from 1990 to 1992 resulted in an average dose of approximately 0.02 millirem per year to individuals in the 50-mile (80-kilometer)-radius population. The collective effective dose equivalent due to atmospheric releases from 1992 SRS operations to the population of 620,100 within 50 miles (80 kilometers) was approximately 6.4 person-rem per year. Atmospheric releases of tritium accounted for more than 90 percent of the offsite population dose; tritium is the only radionuclide of SRS origin that is routinely detected in offsite air (Cummins et al. 1991; Arnett et al. 1992, 1993). Table 4-23 lists average annual atmospheric tritium concentrations in the vicinity of SRS for the three years ending in 1992.

Table 4-23. Average atmospheric tritium concentrations in the vicinity of the Savannah River Site (pCi/m3).

Location	1992	1991	1990
Onsite	340	250	430
Site perimeter	27	21	32
25-mile radius	11	11	12
100-mile radius	8.3	8.5	8.8

a. Arnett et al. (1993).

From 1990 to 1992, the calculated maximum individual average annual dose from atmospheric releases to a hypothetical individual residing at the SRS boundary was 0.12 millirem (Cummins et al. 1991; Arnett et al. 1992, 1993).

In general, liquid releases of tritium account for more than 99 percent of the total radioactivity introduced into the Savannah River from SRS activities (Arnett et al. 1993). The calculated average annual dose to the maximally exposed individual resulting from liquid releases from 1990 to 1992 was 0.21 millirem (Cummins et al. 1991; Arnett et al. 1992; 1993). From 1990 to 1992 liquid releases of radioactive material to the environment from SRS operations resulted in an average dose of 0.04 millirem per year and 0.05 millirem per year to downstream consumers of drinking water from the Beaufort-Jasper and Port Wentworth water treatment plants, respectively. These doses to the current Beaufort-Jasper river-water-consuming population of about 51,000 and the current Port Wentworth river-water-consuming population of about 20,000 would yield a collective effective dose equivalent to these populations of approximately 3 person-rem per year (Cummins et al. 1991; Arnett et al. 1992, 1993).

The SRS analyzes samples from other environmental media that onsite releases might affect and that might provide a pathway for radiation exposure to the public and Site employees; these include samples of milk, food products, drinking water, wildlife, rainwater, soil, sediment, and vegetation. The 1992 SRS Environmental Report (Arnett et al. 1993) describes the sampling program, monitoring locations, and monitoring results for each of these media.

Major nuclear facilities within 50 miles (80 kilometers) of the SRS include a low-level waste burial site operated by Chem-Nuclear Systems, Inc., near the eastern SRS boundary in Barnwell, South Carolina, and the Georgia Power Company Alvin W. Vogtle Electric Generating Plant, directly across the Savannah River from the SRS. Plant Vogtle began commercial operation in 1987, and its releases are controlled to meet U.S. Nuclear Regulatory Commission requirements.

4.13 Utilities and Energy

This section describes SRS electricity consumption, water consumption, fuel usage, and domestic and industrial wastewater treatment. Table 4-24 contains information on the current status of these items at SRS.

Table 4-24. Current capacities and usage of utilities and energy at SRS.

ELECTRICITY	
Consumption	659,000 megawatt hours per year
Load	75 megavolt-amperes
Peak Demand	130 megavolt-amperes
Capacity	340 megavolt-amperes
WATER	
Groundwater usage	12,490 million liters (3.3 billion gallons) per year
Surface water usage (cooling)	75,700 million liters (20 billion gallons) per year
FUEL	
Oil	28.4 million liters (7.5 million gallons) per year
Coal	210,000 metric tons (230,000 tons) per year
Gasoline	4.7 million liters (1.24 million gallons) per year
WASTEWATER	
Domestic capacity	3.97 million liters (1.05 million gallons) per day
Domestic load	1.89 million liters (0.50 million gallons) per day
Industrial capacity[a,b]	1.64 million liters (433,244 gallons) per day
Industrial load[a]	44,000 liters (11,580 gallons) per day

a. F/H Effluent Treatment Facility only.
b. Design capacity; permitted capacity is about 67 percent of this value.

4.13.1 Electricity

The SRS purchases electric power from the South Carolina Electric and Gas Company (SCE&G) through three purchased power-line interconnects to the SRS transmission grid. The recent total annual power consumption for the SRS was approximately 659,000 megawatt-hours. The average load was 75 megavolt-amperes and the peak demand was about 130 megavolt-amperes. South Carolina Electric and Gas sources can supply as much as 340 megavolt-amperes to the SRS grid with existing direct connections. The SRS generating station in D-Area can produce an additional 80 megavolt-amperes capacity, although that plant currently produces only process steam. The SRS transmission grid that would provide power to any spent nuclear fuel facilities consists of more than 145 kilometers (90 miles) of 115-kilovolt lines, four switching stations, and 15 substations. Electric service to all major production areas provides parallel redundant capacity to ensure maximum availability and reliability (WSRC 1993c).

4.13.2 Water Consumption

Groundwater from a deep confined aquifer supplies domestic and process water for the SRS through approximately 100 production wells. The aquifer system sustains single well yields of about 10.2 million liters (2.7 million gallons) per day. Current usage from this source is about 14.0 billion liters (3.7 billion gallons) per year (DOE 1990). The SRS withdraws cooling water for its facilities from the Savannah River at an annual rate of about 75.7 billion liters (20 billion gallons) (WSRC 1993c).

4.13.3 Fuel Consumption

Fuels consumed at SRS include oil, coal, and gasoline. SRS facilities and equipment burn approximately 28.4 million liters (7.5 million gallons) of oil each year. This total includes diesel fuel, No. 6 oil, and No. 2 oil. The SRS burns coal and some waste oils in the D-Area powerhouse to produce steam for Site facilities. Current coal usage is about 208,655 metric tons (230,000 tons) per year. SRS vehicles use approximately 4.7 million liters (1.24 million gallons) of gasoline annually. Under the provisions of the Energy Policy Act of 1992, natural gas will replace gasoline on the SRS within the next 10 years. At that time, SRS usage of natural gas would be approximately 12.2 million cubic meters (429 million cubic feet) per year. At present, the SRS consumes no natural gas (WSRC 1993c).

4.13.4 Wastewater Treatment

By 1995, the SRS Centralized Sanitary Wastewater Treatment Facility will process most of the domestic effluent on the Site. This centrally located facility has a design capacity of 4 million liters (1.05 million gallons) per day. Once operational, the plant will use about 50 percent of this capacity. In addition, five smaller sanitary treatment plants serve more remote areas of the Site. Facilities for spent nuclear fuel management would use the centralized facility.

The F/H Effluent Treatment Facility (ETF), which decontaminates routine process effluents and accidental radioactive releases from operations, treats industrial wastewater in the F- and H-Areas, where the spent fuel management activities would occur.

Effluent Treatment Facility process operations performed on the waste liquids include neutralization (adjusts pH), submicron filtration (removes suspended solids), activated carbon absorption (removes dissolved organic chemicals), reverse osmosis membrane deionization (removes salts), ion exchange (removes heavy metals), and evaporation (separates radionuclides from aqueous condensate). This facility releases two different streams. The treated water stream is sampled and analyzed to ensure that it meets discharge requirements and then is released to Upper Three Runs Creek via a permitted outfall. The waste concentrate (i.e., bottoms from the evaporator process) is transferred to the H-Area waste tank farm for treatment and disposal in the Z-Area Saltstone facility.

The design capacity for the Effluent Treatment Facility is approximately 600 million liters (158 million gallons) per year. The maximum permitted treatment capacity is about 400 million liters (105.7 million gallons) per year. Under normal operating conditions, the facility treats more than 16,000 cubic meters (26 million gallons) of liquid waste per year (WSRC 1993d).

The influent water load to processes discharging to the permitted outfall includes as much as 205 million liters (54 million gallons) per year of F-Area Canyon process wastewater, 120 million liters (32 million gallons) per year of H-Area Canyon process wastewater, 34 million liters (9 million gallons) per year from the F-Area collection and retention basins, 34 million liters (9 million gallons) per year from the H-Area collection and retention basins, 68 million liters (18 million gallons) per year of Effluent Treatment Facility acid, caustic, flush and rinse water, and similar wastewater from other SRS facilities.

4.14 Materials and Waste Management

The historic national defense mission of the SRS has resulted in the generation of high-level radioactive waste, transuranic waste, low-level radioactive waste (low-activity and intermediate-level), hazardous waste, mixed waste (radioactive and hazardous combined), and sanitary waste (nonhazardous, nonradioactive solid waste). This section discusses the treatment, storage, and disposal of waste at the SRS. Section 4.13 discusses domestic and industrial wastewater treatment.

DOE is preparing an environmental impact statement on Waste Management at the Savannah River Site (DOE 1995). The purpose of the EIS is to provide a basis for DOE to select a sitewide strategic approach to managing present and future SRS waste generated as a result of ongoing operations, environmental restoration activities, transition from nuclear production to other missions, and decontamination and decommissioning programs. The Waste Management EIS will support project-level decisions on the operation of specific treatment, storage, and disposal facilities within the near term (10 years or less). In addition, the EIS will provide a baseline for analyses of future waste management activities and a basis for the evaluation of the specific waste management alternatives. The Waste Management EIS will not include management of spent nuclear fuel which is addressed in this document.

DOE treats and stores waste generated from onsite operations in waste management facilities located primarily in E-, F-, H-, N-, S-, and Z-Areas (Figure 4-16). These facilities include the F- and H-Area Effluent Treatment Facility, the High-Level Waste Tank Farms, and the Solid Waste Disposal Facility. The Defense Waste Processing Facility is nearly operational and the Consolidated Incineration Facility is under construction. The SRS places sanitary and inert waste in the Interim Sanitary Landfill and the Burma Road Landfill, respectively.

DOE continues to reduce the amount of waste generated and disposed of at the SRS through waste minimization and treatment programs. DOE accomplishes waste minimization by reducing the volume, toxicity, or mobility of waste before storing or disposing of it. These activities also include more intensive surveying, waste segregation, and use of administrative and engineering controls.

The waste that DOE presently stores on the SRS includes high-level, transuranic, hazardous, mixed waste and some low-level waste. The Site stores high-level waste in underground storage tanks that have received South Carolina Department of Health and Environmental Control industrial wastewater permits, and manages them in accordance with Clean Water Act, Resource Conservation and Recovery Act, and DOE requirements. The SRS stores transuranic mixed waste on interim-status storage pads in accordance with South Carolina Department of Health and Environmental Control requirements and DOE Orders. Hazardous and mixed waste is placed in permitted or interim-status storage in the Hazardous Waste Storage Facilities (both buildings and pads) and in the mixed waste storage buildings.

Figure 4-16. Waste management facilities at the Savannah River Site.

Figure 4-17 shows the high-level liquid waste management process at the SRS. Figure 4-18 shows the process for handling all other forms of solid waste at the Site.

Table 4-25 is a forecast of annual waste generation for all waste forms except sanitary and high-level waste (WSRC 1994c). The volumes listed do not include waste related to decontamination and decommissioning because DOE has not yet completed the planning of these activities. Section 5.14 discusses potential consequences of spent nuclear fuel activities as they relate to the alternative interim storage and treatment scenarios.

4.14.1 High-Level Waste

The SRS generated high-level waste from the recovery of nuclear materials from spent fuel and target processing in the F- and H-Areas. It is stored in 50 underground tanks. These tanks also store other radioactive waste effluents (primarily low-level radioactive waste such as aqueous process waste, including purge water from storage basins for irradiated reactor fuel or fuel elements). The high-level waste is stored to permit the decay of short-lived radionuclides and allow separation of solids (sludge) from soluble waste. Evaporators concentrate soluble waste to reduce original volumes and to immobilize it as crystallized salt by successive evaporations of the liquid supernate. The SRS treats the evaporator overheads in cesium removal columns before transferring them to the F- and H-Area Effluent Treatment Facility. The SRS processes the sludge and salt to prepare them for vitrification at the Defense Waste Processing Facility (high-level waste), when it becomes operational, or stabilization at the Z-Area Saltstone Facility (low-level waste). DOE has prepared a Supplemental EIS related to Defense Waste Processing Facility operations (DOE 1994d).

By December 31, 1991, DOE had stored approximately 127.9 million liters (33.8 million gallons) of high-level radioactive waste on the Site. Estimates of current tank capacity and high-level waste forecasts should be available in 1995. In general, however, due to a number of factors, the most important of which has been the extended outage of the evaporators, the estimated inventory of waste in the high-level tanks is greater than 90 percent of existing capacity (WSRC 1994d). DOE is constructing a replacement high-level waste tank evaporator to augment or replace existing evaporators.

Figure 4-17. Flow diagram for high-level radioactive waste. Figure 4-18. Flow diagram for waste handling at the SRS.

Table 4-25. Average annual waste generation forecast for Savannah River Site (cubic meters). ,b

Waste Type	FY94	FY95	FY96
Transuranic	670	860	760
Low-Level			
Low-Activity	21,350	17,680	17,970
Intermediate-Level	940	580	740
Hazardous	140	130	100
Mixed	120	130	110

b. To convert cubic meters to cubic feet, multiply by 35.314.

4.14.2 Transuranic Waste

At present, DOE uses three methods of retrievable storage for transuranic waste at SRS, based on the time of generation. Transuranic waste generated before 1974 is buried in approximately 120 belowgrade concrete culverts in the Solid Waste Disposal Facility. Transuranic waste generated from 1974 to 1985 is stored on five concrete pads and one asphalt pad that have been covered with approximately 1.2 meters (4 feet) of native soil. DOE stores waste generated since 1985 on 13 additional concrete pads that are not covered with soil. Pads 1 through 17 operate under Interim Status approved by the South Carolina Department of Health and Environmental Control. DOE uses Pads 18 through 19, which are not required to have interim status, to manage nonhazardous transuranic wastes only.

The SRS stores wastes containing 10 to 100 nanocuries per gram of transuranic material with transuranic waste until it can complete Site-specific radiological performance assessments, which will provide disposal limits for transuranic isotopes. SRS transuranic waste inventories and forecasts include both transuranic waste and the 10- to 100-nanocuries-per-gram transuranic wastes.

At the end of 1993, the SRS had approximately 9,900 cubic meters (350,000 cubic feet) of transuranic waste in storage (WSRC 1994e). Based on the 1994-to-1996 average annual generation rate forecast, the Site generates approximately 760 cubic meters (27,000 cubic feet) of transuranic waste annually. Transuranic mixed waste (transuranic and hazardous combined) accounts for approximately 110 cubic meters (3,900 cubic feet) of this volume (WSRC 1994c). DOE is evaluating available storage space for transuranic mixed waste to alleviate any storage capacity deficit.

4.14.3 Mixed Low-Level Waste

The SRS mixed waste program consists primarily of providing safe storage until treatment and disposal facilities are available. The current volume of mixed low-level waste at the SRS is 1,700 cubic meters (60,000 cubic feet) (WSRC 1994e). Based on the 1994-to-1996 average annual generation forecast, the Site generates approximately 118 cubic meters (4,170 cubic feet) of mixed low-level waste annually (WSRC 1994c). DOE is evaluating available storage space to determine when the SRS will exceed its capacity. However, DOE is constructing a Consolidated Incineration Facility in H-Area, which will treat mixed, hazardous, and low-level waste. When the incinerator is operational, existing inventory will be reduced and more storage capacity will become available.

4.14.4 Low-Level Waste

The SRS packages low-level waste for disposal on the Site in accordance with the waste category and its estimated surface dose rate. The Site places low-activity waste in carbon steel boxes and deposits it in an Engineered Low-Level Trench (ELLT). The trenches are several acres in size by 6 meters (20 feet) deep and have sloped sides and floor, allowing drainage to a collection sump. When the trenches are full, DOE backfills and covers them with at least 1.8 meters (6 feet) of soil. The Site packages intermediate-level wastes according to the waste form and disposes of them in slit trenches. DOE will store long-lived wastes, such as resins, until the Long-Lived Waste Storage Building, currently under construction, becomes operational. This building will provide storage until DOE develops treatment and disposal technologies.

The SRS is developing a new disposal facility, known as the E-Area Vault (EAV). This facility will include vaults for low-activity waste, intermediate-level non-tritium waste, and intermediate-level tritium waste.

Based on the 1994-to-1996 average annual generation forecast, the Site generates approximately 19,000 cubic meters (671,400 cubic feet) of low-activity waste and 750 cubic meters (26,600 cubic feet) of intermediate-level waste annually. DOE expects that the Consolidated Incineration Facility will begin operations by the second quarter of Fiscal Year 1996; this facility will have the capability of annually processing as much as 15,850 cubic meters (560,000 cubic feet) of boxed low-activity waste and approximately 186 cubic meters (6,600 cubic feet) of hazardous and mixed waste.

4.14.5 Hazardous Waste

DOE stores hazardous wastes generated at various SRS facilities in buildings in the B- and N-Areas, and on the Solid Waste Storage Pads. The Resource Conservation and Recovery Act regulates these wastes.

The inventory of hazardous waste in storage at the SRS is about 1.6 million kilograms (3.6 million pounds), occupying a volume of about 2,430 cubic meters (86,000 cubic feet) (WSRC 1994e). Based on the 1994-to-1996 average annual generation rate forecast, the Site generates approximately 124 cubic meters (4,370 cubic feet) of hazardous waste annually (WSRC 1994c).

4.14.6 Sanitary Waste

The SRS disposes of most of its solid sanitary waste in onsite landfills, the most recent of which began operation in 1985. Current disposal operations include the Interim Sanitary Landfill. About 30 trucks per work day arrive at this facility carrying approximately 18,125 kilograms (40,000 pounds) of waste that, after compaction, occupies approximately 115 cubic meters (150 cubic yards) of landfill space. The recent implementation of SRS paper and aluminum can recycling programs and disposal of office waste off the Site in a commercial landfill has increased the projected life of the landfill to the fourth quarter of 1996 (WSRC 1994e).

DOE also maintains an inert material landfill on the Site near Burma Road. This facility receives demolition and construction debris. DOE is evaluating the construction of a new SRS sanitary landfill or the use of a commercial landfill.

4.14.7 Hazardous Materials

The SRS 1993 Tier II emergency and hazardous chemical inventory lists 205 reportable hazardous substances present on the Site in excess of the 10,000-pound (4,536-kilogram) threshold quantity (WSRC 1994f). The number and the total weight of any hazardous chemicals used on the Site change daily in response to use. The annual Superfund Amendments and Reauthorization Act (SARA) reports for the SRS include listings of hazardous materials used or stored on the Site during each year.

5. ENVIRONMENTAL CONSEQUENCES

5.1 Overview

This chapter discusses the potential environmental consequences for each spent nuclear fuel management alternative described in Chapter 3. The representative host site locations, as described in Chapter 2, are the F- and H-Areas and an undeveloped site close to H-Area. These sites are representative of available areas that could support spent fuel management missions. Based on generic facility characteristics, this chapter analyzes representative consequences in terms of the environmental attributes of the potential host areas and the Savannah River Site (SRS) at large, as described in Chapter 4. Table 3-2 compares the environmental consequences of each alternative. The impacts associated with the construction and operation of a Navy Expended Core Facility are not included in this chapter, but are included in Appendix D of Volume 1 of this Environmental Impact Statement.

5.2 Land Use

Overall environmental impacts on land use by any of the alternatives would be small because the U.S. Department of Energy (DOE) would construct most new facilities in F- and H-Areas, which are already dedicated to industrial use and which previous activities have disturbed. New construction on the undeveloped representative host site near H-Area would probably be necessary only for the construction of a dry storage vault.

The Centralization Alternative (Alternative 5), under which DOE would transfer all spent nuclear fuel to the SRS, would result in the greatest changes in land use. Under this alternative, the SRS would dedicate between 70 and 100 acres (0.3 and 0.4 square kilometer) for use in spent nuclear fuel management; the exact location and size of the area affected would depend on whether DOE chose to use the wet storage, dry storage, or processing option. Of this affected area, a maximum of approximately 100 acres (0.4 square kilometer) would change from managed pine forest to industrial use.

DOE would retain under its control any lands supporting the spent nuclear fuel management program for the life of the project. No alternative would require the acquisition of public lands.

5.3 Socioeconomics

Socioeconomic consequences resulting from the implementation of any of the alternatives would relate primarily to changes in employment within the region of influence (ROI). DOE has based the analysis in the following section on estimated employment and population data for each SRS spent nuclear fuel alternative, as listed in Table 5-1. The population within the region of influence in 1995 is estimated to be approximately 462,000. The labor force will be about 257,000 persons of which about 242,000 will be employed.

DOE expects the employment level at the Site to decline from about 20,000 (in 1995) to about

15,800 (in 2004) as the SRS mission is redefined. This anticipated decline would be somewhat offset by the jobs created by the spent nuclear fuel management activities. Therefore, none of the alternatives would require additional operations employees because the SRS could fill all operational positions through the reassignment of existing workers. Consequently, this analysis addresses only employment impacts from construction activities. Given the natural variation in construction employment levels, the analysis could not accurately determine the reassignment of existing construction workers. As a result, this assessment analyzed the maximum potential impact, which assumes that all construction employment would represent new jobs that in-migrating workers would fill.

DOE estimated total employment impacts using the Regional Input-Output Modeling System that the U.S. Bureau of Economic Analysis developed for the SRS region of influence. This assessment also analyzed changes in population based on historic data that indicate that 90 percent of SRS employees live in the six-county region.

5.3.1 Potential Impacts

Table 5-1 lists direct increases in construction employment for each alternative and the corresponding change in population. As listed, potential impacts to socioeconomic resources would be smallest under Alternative 1 (No Action) and would be greatest under Option 5b (Centralization - Wet Storage). Therefore, Option 5b provides the bounding case for maximum potential impacts to socioeconomic resources.

a. Construction is related to renovation of reactor basin and Receiving Basin for Offsite Fuels.

Table 5-2 lists indirect employment and corresponding population changes associated with construction phase activities under Option 5b. As listed, the number of full-time construction workers required to support the implementation of this option from 1995 to 2004 would range from approximately 50 to 2,700. When added to the indirect employment of 1,600 jobs in the peak year (2002), the total employment impact in the region would be approximately 4,300 employees.

Table 5-2. Estimated increases in employment and population related to construction activities for Option 5b, from 1995 to 2004. ROI refers to the six-county region of influence.

Factor	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct employment	50	50	50	50	50	1,000	1,900	2,700	2,650	2,600
Secondary employment	30	30	30	30	30	600	1,100	1,600	1,550	1,500
Total employment change	80	80	80	80	80	1,600	3,000	4,300	4,200	4,100
% Change in ROI labor force	0.03	0.03	0.03	0.03	0.03	0.54	1.00	1.41	1.36	1.32
% Change in ROI employment	0.03	0.03	0.03	0.03	0.03	0.57	1.06	1.50	1.45	1.40
Population change (in region)	200	150	150	100	100	3,850	7,450	10,550	10,350	10,100
% Change in ROI population	0.04	0.03	0.03	0.02	0.02	0.81	1.56	2.21	2.16	2.11

Assuming in-migrating workers filled all jobs, the regional labor force and employment would increase by 1.4 percent and 1.5 percent, respectively. These changes would be temporary and would have no adverse impact on the region. After 2004, employment would gradually decline to a relatively constant level of about 50 jobs.

Based on historic data, approximately 90 percent of new employees would live within the six-county region of influence. Assuming each new employee represented one household with 2.72 persons per household, there would be approximately 10,550 additional people in the region during the peak year (2002). These changes would be temporary and would represent an estimated 2.2 percent increase in baseline population levels. Given this minor change in population, DOE expects potential impacts on the demand for community resources and services such as housing, schools, police, health care, and fire protection to be negligible.

Because all the other alternatives would require fewer employees, they would result in smaller changes than those listed in Table 5-2, and would have no adverse impacts on socioeconomic resources in the region of influence.

5.4 Cultural Resources

A Programmatic Memorandum of Agreement (SRARP 1989) between the DOE Savannah River Operations Office, the South Carolina State Historic Preservation Office, and the Advisory Council on Historic Preservation, ratified on August 24, 1990, is the instrument for the management of cultural resources at the SRS. DOE uses this memorandum to identify cultural resources, assess them in terms of eligibility for the National Register of Historic Places, and develop mitigation plans for affected resources in consultation with the State Historic Preservation Officer. DOE would comply with the terms of the memorandum for all activities needed to support spent nuclear fuel management actions.

The potential for adverse impacts on cultural resources would be smallest under Alternative 1 (No Action) and would be greatest under Alternative 5 (Centralization). Any facilities that DOE would construct in F- and H-Areas, north of Road E (Alternatives 1-5), would be in Sensitivity Zones 2 and 3. Section 4.4 describes these zones. The undeveloped representative host site south and east of H-Area (Alternative 5) is in Sensitivity Zone 3. Although there are no known archeological sites in the area, it has never been surveyed. Surveying being conducted near F-Area (north of Road C and west of Road 4 along Upper Three Runs Creek) has recorded some historic and prehistoric sites. However, DOE expects no impacts in F- and H-Areas due to their extensive industrial development. Until DOE has determined the precise locations of facilities connected with any of the alternatives, it cannot predict impacts on cultural resources in the undeveloped site area (Sassaman 1994). However, DOE would mitigate, through avoidance or removal, impacts to potentially significant resources that future site surveys might discover.

5.5 Aesthetic and Scenic Resources

None of the alternatives for spent nuclear fuel management at the SRS would have adverse consequences on scenic resources or aesthetics. Most new construction would be in F- or H-Area, both of which are already dedicated to industrial use. New construction on the undeveloped site, which would occur primarily under Alternative 5, would be adjacent to H-Area in an already heavily industrialized portion of the SRS. In all cases, new construction would not be visible off the Site or from public access roads on the Site. No alternative would produce emissions to the atmosphere that would be visible or would indirectly reduce visibility.

5.6 Geologic Resources

The SRS contains no unique geologic features or minerals of economic value. Therefore, DOE anticipates no impacts to geologic resources at the SRS from any of the spent nuclear fuel management alternatives.

Other sections in this chapter consider the relationships of the Site's specific geology and the region's historic and analyzed seismicity to the local environment and to SRS spent nuclear fuel-related structures and facilities. Section 5.8 discusses the consequences of analyzed seismic events on both surface-water and groundwater resources. Section 5.15 describes estimates of risk that consider both the probability of and the consequences from a wide range of seismic events, ranging from local and regional historically documented earthquakes to postulated lower probability, higher consequence events.

The accident analyses in this chapter, which DOE based on information from approved safety analysis reports for applicable facilities, address the frequency and consequences of historic earthquakes, as well as postulated less likely, but more damaging, seismic events. DOE has evaluated the consequences from seismic challenges to the facilities and structures up to 0.20g lateral ground acceleration.

5.7 Air Quality Consequences

The SRS is in compliance with both Federal and state ambient air quality standards for criteria and toxic air pollutants. As shown in the following tables, the predicted incremental air pollutant impacts would not contribute to exceeding either the National Ambient Air Quality Standards or South Carolina's Ambient Air Quality Standards.

DOE performed analyses using computer models in order to assess the potential air quality impacts of operations under each of the spent nuclear fuel management alternatives. This section describes the results of these analyses. All the concentrations discussed below are ground-level estimations based on results from the ISC2 and FDM models for nonradiological pollutants, and MAXIGASP- and POPGASP SRS-climatology-specific models for radionuclides. The analyses assume that facility operations would result in both radiological and nonradiological emissions. DOE assessed construction impacts qualitatively in relation to the land area to be disturbed under each alternative.

Nonradiological Emissions. DOE analyzed the potential incremental impacts of only those substances for which it expects releases to the atmosphere during the normal operation of spent nuclear fuel facilities. The nonradiological releases evaluated for each alternative include seven criteria pollutants and 23 toxic pollutants. DOE selected the toxic substances for analysis by comparing the anticipated chemical usage at the proposed spent nuclear fuel facilities to the list of 257 toxic air pollutants in the South Carolina Air Pollution Regulations (SCDHEC 1976). The SRS modeled potential emissions of the listed toxic chemicals that DOE anticipates would be used during spent nuclear fuel activities. The following subsections discuss the results for both criteria and toxic pollutants. Tables 5-3 and 5-4 list the estimated maximum incremental concentrations of these pollutants at the Site boundary, while Tables 5-5 and 5-6 contain the incremental rates of release.

Radiological Emissions. DOE evaluated the potential radiological releases to the atmosphere from spent fuel management at the SRS using existing Site historical operations information. Based on the actual 1993 emissions data from the Receiving Basin for Offsite Fuels (WSRC 1994d), DOE estimates that emissions from any of the wet storage options under Alternatives 1 through 4 would

Table 5-3. Estimated incremental air quality impacts at the Savannah River Site boundary from operations of spent nuclear fuel alternatives - criteria pollutants (-g/m3).

Incremental Concentrations from Alternatives

Pollutantb	Averaging Time	Regulatory Standardc	Maximum Potential Concentration	Actual Concentratione	No Action	Decentralization			1992/1993 Planning Basis

c. NA= Emissions data currently unavailable.
- No proposed incremental emissions.

consist of about 2 y 10-7 curies per year of cesium-137. Releases from dry storage activities under these alternatives would be somewhat less. For Alternative 5 where SRS would manage about 2,740 MTHM (3,020 tons) of spent fuel (versus about 206 to 257 MTHM [227 to 283 tons] for the other alternatives), the atmospheric releases of cesium-137 would be proportionally higher.

DOE used actual emissions from F- and H-Areas during 1985 and 1986, a period when the SRS was processing material through the separations facilities at close to maximum capacity to evaluate potential releases from spent nuclear fuel management activities. DOE believes that the isotopes released during this period, and their emission rates, represent maximum emissions that could occur under any of the alternatives (Table 5-7). The results of the analyses are presented in this section and the human health consequences are discussed in Section 5.12. Section 5.15 presents the analysis of the consequences of accidents.

Construction Emissions. Potential impacts to air quality from construction activities would include fugitive dust from the clearing of land, as well as exhaust emissions from support equipment (e.g., earth-moving vehicles, diesel generators). The amount of dust produced would be proportional to the land area disturbed for the new facilities, all of which would be located near the center of the Site. The areas affected by each alternative would be as follows:

- No Action - 0 acres
- Decentralization, 1992/1993 Planning Basis and Regionalization A (by fuel type) - 6 to 9 acres

- Regionalization B (by location) - 7 to 11 acres
- Centralization - 70 to 100 acres
- Shipping fuel offsite - 1 acre

DOE anticipates that overall construction impacts to air quality would be minimal and of a short duration (6 months to 3 years). The SRS sitewide compliance with state and Federal ambient air quality standards would not be affected by any construction-related activities associated with spent fuel management.

Table 5-7. Estimated maximum annual emissions (in curies) of radionuclides to the atmosphere from spent nuclear fuel management activities.

a. Source: Hamby (1993).
b. Source terms are taken from 1985/86 F-/H-Area releases.
c. Historically, less than 10 percent of the atmospheric tritium releases have been from processing operations in the F-/H-Area Canyons.

5.7.1 Alternative 1 - No Action

The SRS would not process any spent nuclear fuel under the No Action alternative. Normal site baseline emissions would continue (Tables 5-3, 5-4, 5-5, 5-6 and 5-7). DOE would not construct any new facilities under this alternative.

5.7.2 Alternative 2 - Decentralization

Atmospheric emissions under two of the Decentralization options (dry storage and wet storage) would be similar to those for No Action. Those from the processing of the spent fuel (Option 2c) would be of somewhat higher concentrations (Tables 5-3, 5-4, 5-5, 5-6 and 5-7). The emissions would originate from existing facilities involved in the management of spent fuel under this alternative as well as new ones that DOE would construct (Figure 3-2).

5.7.3 Alternative 3 - 1992/1993 Planning Basis

Emissions to the atmosphere would be similar to those for Alternative 2 because the amount of fuel managed would be similar [223 and 220 MTHM (246 and 243 tons), Alternative 3 and Alternative 2 respectively] and the facilities required would be the same (Figure 3-2).

5.7.4 Alternative 4 - Regionalization

Regionalization A (by fuel type). Atmospheric emissions would be similar to the releases from Alternative 2 because of the similarity in volumes of fuel managed [213 and 220 MTHM (235 and 243 tons), respectively] and in the facilities involved (Figure 3-2).

Regionalization B (by location). Emissions would be somewhat higher than for Regionalization A for both dry and wet storage options if the SRS receives all the spent fuel in the eastern portion of the country, because the Site would manage about 20 percent more fuel. Atmospheric emissions from processing would not change from those under other alternatives because the amount of aluminum-clad fuel involved would be the same. Facility requirements would also be similar (Figure 3-2).

Shipping all of the current SRS inventory off the Site (Option 4g) would result in the lowest emissions to the atmosphere of any of the options under this alternative. These releases would result from the characterization and canning of the fuel prior to shipment.

5.7.5 Alternative 5 - Centralization

The atmospheric emissions resulting from centralizing all the spent nuclear fuel at the SRS would be the greatest of all the alternatives. The Site would manage about 2,740 MTHM (3,020 tons) of fuel. Releases from storage activities for centralization would be proportionally higher than for the other alternatives where the SRS would manage about 206 to 257 MTHM (227 to 283 tons) of spent fuel. However, emissions from processing under Alternative 5 would be similar to those under the other alternatives because the same amount of aluminum-clad fuel would be processed in each case. The facilities required under all three options would be similar in function (Figure 3-2) but of much larger capacity than for other alternatives.

Shipping all the SRS fuel to another site (Option 5d) would result in the lowest level of atmospheric releases of any alternative, similar to those under Regionalization B, Option 4g.

5.8 Water Quality and Related Consequences

SRS use of surface-water and groundwater resources under any of the alternatives would not substantially increase the volumes currently used for process, cooling, and domestic water on the Site. Table 5-8 summarizes the groundwater and surface water usage requirements for each alternative and option, and compares them to current SRS usages.

The Centralization Alternative (Option 5c), under which DOE would transfer all spent nuclear fuel to the SRS, would result in the largest amount of water use [approximately 378.5 million liters (100 million gallons) per year], which is a small amount compared to current SRS water requirements **of approximately 89.7 billion liters (23.7 billion gallons) per year.** This represents an increase of approximately 0.4 percent above current usage. Therefore, DOE anticipates that water use under any of the alternatives would have minimal impact on the water resources of the Site.

The impact on water quality of the operation of any of the alternatives would also be minimal. Existing SRS treatment facilities could accommodate all new spent fuel-related domestic and process wastewater streams. The expected total SRS flow volumes would still be well within the design capacities of the Site treatment systems. Because these plants would continue to meet National Pollutant Discharge Elimination System limits and reporting requirements, DOE expects no impact on the water quality of the receiving streams. The increased cooling water flows would also meet all discharge permit limits and would have minimal impacts on the receiving water.

Each of the alternatives would contribute to the very small releases of radionuclides that normal SRS operations discharge to the surface water through federally permitted wastewater outfalls.

Table 5-8. Annual groundwater and surface water usage requirements for each alternative. ,b

Alternative	Groundwater Usage per Year	Surface Water Usage per Year	Total Annual
Current SRS Usage	14.0 billion liters	75.7 billion liters	89.7 billion liters
No Action

c. First 10 years only.

Table 5-9 summarizes the estimated maximum amounts of radioactivity that could be released to the **Savannah River in liquid effluents from normal spent nuclear fuel management activities.** DOE used actual liquid releases from F- and H-Area during 1985 and 1986 to estimate potential releases that could occur during spent fuel management activities. DOE believes the isotopes and amounts released during this period are representative of releases that could occur during processing under any of the alternatives. This is because 1985 and 1986 represent periods when the F- and H-Area separations facilities operated at or near peak capacity to process spent nuclear fuel. Estimated releases from wet or dry storage would be less than these amounts. Consequently, the estimated releases given in Table 5-9 represent the upper limit of liquid radiological releases that DOE expects as a result of spent

Table 5-9. Estimated maximum liquid radiological releases (in curies) to the Savannah River from spent nuclear fuel management activities.

b. Source terms are taken from 1985/86 F-/H-Area releases.

c. Less than 1 percent of this quantity was from processing operations in F-/H-Area.

nuclear fuel management activities. The consequences to human health due to these releases are discussed in Section 5.12, Occupational and Public Health and Safety.

Construction of new facilities under any alternative would require amounts of water that would be only a very small percentage of the current daily water use at the SRS. Good engineering practice measures would prevent sediment runoff or spills of fuel or chemicals. Therefore, construction activities should have no impact on surface or groundwater quality at the Site.

DOE also analyzed the potential impacts of accidents in F- and H-Areas on surface and groundwater quality. The analysis evaluated two types of accidental releases: one to the ground surface (e.g., overflow of a wet storage pool) and another directly to the subsurface (e.g., failure of a pool liner). Because pool water could contain some radionuclides, but would not contain any toxic or harmful chemicals, the following evaluation addresses only the consequences of radionuclide releases.

A release of pool water onto the ground from the Receiving Basin for Offsite Fuels, in H-Area, would not flow directly into any stream or other surface-water body. The building is in a graded, gravel-covered area among other buildings and alongside a railroad spur and access road. A tank farm surrounded by an earthen berm is immediately to the south. A channelized drainage ditch begins approximately 244 meters (800 feet) west of the basin building and passes through culverts under a railroad line and Road E before emptying into a tributary of Fourmile Branch about 500 meters (1,650 feet) from the Receiving Basin. The grading at the Site would contain a small volume of water overflowing the basin in the immediate area of the building. In the unlikely event that a larger spill reached the drainage ditch to the west, DOE could contain the water by blocking either of the two culverts through which the drainage ditch passes. After containing the spilled water, DOE could remove and properly dispose of it. DOE would design and construct new facilities containing storage pools in a manner that would confine any overflow or other surface release of pool water. Therefore, DOE believes that there will be no direct release to surface water from spills of pool water at an existing or potential facility.

An overflow from a pool could reach the groundwater by slowly flowing downward from the surface through the unsaturated zone until it reached the water table, which is 9 to 15 meters (30 to 50 feet) below the grade in the F- and H-Areas. Overflow water would take several years to reach the water table, based on a vertical velocity of between 0.9 and 2.1 meters (3 to 7 feet) per year (DOE 1987). As discussed in the following paragraphs, once in the groundwater, a plume would take many years to reach either of the closest surface-water bodies, Fourmile Branch to the south or Upper Three Runs Creek to the north.

DOE has calculated the travel times of groundwater in the F- and H-Areas based on specific information on the hydraulic conductivity, the hydraulic gradient, and the effective porosity of aquifers in this area (WSRC 1993a) and on the use of Darcy's Law. Water would take between 16 and 500 years to travel 1.6 kilometers (1 mile) toward Fourmile Branch or Upper Three Runs Creek. These estimates of travel time agree with values obtained from the results of DOE modeling studies performed on the F- and H-Areas (Geotrans 1993; appended to WSRC 1993a). The reason for this wide range of potential travel time is that the hydraulic conductivity of aquifer materials is highly variable and can vary in the same aquifer by several orders of magnitude. This slow movement through the subsurface, either vertically through the unsaturated zone or horizontally within the aquifer, would facilitate the removal of radionuclides from the spill plume through a number of processes. These include radioactive decay, trapping of particulates in the soil, and ion exchange and adsorption by the soil (Hem 1989). DOE believes that travel time of a contaminant plume through the subsurface in the F- or H-Area or in the adjacent representative host site would be such that no radionuclides would reach Fourmile Branch, Upper Three Runs Creek, or any other surface-water body by this route. For the same reasons, no radioactive contaminants introduced into the subsurface in these areas would move off the Site in groundwater.

DOE does not believe that releases of radionuclides such as those described above would reach SRS drinking-water sources that lie in deep aquifers under the Site. These aquifers are several hundred feet below the ground surface, and a number of thick aquifers and aquitards separate them from the water table aquifer (see Section 4.8). In addition to the distances and the presence of confining layers, vertical flow in the intervening stratified sedimentary aquifers is slow in comparison to horizontal flow. Radionuclide contamination of offsite drinking water sources is even more unlikely given the depth of their source aquifers, the distances involved, and the attenuation of contaminants in the soils, as described above.

DOE also evaluated a second kind of unintentional release in the F- or H-Area, a direct leak to the subsurface from a breach in a storage pool during routine operations. The analysis assumed a 19-liter (5-gallon)-per-day leak as a result of secondary containment or piping failure at a new state-of-the-art wet storage and fuel transfer facility (Creed 1994). The analysis assumed further that the leak would go undetected for 1 month, a conservative assumption given the sensitivity of the leak detection equipment that these new facilities would require. The reliability and sensitivity of the leak detection devices would be equal to or superior to those required by the U.S. Nuclear Regulatory Commission (NRC 1975) for spent nuclear fuel storage facilities in commercial nuclear power plants. DOE would require spent nuclear fuel storage pools (whether fuel unloading pools or storage basins) to have leak detection monitoring devices, pool water level monitors, and radiation monitors designed to alarm both locally and in a continuously staffed central location. Constant process monitoring, mass balance, and facility design (including double-walled containment of vessels and piping) would also be used by DOE to limit operational releases from new wet storage facilities, including fuel unloading pools and storage basins, to near zero.

To provide a common basis for analysis of spent nuclear fuel alternatives at its various sites, DOE developed a generic infrastructure design for a hypothetical spent nuclear fuel complex (Hale 1994). This design includes proposed criteria for temporary wet storage basins, fuel loading and unloading pools, and transfer canals.

Based on the design criteria in Hale (1994), a leak from one of these basins if constructed in F- or H-Area could result in the introduction of radionuclide-contaminated water into the ground at depths as much as 13.4 meters (44 feet) below grade. Such a release would go directly to the water table aquifer or to the unsaturated zone above it, depending on the depth of the water table. In either case, the processes governing the slow plume movement (i.e., the hydraulic conductivity, hydraulic gradient, and effective porosity of aquifers in the F- and H-Areas) and the processes resulting in the attenuation of contaminants and radionuclides (i.e., radioactive decay, trapping of particulates in the soil, ion exchange in the soil, and adsorption to soil particles) described in the previous paragraphs would also prevent or mitigate impacts to surface-or groundwater resources from releases of this type. There could be localized contamination of groundwater in the surface aquifer in the immediate vicinity of the storage facilities. This aquifer is not used as a source of drinking water. DOE believes that no radionuclide contamination of deeper confined aquifers that are sources of onsite or offsite drinking water could occur from a release of this type. And, as noted earlier, these wet storage facilities would be equipped with state-of-the-art leak detection devices, pool level monitors, and radiation monitors that would limit and mitigate any subsurface releases.

5.8.1 Alternative 1 - No Action

5.8.1.1 Option 1 - Wet Storage. During operations under this alternative, current levels of

water usage would not change. Nor would changes occur in thermal discharges from cooling water or the quantity or quality of radioactive and nonradioactive wastewater effluents.

The viable accidents under this alternative would be a release of pool water onto the ground surface or a breach of the liner of the wet storage basins in which the spent nuclear fuel would be stored. As discussed above, radionuclides in the released water would enter the water table aquifer but would not reach any surface-water or any drinking water aquifer on or off the SRS. Basin water contains no toxic or hazardous chemicals. Therefore, accidental releases from the basins would have minimal impacts on surface- and groundwater resources.

Spills of chemicals would not reach surface- or groundwater due to existing proper engineering design and environmental controls, and to rapid containment and cleanup.

5.8.2 Alternative 2 - Decentralization

Operations under either the dry or wet storage option for the Decentralization alternative would increase Site water usage by less than 0.1 percent above current levels. Processing would increase use by about 0.4 percent. Release of nonradioactive and radioactive materials to surface waters would increase only slightly and would be well within discharge permit limits and DOE dose limits. There would be no releases to groundwater during normal operations. Overall impacts to water quantity and water quality would be minimal.

Impacts to water resources due to accidental releases onto the ground or into the subsurface would also be minimal as explained above. Potential contamination would be limited to the surface aquifer.

5.8.3 Alternative 3 - 1992/1993 Planning Basis

DOE expects that the impacts to water resources under the dry storage, wet storage, and processing cases for this alternative would be similar to those described for the same options under Alternative 2, Decentralization. Overall impacts would be minimal.

5.8.4 Alternative 4 - Regionalization

DOE expects that the impacts to water resources under the three options for regionalization by fuel type (Regionalization A) would be similar to those described for the same options under Alternative 2, Decentralization. Regionalization B (by geographic location) would result in impacts somewhat greater than those for Alternative 2 because the SRS would have to manage an additional 37 MTHM (41 tons) of spent fuel. In either case, overall impacts would be minimal. For Option 4g, shipping all SRS fuel to Oak Ridge Reservation, impacts to water resources would be the smallest of any alternative, similar to those for Option 5d - Centralization.

5.8.5 Alternative 5 - Centralization

The first three options for this alternative - dry storage (Option 5a), wet storage (Option 5b), and processing (Option 5c) - assume that DOE would transfer all spent nuclear fuel to the SRS for management. The impacts of operations to water resources under these options would be similar in nature to the impacts for the same options under Alternative 2, Decentralization, as described in Section 5.8.2. However, the extent of the impacts would be greater because the number and size of facilities that DOE would construct and operate and the quantities of fuel it would manage would be larger than those for any other alternative. Even so, DOE expects the overall impacts of construction and operation to be minor. For example, the total volume of water that the SRS would withdraw for construction, cooling, processing, and domestic use under any of these three options would not exceed approximately 378.5 million liters (100 million gallons) per year. This requirement would be approximately 0.4 percent of the 89.7 billion liters (23.7 billion gallons) that the SRS currently uses annually.

Similarly, DOE believes that the overall impacts of accidents under any of these three options would be minor, even though the number and size of the facilities would be greater under this alternative than for any other. Radionuclides released during an accident would not affect any surface-water or any drinking water aquifer. However, surface aquifer resources would receive contamination in the area of any release.

For Option 5d (shipping the spent nuclear fuel off the Site), impacts to water resources would be smaller than those for any other alternative or option. DOE would have to build only one new facility (for fuel characterization) and the spent fuel would remain at SRS only for the first part of the 40-year management period. Overall impacts would be minimal.

5.9 Ecology

DOE expects that construction impacts, which would include loss of some wildlife habitat due to land clearing, would be greatest under the Centralization Alternative, Dry Storage option. Representative impacts from operations would include disturbance and displacement of animals caused by movement and noise of personnel, equipment, and vehicles; however, these impacts would be minor under all the proposed alternatives. Construction and operation would not disturb any critical or sensitive habitat, nor would they affect any wetland areas. Releases of radionuclides to the environment from any of the proposed alternatives would be small and would not be expected to accumulate in aquatic or terrestrial ecosystems or measurably affect the health or viability of plant and animal communities.

5.9.1 Alternative 1 - No Action

Under this alternative, DOE could refurbish or modify existing wet storage facilities and would confine any activity to these facilities. As a consequence, DOE expects no impacts to ecological resources. Impacts of operations under this alternative would be minimal, limited to some minor disturbance of animals by vehicular traffic.

5.9.2 Alternative 2 - Decentralization

5.9.2.1 Option 2a - Dry Storage. This option would require some new construction, but any

construction activity would occur either within the boundaries of F- and H-Areas, which are already heavily developed, or adjacent to them. As a result, this construction would have little or no impact on ecological resources. There would be no impacts to wetlands, threatened or endangered species, socially or commercially important species (such as the eastern wild turkey), or disturbance-sensitive species (such as wood warblers and vireos). Impacts of operations under this option would be limited to some minor disturbance of animals by slight increases in vehicular traffic. No threatened, endangered, or candidate species occur in the area of operations. Species likely to be disturbed or killed by vehicles (e.g., cotton rat, gray squirrel, opossum, and white-tailed deer) are common to ubiquitous in the area. Overall impact to ecological resources would be minimal.

5.9.2.2 Option 2b - Wet Storage. Construction impacts would be similar to those described

for dry storage (Option 2a). Impacts of operations under this option would also be similar to those described for dry storage (Option 2a). Overall impacts to ecological resources would be minimal.

5.9.2.3 Option 2c - Processing and Storage. Construction and operations impacts for this

option would also be similar to those for dry storage (Option 2a). Overall impacts would still be minimal.

5.9.3 Alternative 3 - 1992/1993 Planning Basis

Both construction and operational impacts for the three options under this alternative would be similar to those described for Alternative 2 - Decentralization. Overall impacts would be minimal.

5.9.4 Alternative 4 - Regionalization

Under the Regionalization A alternative, impacts to ecological resources would be minimal as described for Alternative 2. Impacts due to the Regionalization B options would be somewhat greater due to the larger volume of spent fuel that the SRS would manage. Overall impacts would still be minimal, however.

The smallest impacts would occur under Option 4g because DOE would ship all spent fuel off the Site.

5.9.5 Alternative 5 - Centralization

5.9.5.1 Option 5a - Dry Storage. The discussion that follows assumes that any facility

development would take place in an area that does not contain any pristine wetlands, old growth timber, threatened and endangered species, or designated critical habitat. More specifically, because the upland areas south and east of H-Area are dominated by planted pine (primarily loblolly and slash) stands, the discussion of impacts assumes that any facility development in support of spent nuclear fuel management would take place in an area of 5- to 40-year-old pines. Finally, the analysis assumes that any facility development would require a site-specific National Environmental Policy Act (NEPA) review as required under 10 CFR Part 1021 and in accordance with the Council on Environmental Quality's NEPA implementing regulations (CFR 1991b).

The proposed interim dry storage facility and support facilities, requiring approximately 0.28 square kilometers (70 acres) to 0.4 square kilometer (100 acres) of land, would be built somewhere within the largely wooded roughly 2.8 square kilometer (700-acre) area south and east of H-Area west of F-Road, and north of Fourmile Branch. This area has a number of advantages; among them: it would be relatively easy to connect with existing utilities (gas, water, sewer); it would minimize the amount of supporting infrastructure (e.g., railroad spurs, access roads, and transmission lines) that would have to be built; and it would enable DOE to consolidate spent nuclear fuel management activities in an area that has been altered many times over the years by farming (before 1951) and timber management activities (after 1951).

Construction activities would result in the clearing of as much as approximately 0.4 square kilometer (100 acres) of planted 5- to 40-year-old loblolly or slash pine for new facilities on the undeveloped representative host site south and east of H-Area. This land clearing would involve a relatively small number of loggers and heavy equipment operators, but probably would drive most birds and larger, more mobile animals from the area. Some smaller, less mobile animals, such as turtles, toads, lizards, mice, and voles, probably would be killed. Aside from the loss of 0.28 to 0.4 square kilometer (70-100 acres) of planted pines that provide habitat for a limited number of reptiles, birds, and mammals, construction impacts would be minor.

Any land clearing and timber harvesting conducted on the undeveloped host site would be carefully planned and conducted according to widely accepted Best Management Practices to minimize erosion and soil loss and to prevent impacts to downgradient wetlands and streams. DOE and SRS policy is to achieve "no net loss" of wetlands. DOE has issued a guidance document, Information for Mitigation of Wetlands Impacts at the Savannah River Site (DOE 1992), for project planners that puts forth a practical approach to wetlands protection that begins with avoidance of impacts (if possible), moves to minimization of impacts (if avoidance is impossible), and requires compensatory measures (wetlands restoration, creation, enhancement, or acquisition) in the event that impacts cannot be avoided.

In the event that new facility development was required, DOE would perform predevelopment surveys to ensure that its activities would not affect threatened and endangered species or sensitive habitats. To the extent practicable, land clearing and timber harvesting would be restricted to times of the year when songbirds and game birds were not nesting or rearing young. In South Carolina, most songbirds nest, rear, and fledge young from March to September (Sprunt and Chamberlain 1970). Quail, dove, and wild turkey in the region normally nest and fledge young during the spring and summer (Sprunt and Chamberlain 1970).

No threatened or endangered plants or animals are known to be present in the area under consideration for development. Construction activities probably would not affect two small wetlands (Carolina bays) lying in the east-central portion of the undeveloped host site. Construction activities would not affect plant and animal diversity locally or regionally, because the managed loblolly and slash pine stands that would be removed are not unique, nor do they provide habitat for any protected, sensitive, unusual, or Federally listed plant or animal species.

Impacts of operations under this option would be similar to, but slightly greater than, those described for Option 2a. Overall impacts to ecological resources would be minor.

5.9.5.2 Option 5b - Wet Storage. Construction impacts under this option would be less than

those described for Option 5a because less land area would be required for new facilities. Impacts of operations under this case would be similar to those described for Option 5a. Overall impacts to ecological resources would be minor.

5.9.5.3 Option 5c - Processing and Storage. Construction impacts under this case would

be similar to those described for Option 5a. This case would require the largest number of workers of all the cases under consideration. It would result in more noise, more traffic, and a generally higher level of disturbance to terrestrial wildlife (specifically reptiles, songbirds, and small and large mammals) accustomed to feeding, foraging, perching, hunting, nesting, or denning in the area. Some animals would be driven from the area permanently, while others probably would become accustomed to the increased noise and activity levels, and would return to the area. Overall impacts to ecological resources would be minor.

5.9.5.4 Option 5d - Shipment off the Site. Construction impacts under this case would be

smaller than those for any other alternative, excluding Alternative 1 - No Action. Impacts of operation under this case would also be minimal, limited to some minor disturbances of animals by vehicular traffic. Overall impacts to ecological resources would be minimal.

5.10 Noise

As described in Section 4.10, noises generated on the SRS do not travel off the Site at levels that affect the general population. Therefore, SRS noise impacts for each alternative would be limited to noise resulting from the transportation of personnel and materials to and from the Site that could affect nearby communities and from onsite sources that could affect some wildlife near these sources. DOE would address the effects of noise on wildlife near spent nuclear fuel management facilities under any alternative in a project-specific NEPA evaluation.

Transportation noises would be a function of the size of the workforce (i.e., an increased workforce would produce increased employee traffic and corresponding increases in deliveries by truck and rail and a decreased workforce would produce decreased employee traffic and corresponding decreases in deliveries). The analysis of traffic noise took into account railroad noise and noise from the major roadways that provide access to the SRS. DOE does not expect the number of freight trains per day in the region and through the Site to change as a result of any of the alternatives, although some trains could be dedicated to the transport of spent nuclear fuel. Rail shipments of spent nuclear fuel, regardless of the alternative, would not substantially increase the rail traffic on the CSX line through the SRS. Therefore, vehicles used to transport employees and personnel on roadways would be the principal sources of community noise impacts. This analysis used the day-night average sound level (DNL) to assess community noise, as suggested by the Environmental Protection Agency (EPA 1974; 1982) and the Federal Interagency Committee on Noise (FICON 1992). The analysis based its estimate of the change in day-night average sound level from the baseline noise level for each alternative on the projected changes in employment and traffic levels. The baseline levels are those for 1995. The analysis also considered the combination of construction and operation employment. The traffic noise analysis considered SC 125 and SC 19, both of which are used to access the SRS. Changes in noise level below 3 decibels would not be likely to result in a change in community reaction (FICON 1992).

DOE projects no new employment due to operations for any of the alternatives. Some additional construction jobs may be required but overall SRS employment would not exceed the 1995 baseline levels, except for Alternatives 5a, 5b, and 5c. The maximum Site employment of about 20,000 jobs would occur in 1995 for all alternatives except 5a, 5b, and 5c for which the peak would occur in about 2002 due to a peak in construction employment. The general decrease in employment after 1995 could result in some decrease in vehicle trips to and from the Site. There would be at most a few truck trips per day to and from the Site carrying spent nuclear fuel under any of the alternatives. This increase in truck trips would not result in a perceptible increase in traffic noise levels along the routes to the SRS. The day-night average sound level along SC 125 and SC 19 and other access routes would probably decrease slightly except in the peak construction years under Alternatives 5a, 5b, and 5c, as a result of the overall decrease in employment levels at the SRS after 1995. DOE expects no change in the community reaction to noise along these routes. Consequently, no mitigation efforts are necessary.

5.11 Traffic and Transportation

This section discusses the consequences of both the onsite transportation of spent nuclear fuel and the increased traffic patterns due to construction activities at the SRS. Traffic due to operations of spent nuclear fuel facilities will remain at or below current Site levels because workers for the new activities will be drawn from the existing SRS workforce. The consequences of the transportation of spent fuel between the SRS and other DOE sites are described in Appendix I of Volume 1 of this Environmental Impact Statement (EIS).

5.11.1 Traffic

Traffic impacts would be bound by Alternative 5b (Centralization - Wet Storage) which would result in the greatest number of additional construction workers (and vehicles) onsite. Level of service, a measure of traffic flow, was estimated for each road to and from the SRS. Traffic delays could be experienced at SC 19 and SC 230 intersections during peak hours. However, the number of construction vehicles in support of spent nuclear fuel construction activities would contribute less than 17 percent (HNUS 1994) to the total traffic flow. Therefore, the change in level of service due to Alternative 5b would be minimal.

5.11.2 Transportation

This section discusses the potential radiological consequences due to incident free transportation and accidents during transport. All SRS onsite shipments are carried out by rail.

5.11.2.1 Onsite Spent Nuclear Fuel Shipments. DOE based the number of fuel

shipments on the amount and type of spent nuclear fuel stored at various SRS locations and the final storage location or disposition specified in the spent nuclear fuel alternatives. The number of shipments from each location was determined by dividing the amount of spent nuclear fuel at each location by the capacity of the shipping cask. Individual shipments from the various facilities were summed to obtain the total number of shipments for each alternative (HNUS 1994).

Onsite shipments are those that originate and terminate at the SRS. Movements of spent nuclear fuel within functional areas (e.g., H-Area or F-Area) are operational transfers, not onsite shipments; therefore, this analysis does not consider them.

5.11.2.2 Incident-Free Transportation Analysis. Under each alternative, DOE analyzed

incident-free (normal transport) radiological impacts to transport vehicle crews and members of the general public from onsite rail shipments. The analysis calculated occupational radiation doses to the transport vehicle crew members (four locomotive operators). Because the general public does not have immediate access to areas where the SRS would transport spent nuclear fuel, the analysis assumed that any general public dose is to escorted individuals on the Site waiting at any of several train crossings at the time a fuel shipment passed. The analysis calculated radiological doses to the general public using the Riskind (Yuan et al. 1993) computer code. The results are presented in Table 5-10.

The magnitude of incident-free consequence depends on the dose rate on the external surface of the transport vehicle, the exposure time, and the number of people exposed. For each receptor, the analysis assumed the external dose rate 2 meters (6.6 feet) from the shipping cask was 100 millirem per hour (HNUS 1994), which is the SRS procedurally-allowed maximum dose rate during onsite fuel shipments. Actual receptor dose rates would depend on receptor distance from the shipping cask [5 meters (16.4 feet) for the general public]. The duration of exposure would depend on the transport vehicle speed and the number of shipments. In addition, occupational exposure time would depend on the distance of each shipment.

The analysis calculated health effects measured as the number of latent cancer fatalities (LCFs) by multiplying the resultant occupational and general public doses by risk factors of 4 x 10-4 and 5 x 10-4 latent cancer fatalities per person-rem (DOE 1993a), respectively.

Table 5-10 summarizes the collective doses (person-rem) and health effects (latent cancer fatalities) associated with the incident-free onsite shipment of spent nuclear fuel at the SRS. Collective

Table 5-10. Collective doses and health effects for onsite, incident-free spent nuclear fuel shipments by alternative.

Option	Occupational (person-rem)	General Public (person-rem)	Number of LCFsa

			Occupational	General Public
No Action				
Option 1b -Wet Storage	1.5x100	1.4x10-1	6.0x10-4	7.0x10-5
Decentralization				
Option 2a - Dry Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 2b - Wet Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 2c - Processing	5.3x10-1	3.7x10-2	2.1x10-4	1.9x10-5
Planning Basis				
Option 3a - Dry Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 3b - Wet Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 3c - Processing	5.3x10-1	3.7x10-2	2.1x10-4	1.9x10-5
Regionalization				
Option 4a - Dry Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 4b - Wet Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 4c - Processing	5.3x10-1	3.7x10-2	2.1x10-4	1.9x10-5
Option 4d - Dry Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 4e - Wet Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 4f - Processing	5.3x10-1	3.7x10-2	2.1x10-4	1.9x10-5
Option 4g - Ship Out	NAb	NAb	NAb	NAb
Centralization				
Option 5a - Dry Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 5b - Wet Storage	2.5x100	2.3x10-1	1.0x10-3	1.2x10-4
Option 5c - Processing	5.3x10-1	3.7x10-2	2.1x10-4	1.9x10-5
Option 5d - Ship Out	NAb	NAb	NAb	NAb

a. LCF = latent cancer fatality.
b. NA = not applicable.

doses and latent cancer fatalities for members of the public would be approximately a factor of 10 less than those for the occupational worker. The data indicate that the lowest collective doses and lowest latent cancer fatality would be associated with the Processing option under the Decentralization, Planning Basis, Regionalization, and Centralization alternatives.

5.11.2.3 Transportation Accident Analysis. DOE analyzed radiological impacts from

potential accidents to both the onsite maximally exposed individual (MEI), and offsite members of the general public from onsite rail shipments. The analysis calculated doses using the Riskind (Yuan et al. 1993) computer code with site-specific meteorology, demographics, and spent fuel activity. Risk was calculated using site-specific rail accident rates and accident probabilities (HNUS 1994).

The magnitude of accident consequence would depend on the amount of radioactive material to which the individual(s) was exposed, the exposure time, and the number of people exposed. The analysis assumed that the maximum reasonably foreseeable amount of radioactive material for the type of spent fuel shipped on the SRS was released (HNUS 1994). The assumed duration of exposure for each receptor was 2 hours. The assumed maximally exposed individual was an SRS worker downwind of the accident at distances of 50 and 100 meters (164 and 330 feet).

The analysis calculated offsite exposure using both rural and suburban population density-specific census data. The rural and suburban population densities have an average of 6 persons per square kilometer and 244 persons per square kilometer, respectively. The west-northwest sector has the highest population density within 80 kilometers (50 miles) of the SRS.

The analysis used site-specific meteorology at the 50th and 95th percentile to determine dose consequences. Joint probability includes both the event frequency and the probability of the maximum reasonably foreseeable type of accident occurring.

The analysis calculated health effects measured as the number of latent cancer fatalities by multiplying the resultant occupational and general public doses by the risk factors of 4 x 10-4 and 5 x 10-4 latent cancer fatalities per person-rem (DOE 1993a), respectively. Risk was calculated by multiplying the resultant doses by the joint probability of 1 x 10-4 (HNUS 1994).

Tables 5-11 and 5-12 summarize the collective doses and associated latent cancer fatalities for postulated onsite rail accidents with subsequent releases of radioactive material to the environment. The dose consequences of an accidental release of radioactive material was assessed for the 95th and typical 50th percentile meteorological conditions (i.e., those that would result in lower doses 95 and 50 percent of the time, respectively). In all cases the estimated number of latent cancer fatalities would be low.

5.11.3 Onsite Mitigation and Preventative Measures

All onsite shipments must be in compliance with DOE Savannah River Directive Implementation Instruction 5480.3, "Safety Requirements for the Packaging and Transportation of Hazardous Materials, Hazardous Substances, and Hazardous Wastes." DOE, DOE-SR, or the Nuclear Regulatory Commission (NRC) must approve packages used for onsite shipments with a certificate of compliance. If DOE or NRC has not certified an onsite package as Type B, the shipper must establish administrative controls and site-mitigating circumstances that will ensure package integrity. The administrative and emergency response considerations must provide sufficient control so that accidents would not result in loss of containment, shielding, or criticality; or the uncontrolled release of radioactive material would not create a hazard to the health and safety of the public or workers.

Table 5-11. Impacts on maximally exposed individual from spent nuclear fuel transportation accident on the Savannah River Site.

Dose Percentile	Distance (meters)	Dose to MEIa (rem)	Number of LCFsb per year	Risk
50 percent	100	0.16	6.4x10-5	1.6x10-5
95 percent	50	0.37	1.5x10-4	3.7x10-5

a. MEI = maximally exposed individual.
b. LCF = latent cancer fatality.

Table 5-12. Impacts on offsite population from spent nuclear fuel transportation accident on the Savannah River Site.

Population Density Category	Dose Percentile	Offsite Population Dose (person-rem)	Number of LCFsa per year	Risk
Rural	50th	1.7	8.7x10-4	1.7x10-4
Rural	95th	7.1	3.6x10-3	3.6x10-3
Suburban	50th	5.2	2.6x10-3	2.6x10-3
Suburban	95th	21.3	1.1x10-2	1.1x10-2

a. LCF = latent cancer fatality.

In the event of an accident, SRS has established an emergency management program. This program incorporates activities associated with emergency planning, preparedness, and response.

5.12 Occupational and Public Health and Safety

5.12.1 Radiological Health

This human health effects analysis relied principally on data on F- and H-Area emissions documented for the 1985, 1986, and 1993 operating years (Marter 1986; 1987; WSRC 1994d). During the 1985-1986 period, F- and H-Areas processing facilities operated at high capacity; DOE believes, therefore, that these emissions represent conservative estimates as to the emissions that could result from spent nuclear fuel management activities at the SRS. This air and surface-water emissions information defined the source terms for the baseline evaluation (No Action alternative) of health effects discussed in this section. To estimate health effects, this analysis defined six human receptor groups:

- The F- and H-Area workers assigned to F- and H-Area operations involving nuclear materials
- The F- and H-Area workers assigned to the Receiving Basin for Offsite Fuels for storage operations
- The maximally exposed individual residing at the SRS boundary
- The projected 1994 offsite population of 628,200 persons residing within an 80-kilometer (50-mile) radius of F- and H-Areas
- The maximally exposed individual potentially affected by SRS surface-water emissions
- The approximate offsite population of 65,000 persons whom SRS surface-water emissions could affect.

With the exception of the worker group, this analysis calculated exposures for the remaining four receptor groups using the baseline source terms as input data to automated atmospheric and surface-water transport, human intake, and human dosimetry models configured for routine use at SRS

(Hamby 1994). The analysis estimated worker exposures using averaged dosimetry data recorded for F- and H-Area workers from 1983 through 1987 and Receiving Basin for Offsite Fuels workers for 1993 (Matheny 1994), corrected for an assumed occupancy factor of 0.25 (i.e., a worker could be potentially exposed during one-quarter of his/her shift). This correction was applied to the 1983-1987 data only. At the SRS, the waterborne exposure pathway does not exist for the worker receptor group because Site drinking water is drawn from deep aquifers unaffected by any radiological releases.

The analysis developed incremental receptor group exposure estimates (millirem per year, person-rem per year; effective dose equivalent) based on spent fuel quantities for each of the nonbaseline alternatives (i.e., Alternatives 2 through 5) and their options by applying calculated ratios of metric tons of heavy metal (MTHM) for each alternative and option compared to the No Action alternative. DOE used these ratios as incremental scaling factors to estimate exposures under each option. The calculation of the MTHM ratios used the data presented in Table 3-1. Table 5-13 lists the results of the exposure estimate calculations. Since these incremental exposures include contributions to the effective dose equivalent from existing (No Action) spent fuel management at the SRS, the change in health effects for each alternative can be estimated as the difference between the alternatives presented.

The analysis calculated the potential health effects expressed in the exposed receptor groups consistent with risk determination guidance issued by the DOE Office of NEPA Oversight (DOE 1993a) and International Commission on Radiological Protection Publication 60 (ICRP 1991). For exposed individuals and populations, the potential health effect (detriment) of interest is latent fatal cancer. For exposed individuals, this analysis presents the health effect as the maximum incremental probability for detriment expression; for exposed populations, it presents the annual incremental detriment incidence. For completeness, it also provides the "project life" (i.e., 40 years) detriment incidence as the annual incidence multiplied by 40. Table 5-14 (worker) and Table 5-15 (maximally exposed individual and offsite population) summarize the health effects calculations.

The Centers for Disease Control and Prevention is conducting a comprehensive reconstruction of historic offsite doses associated with SRS operations. The results of this investigation are not yet available.

5.12.2 Nonradiological Health

DOE used the operations air quality data listed in Tables 5-3, 5-4, 5-5 and 5-6 (and Table 8 of WSRC 1994a) to evaluate health impacts associated with potential exposure to the following two compound classes: criteria pollutants and toxic pollutants. The analysis evaluated two hypothetical receptor locations: (1) a worker in S-Area and (2) a maximally exposed individual at the SRS boundary. However, it was unnecessary to postulate an intake of criteria pollutant or toxic compounds by these receptors because airborne concentration standards are available for these compounds.

Tables 5-3 and 5-4 list 8 criteria pollutants and 23 toxic compounds. The toxic compounds were classified as carcinogens and noncarcinogens consistent with Environmental Protection Agency carcinogenicity group (weight of evidence) designations published in the Integrated Risk Information

Table 5-13. Incremental radioactive contaminant annual exposure summary.

Alternative	Onsite Workers[a] (mrem/year)[c]	(person-rem/year)	MEI Offsite[a,b,d] (mrem/year) Air	Water	Offsite Population[a,d] (person-rem/year) Air	Water

a. Number of latent fatal cancers over a lifetime which could be attributed to one year of spent nuclear fuel management activities.

System (IRIS) data base (DOE 1994b). For purposes of health effects analysis, carcinogens are those compounds designated Group A (human carcinogens), Group B1 (probable human carcinogen, limited evidence in human studies), Group B2 (probable human carcinogen, inadequate evidence or no data from human studies), and Group C (possible human carcinogen). Using this designation, three of the 23 toxic compounds are carcinogens: benzene (Group A), formaldehyde (Group B1), and methylene chloride (Group B2).

Carcinogen health effects are expressed as the incremental probability of an individual developing cancer, assuming a lifetime (70 years) of exposure to the carcinogen. DOE used cancer risk (slope) factors published in IRIS (Integrated Risk Information System) to obtain unit risk factors (risk per concentration) needed to calculate incremental probability. Carcinogens with insufficient (i.e., incomplete or unavailable carcinogen assessment data) information listed in the Integrated Risk Information System data base precluded a quantitative risk assessment; this analysis evaluated them as noncarcinogens.

Table 5-15. Incremental fatal cancer incidence and maximum probability for the maximally exposed individual and offsite population (air and water pathways).

a. Number of latent fatal cancers over a lifetime that could be attributed to one year of spent nuclear fuel management activities.

This analysis evaluated noncarcinogenic and priority pollutant compound health effects by adding hazard quotients to obtain a hazard index. The hazard quotient is the ratio of compound concentration or dose to a Reference Concentration (RfC) or Dose (RfD) (EPA 1989). The regulatory standard used in this analysis was the more stringent of the following: (1) Occupational Safety and Health Administration (OSHA) 8-hour permissible exposure limit (PEL), (2) American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV), or (3) State of South Carolina air quality standards. The use of the noncancer hazard index assumed a level of exposure (i.e., RfC) below which adverse health effects are unlikely. The hazard index is not a statistical probability; therefore it cannot be interpreted as such.

Table 5-16 summarizes nonradiological health effects attributable to atmospheric emissions of toxic and criteria pollutant compounds. Because no hazard index value would exceed unity (1.0), adverse health effects are unlikely under any alternative.

5.12.3 Industrial Safety

This section describes the following measures of impact for workplace hazards: (1) total reportable injuries and illnesses and (2) fatalities in the work force. This analysis considers injury/illness and fatality incidence rates for construction workers separately because of the relatively more hazardous nature of construction work. Table 5-17 lists the incidence of injuries/illnesses and fatalities for construction and non-construction workers. These data are for the highest employment

Table 5-16. Nonradiological annual incremental health effects summary.

5.13 Utilities and Energy

The existing capacities and distribution systems at the SRS for electricity, steam, water, and domestic wastewater treatment are adequate to support any of the five alternatives. Table 5-18 summarizes estimates of the annual requirements for electricity, steam, and domestic wastewater treatment for each alternative and case, and compares them to current SRS usage of these resources.

Table 5-8 lists information on water usage by alternative. The utility and energy requirements for all

Table 5-18. Estimates of annual electricity, steam, and domestic wastewater treatment

requirements

a. Source: WSRC (1994b).
b. Water requirements are shown in Table 5-8.
c. To convert kilograms to pounds, multiply by 2.2046.
d. To convert liters to gallons, multiply by 0.26418.

the alternatives represent a small percentage of current requirements. No new generation or treatment facilities would be necessary; connections to existing networks would require only short tie-in lines.

Increases in SRS fuel consumption would be minimal because overall activity on the Site would not increase due to changes in the SRS mission and the general reduction in employment levels. The overall impacts of any of the alternatives on the SRS utilities and energy resources would be minimal.

The smallest increase in demand would result from the No Action alternative, which would be similar to current spent nuclear fuel-related requirements at the SRS. The largest increases would be due to the centralization of spent nuclear fuel at the SRS (Alternative 5). Alternative 5 would result in a maximum additional electrical demand of about 110,400 megawatt-hours annually (Option 5c), and an increased steam consumption of about 19.1 million kilograms (42.1 million pounds) per year (Option 5c). Water requirements would also be greatest under this Alternative (Table 5-8). Annual withdrawals of Savannah River water for cooling purposes would reach about 310.8 million liters (82.1 million gallons) and groundwater usage for domestic and processing purposes would total approximately 69.6 million liters (18.4 million gallons). The volume of domestic wastewater requiring treatment would range from approximately 35 to 70 million liters (9 to 18 million gallons) per year. This additional water usage amounts to an increase of about 10 percent over current SRS water requirements.

Among the three management options, processing would result in the greatest increase in demand on utilities and energy in comparison to either the dry or wet storage options. In general, dry and wet storage would be similar in their requirements of these resources.

5.14 Materials and Waste Management

This section discusses potential impacts of the management of materials and wastes associated with the implementation of alternatives identified for spent nuclear fuel management. Sections 5.7 and 5.12 (Air Quality and Occupational and Public Health and Safety, respectively) discuss the impacts of hazardous and toxic materials as they relate to routine operations and accidents.

DOE has projected rates and volumes of waste and impacts of waste generation at SRS for low-level, transuranic, and high-level wastes for each of the alternatives for spent nuclear fuel management. Table 5-19 summarizes the estimated annual average and total volume of these three waste types that **each alternative would produce during a 40-year management period.** The discussion

Table 5-19. Annual average and total volume (cubic meters)[d] of radioactive wastes produced under each alternative during the 40-year interim management period.

below also identifies the impacts that the waste produced by spent nuclear fuel activities would have on the existing SRS capacity to manage each waste type.

DOE has not developed estimates of low-level mixed, hazardous, or solid sanitary wastes that spent nuclear fuel management activities at the SRS could generate, although it is anticipated that these activities would produce these waste types only in limited quantities. Further, the discussions in Section 5.14.2 related to the impacts of spent fuel management wastes on the SRS waste capacities do not include considerations of wastes that will result from Site cleanup because assessments for these activities are still underway and will undergo NEPA review as part of the SRS Waste Management Environmental Impact Statement (DOE 1995).

Volume 1 of this spent nuclear fuel EIS provides information concerning the major Federal environmental laws and regulations, Executive Orders, and DOE Orders that apply to pollution prevention at the Savannah River Site. The DOE views source reduction as the first priority in its pollution prevention program, followed by an increased emphasis on recycling. Source reduction will reduce the waste management burden while eliminating the potential for future liability and cleanup. Recycling and using recycled materials will conserve resources and landfill space. Waste treatment and disposal are considered only when prevention or recycling is not possible or practical. Since creating a Savannah River Site waste minimization program (the precursor of the SRS pollution prevention program) in 1990, the amounts of wastes of all types (excluding low-level wastes, which are a by-product of environmental restoration activities) generated have decreased, with greatest reductions in hazardous and mixed wastes (Hoganson and Miles 1994).

5.14.1 Alternative Comparison

The first four alternatives would generate similar amounts of radioactive waste because the activities that produce the wastes would be similar under each of the alternatives. Most of the low-level and transuranic wastes would be generated during the first part of the 40-year management period while DOE was transferring existing inventory and renovating the Receiving Basin for Offsite Fuels and a reactor basin. The characterization and canning of the current inventory prior to placement into storage would also result in some waste generation. Once in storage, management activities would produce only small amounts of radioactive waste for the rest of the 40-year period.

The dry- and wet-storage options would both produce about 16,000 cubic meters (20,912 cubic yards) of low-level waste and between 640 cubic meters (836 cubic yards) and 800 cubic meters (1,046 cubic yards) of transuranic waste during the 40-year management period. Both options would generate small amounts of high-level waste. The processing of the existing aluminum-clad fuels and storage of the others (the third option under each alternative) would generate all three types of waste: low-level and high-level wastes in appreciably greater volumes, and transuranic waste in slightly greater volumes.

Alternative 5 (excluding the Ship Out option) could result in somewhat larger volumes of radioactive waste than the other four alternatives. However, any increase in waste would not be directly proportional to the larger amounts of fuel that would be managed on the Site, because most of the originating sites would characterize and can their fuel prior to shipment so that it could be placed directly into storage at the SRS. Therefore, the radioactive wastes produced during centralization at the Site would come from the initial fuel transfer and pool renovations and from characterizing and canning small amounts of new fuel. The processing of existing aluminum-clad fuels would produce the same types and volumes of waste as for the other alternatives.

The option for shipping the SRS inventory off the Site for regionalization or centralization elsewhere would also result in the production of some radioactive waste. This would occur during characterization and canning prior to shipment and would generate the smallest volumes of waste of any alternative action: 4,000 cubic meters (5,228 cubic yards) of low-level waste and 180 cubic meters (235 cubic yards) of transuranic waste. This waste would be produced only during the initial 10 years of the management period.

5.14.2 Impact on the SRS Waste Management Capacity

The impact of spent nuclear fuel activities on SRS waste management capacities would be minimal because the Site could accommodate the waste with existing and planned radioactive waste storage and disposal facilities. DOE would transfer high-level waste to the F/H Tank Farms for volume reduction and then to the Defense Waste Processing Facility (DWPF) for conversion into a borosilicate glass form suitable for prolonged storage. The SRS would use the Consolidated Incineration Facility, once operational, to treat the low-level waste. This facility has sufficient permitted capacity [105,500 cubic meters (137,889 cubic yards) per year] to treat the anticipated volume of these materials. However, actual through-put volume is dependent upon operational variables and waste characteristics. The F/H Effluent Treatment Facility would treat liquid low-level waste. This facility has sufficient design process capacity [598 million liters (158 million gallons) per year] to treat the anticipated volumes of these materials. DOE would manage the transuranic wastes with existing and planned storage capacity.

5.15 Accident Analysis

Operations involving the receipt, handling, processing, or storing of spent nuclear fuel would involve radioactive materials or toxic chemicals. These materials would be received, treated, stored, transferred between facilities, disposed of on the Site, and shipped off the Site. Under certain circumstances, these materials could be involved in an accident.

An accident is a series of unexpected or undesirable events initiated by equipment failure, human error, or a natural phenomenon such as severe weather, earthquake, or volcanism. These events can cause the release of either radioactive or chemically toxic materials inside a facility or to the environment.

This section summarizes analyses of possible accidents involving spent nuclear fuel operations at the SRS. To provide a perspective on potential accidents, this section summarizes various accidents associated with spent nuclear fuel activities that have occurred at the SRS (historic accidents) and reviews previous accident analyses for Site operations. This section uses the results of previous analyses as a baseline for determining the impacts for the alternatives that involve new facilities. For each alternative, this section discusses the accidents with the largest point estimates of risk (radiological impacts in terms of potential fatal cancers x frequency of the initiating event).

The facilities considered for each alternative are either existing facilities for which the approved safety analyses were used, or new facilities (WSRC 1994b) for which existing safety analysis results were substituted by evaluating the type of accident(s) that could be postulated to occur based on the projected function of the facility. Two facilities that contain very small amounts of contact-handled spent nuclear fuel, Buildings 331-M and 773-A, were not included in this analysis because accidents analyzed for the major facilities would bound the consequences of possible accidents in these two locations.

This section addresses historic accidents, facility radiological accidents, chemical hazard accidents, and secondary impacts. Section 5.11 addresses onsite transportation accidents.

5.15.1 Historic Accidents at the Savannah River Site

Impacts from accidents can involve fatalities, injuries, or illness. Fatalities can be prompt (immediate) such as in construction accidents or latent (delayed) such as an increase in latent fatal cancers due to radiation exposure. Section 5.12 addresses worker injuries, illnesses, and the potential for increased cancer risk anticipated from normal operations of the facilities. Nonradiation accidents have dominated impacts to workers at the SRS (Durant et al. 1987); impacts to the public from historic SRS accidents have been negligible.

The SRS has maintained an operational event data base on its facilities since the 1950s. This data base currently contains approximately 450,000 entries including data on the Receiving Basin for Offsite Fuel, the principal wet storage pool facility at the SRS; and both F-and H-Area Canyons. For this EIS, DOE reviewed the data base to identify historic spent nuclear fuel-related accidents at these facilities. Fuel cutting events, fuel handling events, and various liquid releases related to spent nuclear fuel management over the 40-year operating history of the SRS were examined. The purpose of the data base review was to provide an historic perspective on the types of accidents that have occurred at the SRS. Events representative of fuel failures include higher than expected contamination levels in fuel storage basin water and evidence of fuel canister cracking at a weld. Fuel handling incidents were due in large part to crane operator errors or crane and handling equipment failures. The data base also includes reports of incorrect fuel cropping, where the active region of fuel was exposed under water. These historical events provided a basis for the selection of representative accidents covering the spectrum of spent nuclear fuel management activities. No significant offsite impacts have resulted from these historic occurrences.

5.15.2 Potential Facility Accidents

The SRS spent nuclear fuel alternatives have the potential for radiological accidents (see Attachment A, Table A-2) that could affect the health and safety of workers and the public. The concerns and characteristics that are common to these accidents would be common regardless of whether the cause were a natural phenomenon or human error. For health effects to occur, an accident must allow a release of hazardous material to, or an increase in radiation levels in, the facility or the environment. The released material must be transported to locations frequented by humans. The quantities of hazardous materials that reach locations where people are and the ways they interact with people are important factors in the determination of health effects.

A number of studies have investigated the ways in which radioactivity reaches humans, how the body absorbs and retains it, and the resulting health effects. The International Commission on Radiological Protection has made specific recommendations for estimating these health effects (ICRP 1991). This organization is the recognized body for establishing standards for the protection of workers and the public from the effects of radiation exposure. Health effects include acute damage (up to and including death) and latent effects, including cancers and genetic damage. An SRS-developed computer code, AXAIR89Q, estimates potential radiation doses to maximally exposed individuals or population groups from accidental releases of radionuclides.

The AXAIR89Q code is a highly automated site-specific environmental dispersion and dosimetry code for postulated airborne releases. The environmental dispersion models used are based on NRC Regulatory Guide 1.145 (NRC 1983). The exposure pathways considered in the AXAIR89Q code include inhalation of radionuclides and gamma irradiation from the radioactive plume.

Doses from the inhalation of radionuclides in air depend on the amount of radionuclides released; the dispersion factor; the physical, chemical, and radiological characteristics of the radionuclides; and various biological parameters such as breathing rate and biological half-life. The AXAIR89Q code uses a conservative breathing rate of 12,000 cubic meters (424,000 cubic feet) per year for adults. The dose commitment factors used in the environmental dosimetry code, as described in the following section, are from Internal Dose Conversion Factors for Calculation of Dose to the Public (DOE 1988).

External gamma radiation doses from the traveling plume depend on the spatial distribution of the radionuclides in the air, the energy of the radiation, and the extent of shielding. The AXAIR89Q code takes no credit for shielding in calculating doses. The code calculates gamma doses using a nonuniform Gaussian model, which has more realistic modeling than doses from the conventional uniform semi-infinite plume model.

In addition to using the worst sector, 99.5 percentile meteorology, conservative breathing rates, and taking no credit for shielding, the AXAIR89Q code also takes no credit for the probable plume rise from stack releases. Therefore, the offsite maximum individual doses calculated by AXAIR89Q provide conservative bounding estimates of radiological consequences to exposed individuals and populations from postulated accidental atmospheric releases.

AXAIR89Q has been validated for compliance to accepted standards for such software. Attachment A, Accident Analysis, discusses AXAIR89Q and its predecessor, AXAIR. When used in conjunction with models for predicting health effects, the results from AXAIR89Q can be compared with other site-specific codes such as RSAC-5, because both codes provide relative radionuclide concentrations based on the guidance provided in NRC Regulatory Guide 1.145.

This section summarizes the potential for radiological accidents and their consequences for the cases under each alternative. Attachment A describes the methodology and assumptions used in the assessment; describes radiological accident scenarios in more detail; provides source terms and references used to estimate the doses and impacts for each alternative and case; and includes scaling factors that the DOE decisionmaker can apply to the source term or dose for each facility associated with a case.

DOE assessed the potential impacts from a selected spectrum of radiological release accidents, ranging from low (1 x 10-6 event per year) to high (more than 1 event per year) frequencies of occurrence, along with the associated impacts (doses and potential latent fatal cancers) that could result. The accidents used as references are attributed to individual facilities based on their functions and processes (see Attachment A, Table A-3), not to specific cases or alternatives. This enables a comparison of alternatives depending on which facilities support a specific case or alternative. Figure 5-1 is a flowchart for the preparation of accident analysis information. No new analyses occurred because existing documentation adequately supports a quantitative or qualitative estimation of potential impacts, as required by the National Environmental Policy Act of 1969. The assessment of postulated radiological accidents associated with spent nuclear fuel at the SRS indicates that the highest point estimate of risk to the public within 80 kilometers (50 miles) of the Site would be 1.4 x 10-3 latent fatal cancer per year. The estimated dose to the same population from all causes, including natural background sources, would be about 19,000 person-rem per year (DOE 1990), which could cause about nine latent fatal cancers per year in the same population. For perspective, natural background radiation sources would result in approximately 6,000 times the risk associated with the largest consequence accident postulated in this EIS for the various spent nuclear fuel management alternatives.

DOE did not quantitatively analyze the potential health effects for SRS workers less than 100 meters (328 feet) from radiological accidents. Computer codes used to calculate radiological doses can experience potentially large errors as a source disperses throughout a building. However, DOE did carry out a qualitative evaluation of the potential radiological effects to SRS workers in the immediate vicinity of an accident related to spent fuel management. DOE estimates that the consequences of an accident for the most part would result in higher than normal radiation doses. However, no fatalities would occur except in the event of an inadvertent criticality in FB-Line, where up to four fatalities may result. This evaluation is discussed in more detail in Section A.2.6.2 of Attachment A.

5.15.2.1 Alternative 1 - No Action. This alternative identifies the minimum actions deemed necessary for continued safe and secure management of spent nuclear fuel at the SRS. As explained in Chapter 3, this is not a status quo condition. Spent nuclear fuel would be maintained close to defueling or current storage locations with minimal facility upgrade or equipment replacement. Only local transport would occur. SRS activities required to safely store spent nuclear fuel would continue. This alternative would require SRS to place corroded and pitted fuel elements in cans to minimize spread of material into the pool. DOE estimated potential radiological accident impacts that could occur under this alternative using existing DOE-approved safety analyses for the interim wet storage of Figure 5-1. Accident analysis process. spent nuclear fuel at SRS facilities. As indicated in Attachment A, Table A-3, the facilities required under this alternative would consist of existing facilities, including necessary upgrades to support safe interim wet storage. In addition, Attachment A, Table A-4, provides a reference accident spectrum associated with these facilities for this alternative. Attachment A, Table A-2, lists the references for the source terms considered in analyzing potential accidents under this alternative, as well as their estimated frequencies. Table 5-20 lists the accident scenario with the highest point estimates of risk to the general public. Table 5-21 compares the potential radiological accidents and health effects of the interim wet storage (Option 1) of spent nuclear fuel for the No Action alternative.

Table 5-20. Highest point estimates of risk among receptor groups (Option 1).

	Receptor Groups	
	Maximally Exposed Offsite Individual	Population to 80 kilometers
Overall Point Estimate of Risk[a]	1.6x10-7 (Fuel Assembly Breach)	1.4x10-3 (Fuel Assembly Breach)

a. Units of latent fatal cancers per year.

5.15.2.2 Alternative 2 - Decentralization. Accident assessments considered for this

alternative include those considered for the No Action alternative for wet storage (Option 2b) plus assessments for the dry storage (Option 2a) of spent nuclear fuel and for the processing of spent fuel (Option 2c). Option 2c (processing) assumes the use of existing facilities to dissolve, separate, and further stabilize spent nuclear fuel. For cases that include some treatment (e.g., canning) of spent nuclear fuel, such treatment is referred to as "stabilization," not processing. The amount of fuel of various types to be considered would include those quantities from the production reactors, existing research fuel, foreign research reactor fuel, and fuel transported for safety or research activities.

5.15.2.2.1 Option 2a - Dry Storage - DOE estimated potential radiological accident

impacts that could occur in this case using existing DOE-approved safety analysis reports submitted to DOE by Westinghouse Savannah River Company for vault storage of special nuclear material from existing facilities.

DOE has not incorporated the technology to support interim dry storage of spent nuclear fuel at the SRS. To provide a basis for evaluating the potential impacts from this alternative case, this assessment used data from existing safety analyses for special nuclear material storage facilities and extrapolated these data to apply to spent nuclear fuel. DOE also considered radiological accidents associated with wet storage, at least in the near term, because the spent nuclear fuel is currently in wet storage. Similarly, this assessment includes fuel handling accidents throughout the transition phase (i.e., until fuel is in interim dry storage). As indicated in Attachment A, Table A-4,

Table 5-21. Radioactive release accidents and health effects for spent nuclear fuel alternatives. ,b

			Potential Fatal Cancers				Point Estimate of Risk[c]			
Alternative (by case)	Accident Scenario	Frequency (per year)	Maximally exposed offsite individual[d]	Population to 80 kilometers[d]	Worker[e]	Colocated Worker[e]	Maximally exposed offsite individual	Population to 80 kilometers[f]	Worker	Colocated Worker

a. The safety analysis reports from which information was extracted for these accidents were written before the issuance of DOE Order 5480.23; previous Orders did not require the inclusion of workers.
b. The safety analysis reports from which information was extracted for these accidents were written before the issuance of DOE Order 5480.23; previous Orders did not require the inclusion of colocated workers.
c. Units for point estimates of risk are given in potential latent fatal cancers per year.
d. ICRP 60 risk factor for the general public (5.0 x 10-4 fatal cancer per year) was used to determine potential latent fatal cancers.
e. ICRP 60 risk factor for workers (4.0 x 10-4 fatal cancer per year) was used to determine potential latent fatal cancers.

the facilities required under this alternative would consist of existing and new facilities necessary to support the safe handling, stabilization, and dry storage of spent nuclear fuel. In addition, Table A-4 identifies a potential accident spectrum associated with these facilities for this case. Attachment A, Table A-2, lists the references for the source terms considered in analyzing potential accidents under this alternative case, as well as the estimated frequency of occurrence for each accident. Table 5-21 lists the potential radiological accidents and health effects associated with dry storage of spent nuclear fuel for the Decentralization alternative. For the transition period of wet to dry storage, Table 5-22 lists the accident scenario with the highest overall point estimate of risk to the general public.

Table 5-22 lists the accident scenario with the highest point estimate of risk (after transition) to the general public when the fuel had been moved from wet storage (after approximately 15 years) and **placed in interim dry storage.** This indicates a substantial reduction in risk (more than six orders of magnitude) when fuel handling events are no longer potential accident initiators.

Table 5-22. Highest point estimates of risk among receptor groups (Option 2a).

	Receptor Groups	
	Maximally Exposed Offsite Individual	Population to 80 kilometers
Overall Point Estimate of Riska	1.6x10-7 (Fuel Assembly Breach)	1.4x10-3 (Fuel Assembly Breach)
Transitioned to Dry Storage Point Estimate of Riska	1.5x10-12 (Dry Vault Material Release)	4.9x10-9 (Dry Vault Material Release)

a. Units of latent fatal cancers per year.

5.15.2.2.2 Option 2b - Wet Storage - DOE estimated potential radiological accident

impacts that could occur under this case using existing DOE-approved safety analysis reports and amendments submitted to DOE by Westinghouse Savannah River Company for existing wet storage facilities.

As indicated in Attachment A, Table A-4, the facilities (modules as defined in the WSRC 1994b and Figure 3-2) would consist of existing facilities and specific upgrades necessary to support safe interim wet storage. In addition, Table A-4 identifies the reference accident spectrum associated with these facilities for this option. Attachment A, Table A-2, lists the references for the source terms considered in analyzing potential accidents under this alternative option, as well as the estimated frequency of occurrence for each accident. Table 5-21 lists the radiological accidents and consequences of the wet storage (Option 2b) of spent nuclear fuel for the Decentralization alternative.

Table 5-23 lists the accident scenario with the highest point estimate of risk to the general public. For wet pool storage options, there are no transition phases.

Table 5-23. Highest point estimates of risk among receptor groups (Option 2b).

	Receptor Groups	
	Maximally Exposed Offsite Individual	Population to 80 kilometers
Overall Point Estimate of Risk[a]	1.6x10-7 (Fuel Assembly Breach)	1.4x10-3 (Fuel Assembly Breach)

a. Units of latent fatal cancers per year.

5.15.2.2.3 Option 2c - Processing and Storage - Processing for the SRS is defined

as the operation of the separations facilities in F- or H-Areas. The H-Area facilities were designed to recover uranium and plutonium from spent production reactor fuel, and the F-Area facilities were designed to recover plutonium.

DOE estimated potential radiological accident impacts that could occur under this option using existing DOE-approved safety analysis reports submitted to DOE by Westinghouse Savannah River Company for processes and for vault storage of special nuclear material from existing facilities. DOE also considered radiological accidents associated with wet storage, because the spent nuclear fuel is currently in wet storage. Similarly, it included fuel handling accidents throughout the processing phase (i.e., until special nuclear material is in interim dry storage). As indicated in Attachment A, Table A-4, the facilities required under this option would consist of existing and new facilities necessary to support safe handling and processing of spent nuclear fuel into special nuclear material for dry storage. In addition, Table A-4 identifies the reference accident spectrum associated with these facilities for this case. Attachment A, Table A-2, lists the references for the source terms considered in analyzing potential accidents under this alternative case, as well as the estimated frequency of occurrence for each accident. Table 5-21 lists the radiological release accidents and health effects for the processing of spent nuclear fuel to special nuclear material for the Decentralization alternative.

Table 5-24 lists the accident scenario with the highest overall point estimate of risk to the general **public from the transition period of wet spent fuel storage into processing for special nuclear material.**

When the fuel had been processed from wet storage to special nuclear material and placed in its interim dry storage, Table 5-24 lists the accident scenario with the highest point estimate of risk after transition to the general public. This indicates a substantial reduction in risk (more than six orders of magnitude) when fuel handling events and processing events are no longer potential accident initiators.

Table 5-24. Highest point estimates of risk among receptor groups (Option 2c).

	Receptor Groups	
	Maximally Exposed Offsite Individual	Population to 80 kilometers
Overall Point Estimate of Risk[a]	1.6x10-7 (Fuel Assembly Breach)	1.4x10-3 (Fuel Assembly Breach)
Transitioned to Dry Storage Point Estimate of Risk[a]	1.5x10-12 (Dry Vault Material Release)	4.9x10-9 (Dry Vault Material Release)

a. Units of latent fatal cancers per year.

For this option, DOE assumes it could not process some fuel clad in stainless steel or zirconium into special nuclear material and, therefore, would dry-store it as fuel. The technology for dry storage of nonaluminum-clad fuel has been demonstrated and is assumed to pose no greater risk than monitored dry storage of special nuclear material.

5.15.2.3 Alternative 3 - 1992/1993 Planning Basis. Because this alternative would be

consistent with the status quo at the SRS, existing documents contain sufficient information to examine its accident analysis impacts. The SRS would continue to receive the spent nuclear fuel designated for the Site, and DOE would complete facilities already planned to accommodate the existing inventory and the spent nuclear fuel receipts. This alternative would require the same facilities already used to support the cases discussed in the Section 5.15.2.2. The major difference would be the amount of fuel ultimately stored because this alternative assumes the continued receipt of fuel beyond that shipped to the SRS under the Decentralization alternative.

5.15.2.3.1 Option 3a - Dry Storage - DOE estimated potential radiological accident

impacts that could occur under this case using existing DOE-approved safety analysis reports for vault storage from existing facilities and the study discussed for Option 2a. DOE also considered radiological accidents associated with wet storage, at least in the near term, because the spent nuclear fuel is currently in wet storage. Similarly, it included fuel handling accidents throughout the transition phase (i.e., until the fuel is in interim dry storage). As indicated in Attachment A, Table A-4, the facilities required under this option would consist of existing and new facilities necessary to support the safe handling and stabilization of spent nuclear fuel for dry storage. In addition, Table A-4 identifies the reference accident spectrum associated with these facilities for this case. Attachment A, Table A-2, lists the authorization basis references for the source terms considered in analyzing potential accidents under this option, as well as the estimated frequency of occurrence for each accident. Table 5-21 lists the radiological release accidents and health effects for the dry storage of spent nuclear fuel for the 1992/1993 Planning Basis alternative. For the entire period, the accident scenarios with the highest point estimates of risk to the general public would be the same as those for Option 2a, as listed in Table 5-22.

5.15.2.3.2 Option 3b - Wet Storage - DOE estimated potential radiological accident

impacts that could occur under this case using existing DOE-approved safety analysis reports and from amendments submitted to DOE by Westinghouse Savannah River Company for wet storage for existing facilities. As indicated in Attachment A, Table A-4, the facilities required under this option would consist of existing facilities and upgrades necessary to support safe interim wet storage. In addition, Table A-4 identifies the reference accident spectrum associated with these facilities for this option. Attachment A, Table A-2, lists the references for the source terms considered in analyzing potential accidents under this option, as well as the estimated frequency of occurrence for each accident. Table 5-21 lists the radiological release accidents and health effects of the wet storage (Option 3b) of spent nuclear fuel for the 1992/1993 Planning Basis alternative. The accident scenario with the highest point estimate of risk to the general public would be the same as that for Option 2b, as listed in Table 5-23.

5.15.2.3.3 Option 3c - Processing and Storage.

Table 5-21 lists the radioactive **release accidents and health effects for the processing of spent nuclear fuel for this option.** After processing is complete, the accident scenario with the highest point estimate of risk would be associated with the storage of special nuclear materials, as discussed for Option 2c and listed in

Table 5-24.

5.15.2.4 Alternative 4 - Regionalization. This alternative comprises Regionalization A and

Regionalization B subalternatives. Under the Regionalization A subalternative (Options 4a, 4b, and 4c), the SRS would receive all aluminum-clad fuel from the other sites considered in this EIS and would transfer its existing inventory of stainless steel- and Zircaloy-clad fuel to other DOE sites, as appropriate. These proposed activities would reflect current and past activities, so sufficient information and analyses are available to enable the scaling or other extrapolation of radiological accident impacts. The total amount of spent nuclear fuel to be managed under Regionalization A would be slightly less than that for Alternatives 2 and 3; the decisionmaker could use this amount to adjust the estimated point estimate of risk by the use of an appropriate adjustment (scaling) factor, as discussed in Attachment A, Section A.2.9.

Under the Regionalization B subalternative (Options 4d, 4e, 4f, and 4g), the SRS would receive all existing and new spent nuclear fuel east of the Mississippi River. The decisionmaker could use the change in spent nuclear fuel inventories to adjust the estimated point estimate of risk by the use of an appropriate adjustment (scaling) factor, as discussed in Attachment A, Section A.2.9. For the purposes of this evaluation, Option 4g (Section 5.15.2.4.7) assumes that DOE would ship all fuel off the Site to the Oak Ridge Reservation.

5.15.2.4.1 Option 4a - Dry Storage - This case is similar to Option 2a, with the

exception of the quantity and type of fuel to be stored. As with Option 2a, this assessment evaluated existing analyses; the point estimates of risk are the same as those for Option 2a.

5.15.2.4.2 Option 4b - Wet Storage - This case is similar to Option 2b, with the

exception of a slightly smaller quantity of fuel to be stored. As with Option 2b, this assessment evaluated existing analyses, and the point estimates of risk are the same as those for Option 2b.

5.15.2.4.3 Option 4c - Processing and Storage - For this option, the accident

analysis evaluation is similar to Option 2c. DOE assumes that it could process spent nuclear fuel associated with regionalization at SRS with existing facilities, because they are designed to process aluminum-clad fuel. However, the small amount of aluminum-clad fuel received after major processing options are completed would be placed in wet storage.

5.15.2.4.4 Option 4d - Dry Storage - The accident analysis evaluation for this option

is similar to that for Option 2a, with the exception of the increased inventories and types of fuel to be stored.

5.15.2.4.5 Option 4e - Wet Storage - The accident analysis evaluation for this option

is similar to that for Option 2b, with the exception of the increased inventories and types of fuel to be stored.

5.15.2.4.6 Option 4f - Processing and Storage - For this option, the accident

analysis evaluation is similar to Option 2c. DOE assumes that it could process all the current SRS aluminum-clad spent nuclear fuel with existing facilities. However, all receipts of spent nuclear fuel will be placed in dry storage as discussed for Option 4d.

5.15.2.4.7 Option 4g - Shipping Off Site - This option assumes that DOE would

characterize the fuel and ship it all off the Site. Thus, the potential radiological accidents considered are the same as those for Alternative 1.

5.15.2.5 Alternative 5 - Centralization. This alternative for the SRS would involve fuel

types and new facilities beyond those considered for any other alternative. For instance, under this alternative, the SRS would receive spent nuclear fuel from the U.S. Navy. One of the new facilities that would be necessary to support this type of spent nuclear fuel is the Expended Core Facility (ECF). Volume 1, Appendix D, includes a detailed accident analyses for this proposed facility using SRS-specific parameters.

This alternative would bound the maximum number of spent nuclear fuel-related accident scenarios that DOE could expect at the SRS, due to the number of new facilities at the Site that would have to accommodate the diversity and the increased amount of the fuel to be managed. The decisionmaker could use this maximum amount of spent nuclear fuel to adjust the estimated risk by the use of an appropriate scaling factor, as discussed in Attachment A, Section A.2.9. For the purposes of this evaluation, Option 5d (Section 5.15.2.5.4) assumes that DOE would ship all fuel off the Site to another DOE facility.

5.15.2.5.1 Option 5a - Dry Storage - The major difference in dry storage facilities

between this alternative and the others would be the addition of a facility for Naval spent nuclear fuels and the large quantity of spent fuel shipped to the SRS from the Hanford Site. DOE estimated potential radiological accident impacts that could occur under this option using DOE-approved safety analysis reports submitted to DOE by Westinghouse Savannah River Company for vault storage in existing facilities at the SRS and the study discussed for Option 2a. In addition, DOE considered radiological accidents associated with wet storage, at least in the near term, because the SRS spent nuclear fuel is currently in wet storage. Similarly, it included fuel handling accidents throughout the transition phase (i.e., until fuel is in interim dry storage). As indicated in Attachment A, Table A-4, the facilities required under this option would consist of existing and new facilities necessary to support the safe handling and stabilization of spent nuclear fuel for dry storage. In addition, Table A-4 identifies the reference accident spectrum associated with these facilities for this case. Attachment A, Table A-2, lists the references for the source terms considered in analyzing potential accidents under this option, as well as the estimated frequency of occurrence for each accident. Table 5-21 compares the radiological release accidents and health effects for the dry storage of spent **nuclear fuel for the Centralization alternative.** From the transition period of wet to dry storage, the accident scenario with the highest point estimate of risk to the general public would be the same as that for Option 2a, as listed in Table 5-22. When the fuel had been moved from wet storage (after approximately 25 years) and placed in interim dry storage, the accident scenario with the highest point estimate of risk to the population would be the same as the Option 2a dry storage phase.

5.15.2.5.2 Option 5b - Wet Storage - The accident analysis evaluation for this option

is similar to that for Option 2b, with the exception of the amount and type of fuel to be stored.

5.15.2.5.3 Option 5c - Processing and Storage - For this option, the accident

analysis evaluation is similar to Option 2c. DOE assumes that it could process the current SRS aluminum-clad spent nuclear fuel with existing facilities. However, the SRS would place all receipts of fuel in dry storage, as discussed for Option 5a.

5.15.2.5.4 Option 5d - Shipping Off Site - This option assumes that DOE would

perform the characterization of the fuel at the SRS, and then would ship all fuel off the Site. Thus, the potential radiological accidents considered are the same as those for the No Action alternative.

5.15.3 Chemical Hazard Evaluation

For toxic chemicals, several government agencies recommend the quantification of health effects as threshold values of concentrations in air or water that cause short-term effects. The long-term health consequences of human exposure to toxic chemicals are not as well understood as those for radiation. Thus, the potential health effects from toxic chemicals are more subjective than those from radioactive materials.

This section provides a quantitative discussion for an analyzed chemical accident at the Receiving Basin for Offsite Fuel facility and qualitative discussions addressing chemical hazards for each of the other existing SRS facilities involved in the receipt, processing, transport, or storage of spent nuclear fuel.

5.15.3.1 Receiving Basin for Offsite Fuel. The maximum reasonably foreseeable chemical

hazard accident for the Receiving Basin for Offsite Fuel would involve the release of nitrogen dioxide vapor following the complete reaction of a drum of target cleaning solution (13.4 percent nitric acid) with sodium nitrite (WSRC 1993b). The initiator for this accident is a leak from a storage tank into the target cleaning solution and involves multiple failures or maloperations with an accident probability comparable to that of a natural phenomena accident. Table 5-25 shows the concentration of nitrogen dioxide vapor that an individual at the SRS boundary and a maximally exposed colocated worker could receive.

Table 5-25. Results of analyzed chemical accident.

Receptor Group	Frequency (per year)	NO2 Concentration (mg/m3)
Maximally Exposed Offsite Individual	1.0 x 10-3	0.083
Colocated Worker	1.0 x 10-3	0.64

To determine the potential health effects from this bounding chemical accident scenario, this assessment was to compare the resulting airborne concentrations of nitrogen dioxide at various receptor distances against Emergency Response Planning Guideline (ERPG) values, where available. Because there were no ERPG values available for nitrogen dioxide, the assessment substituted other chemical toxicity values as follows:

- For Emergency Response Planning Guideline 1, the assessment substituted threshold limit values/time-weighted average (TLV/TWA) values (ACGIH 1987). The time-weighted average is the average concentration for a normal 8-hour workday and a 40-hour workweek from which nearly all workers could receive repeated exposure, day-after-day, without adverse effect.
- For Emergency Response Planning Guideline 2, the assessment substituted level of concern (LOC) values [equal to 0.1 of the immediately dangerous to life or health (IDLH) value; - see below]. The level of concern value is the concentration of a hazardous substance in the air above which there could be serious irreversible health effects or death as a result of a single exposure for a relatively short period of time (EPA 1987).
- For Emergency Response Planning Guideline 3, the assessment substituted immediately dangerous to life or health values. This value is the maximum concentration from which a person could escape within 30 minutes without a respirator and without experiencing any impairment of escape or irreversible side effects (NIOSH 1990).

These values as they apply to nitrogen dioxide are as follows:

- Time-weighted average value = 5.6 milligrams per cubic meter
- Level of concern value = 9.4 milligrams per cubic meter
- Immediately dangerous to life or health value = 94.0 milligrams per cubic meter

5.15.3.2 Reactor Basins. There are no postulated chemical accidents for the reactor basins that would cause an impact to an individual at the SRS boundary or a colocated worker.

5.15.3.3 H-Area. There are no postulated chemical accidents for the H-Area Canyon that would cause an impact to an individual at the SRS boundary or a colocated worker. DOE has performed an accident analysis for the H-Area Canyon facility workers that indicates the existence of potential injuries due to chemical contamination or exposure to hazardous vapors at or above the level of concern exposure limit (Du Pont 1983a). The analysis does not project exposure to hazardous vapors at or above the immediate danger to life and health level to occur.

The probability that a worker could be accidentally exposed to any of the hazardous liquids identified in Attachment A, Table A-14, is bounded by a frequency of 2.8 x 100 per year (Du Pont 1983a). The most likely injury is an acid burn to the skin.

The probability for exposure to hazardous vapors at or above the level of concern exposure limit is 8.5 x 10-1 per year (Du Pont 1983a). The potential for chemical uptakes and for illness would depend on the safety measures taken before the exposure, the duration of the exposure, and the mitigating actions taken after the exposure.

5.15.3.4 F-Area. There are no postulated chemical accidents for the F-Area Canyon that would cause an impact to an individual at the SRS boundary or a colocated worker. DOE has performed an accident analysis for the F-Area Canyon facility workers that indicates the existence of potential injuries due to chemical contamination or exposure to hazardous vapors at or above the level of concern exposure limit (Du Pont 1983b). The analysis does not project exposure to hazardous vapors at or above the immediate danger to life and health level to occur.

The probability that a worker could be accidentally exposed to any one of the hazardous liquids identified in Attachment A, Table A-15, is bounded by a frequency of 1.2 x 100 per year (Du Pont 1983b). The most likely injury is an acid burn to the skin.

The probability for exposure to hazardous vapors at or above the level of concern exposure limit is 3.2 x 10-1 per year (Du Pont 1983b). The potential for chemical uptakes and for illness would depend on the safety measures taken before the exposure, the duration of the exposure, and the mitigating actions taken after the exposure.

5.15.4 Secondary Impacts

The primary focus of the accident analysis is to determine the magnitude of the consequences of postulated accident scenarios on public and worker health and safety. However, DOE recognizes that chemical and radiological accidents can also adversely affect the surrounding environment (i.e., secondary impacts). Accordingly, DOE has qualitatively evaluated each of the eight radiological accident scenarios considered in this analysis for potential secondary impacts. The following paragraphs discuss the results of the evaluation, and Table 5-26 summarizes expected secondary impacts for each accident scenario.

5.15.4.1 Biotic Resources. With the exception of a direct discharge of disassembly basin water to an onsite stream, DOE does not expect radiological contamination resulting from any of the analyzed accidents to reach any onsite or offsite surface water. DOE previously evaluated the case of a direct discharge of disassembly basin water (DOE 1990) and believes that impacts on biotic resources would be minor. Therefore, the impacts on aquatic biota from any of the accident scenarios would be minor. Small areas of minor surface contamination likely would be outside the industrialized area of a postulated accident. Terrestrial biota in or near the contaminated area would be exposed to small quantities of radioactive materials and ionizing radiation until the affected area could be decontaminated. DOE believes that the impacts on biotic resources from this exposure would be minor.

5.15.4.2 Water Resources. DOE expects no adverse impacts on water quality from any of the postulated accident scenarios. Accident A7 (External Spill/Liquid Discharge) would be expected to have the most significant impact. With the exception of the reactor disassembly basins, the location and configuration of existing or potential facilities would prevent a direct release of radionuclide-contaminated water to surface water. However, contamination of the surface aquifer in the area of the release would be likely. The processes governing the slow plume movement and attenuation of contaminants described in Section 5.8 would prevent the contamination from reaching surface- or groundwater resources. Similarly, radionuclide contamination of onsite or offsite drinking

Table 5-26. Qualitative summary of expected secondary impacts.

		Environmental or social factor							
Accident Scenario	Accident Description	Biotic Resources	Water Resources	Endangered Species	Land Use	Economic Impacts	National Defense	Environmental Contamination	Treaty Rights
A1	Fuel assembly breach	No adverse effects on biota expected.	No adverse effects expected to surface or groundwater resources.	No impacts expected. No irreversible impacts.	No change expected.	Limited economic impacts are expected. Any required cleanup could be handled with existing workforce.	No effect.	Local contamination expected around site of the accident. Minor contamination outside the immediate facility area unlikely to require cleanup of more than 10 acres.	No impact to Native American or public lands expected.
A2	Material release (processing)	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.
A3	Material release (dry vault)	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.
A4	Material release (adjacent facility)	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.
A5	Criticality in water	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.
A6	Criticality	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.

	during processing								
A7	External spill/liquid discharge	Same as A1.	Surface-water table contamination expected in area of the release. No adverse effects expected to surface-water or drinking water aquifers.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.	Same as A1.
A8	Internal spill/liquid discharge	Same as A1.	No adverse impact to water resources. The spill is expected to be contained entirely within the building structure.	Same as A1.	Same as A1.	Limited contamination is expected outside the effected building.	Same as A1.	Same as A1.	Same as A1.

water sources would be unlikely. DOE evaluated the effects of a direct discharge of disassembly basin water on water resources (DOE 1990) and believes that impacts on water resources would be minimal.

5.15.4.3 Economic Impacts. DOE expects limited economic impacts as a result of any of the postulated accidents. Any cleanup required would be localized, and the existing workforce and equipment could perform it. Contamination should be contained within a small area inside the SRS boundaries for all eight postulated accident scenarios. The existing workforce could accomplish any required cleanup.

5.15.4.4 National Defense. None of the postulated accidents would affect the DOE national defense mission. Spent nuclear fuel management activities do not involve the production of materials needed for national defense.

5.15.4.5 Environmental Contamination. DOE expects that none of the postulated accident scenarios would result in large areas of contamination. Local contamination is likely around the site of an accident, but in all scenarios should be contained within the SRS boundaries. Minor contamination outside the immediate area of the accident is unlikely to require cleanup of more than a small area inside the Site boundary. Impacts in all cases should be minimal.

5.15.4.6 Endangered Species. There are no Federally listed threatened or endangered species habitats in the immediate vicinity of existing or potential spent nuclear fuel storage or processing facilities (see Section 4.9.4). None of the postulated accident scenarios would likely result in large areas of surface contamination outside the immediate facilities, and DOE does not expect adverse impacts to surface water. Therefore, none of the postulated accident scenarios is likely to impact threatened or endangered species.

5.15.4.7 Land Use. No accident scenario should result in large areas of contamination, nor would the impacts be irreversible. DOE expects no change in land use.

5.15.4.8 Treaty Rights. The environmental impacts of each of the accident scenarios should be contained within the SRS boundaries. Because there are no Native American or public lands within the site boundaries, treaty rights would not be affected.

5.15.5 Adjusted Point Estimate of Risk Summary

The accident scenarios described in Section 5.15.2 differ only slightly between the various alternatives. These scenarios did not account for variations in spent nuclear fuel shipments (including onsite operational transfers) and spent fuel storage inventories across the alternatives. To provide a realistic comparison across alternatives, DOE developed adjustment factors to adjust frequencies or consequences, depending on the specific circumstance of each alternative. Attachment A, Section A.2.9, provides the methodology and justifications used to develop appropriate adjustment factors. This section provides the adjusted point estimates of risk for each accident scenario by receptor group to demonstrate a relative comparison of each alternative on a case-by-case basis. Tables 5-27, 5-28, and 5-29 summarize the adjusted point estimates of risk for each alternative for the maximally exposed individual, the general population to 80 kilometers, and the colocated worker.

5.16 Cumulative Impacts

The Savannah River Site (SRS) contains major U.S. Department of Energy (DOE) and non-DOE facilities, unrelated to spent nuclear fuel, that would continue to operate throughout the life of the spent nuclear fuel management program. The activities associated with these existing facilities produce environmental consequences that this document has included in the baseline environmental conditions (Chapter 4) against which it assesses the consequences of the spent nuclear fuel alternatives. Impacts of both the construction and operation of SRS spent nuclear fuel facilities would be cumulative with the impacts of existing and planned facilities unrelated to spent nuclear fuel.

This cumulative impact assessment considered the incremental and synergistic effects of the operation of the Defense Waste Processing Facility, which is nearing completion, and the Consolidated Incineration Facility, which is under construction, when appropriate and when data existed. For example, the Air Quality analysis factored in emissions from these two facilities when considering potential impacts of operations of spent nuclear fuel facilities. The small volumes of liquid effluent (treated sanitary wastes) currently entering the environment from the Defense Waste Processing Facility, on the other hand, were considered part of the Water Quality baseline. The only major stand alone facilities scheduled to be built in the near future on the SRS are the Savannah River Ecology Laboratory Conference Center and the new Centralized Sanitary Wastewater Treatment Facility. A number of other planned facilities have not been factored into the cumulative impacts analysis because final funding approval has not been received or because decisions on these facilities involve major

Table 5-27. Adjusted point estimates of risk for the maximally exposed offsite individual (radiological accidents).

		No Action	Decentralization			92/93 Planning Basis			Regionalization - A			Centralization

a. Units for adjusted health effects are given in terms of potential fatal cancers.

b. Units for adjusted point estimates of risk are given in terms of potential fatal cancers per year.

c. The accident scenario is not included in the spectrum of potential accidents for this case.

d. Adjustment factors were calculated using March 1994 data and information. In-process revisions to these data and information should not result in changes to these factors by more than 10 percent.

Table 5-28. Adjusted point estimates of risk for the colocated worker (radiological accidents).

a. Units for adjusted health effects are given in terms of potential fatal cancers.
b. Units for adjusted point estimates of risk are given in terms of potential fatal cancers per year.
c. The accident scenario is not included in the spectrum of potential accidents for this case.
d. The safety analyses from which information was extracted for these accidents were written before issuance of DOE Order 5480.23; previous Orders did not require the inclusion of colocated workers.

Table 5-29. Adjusted point estimates of risk for the general population - 80 kilometers (radiological accidents).

c. The accident scenario is not included in the spectrum of potential accidents for this case.

unresolved DOE policy issues. For example, this cumulative impact assessment does not consider long-term reconfiguration issues. Table 5-30 presents a summary of cumulative impacts associated with the various spent fuel management alternatives.

5.16.1 Land Use

The land committed to spent nuclear fuel management activities at the SRS would lie, for the most part, within existing onsite industrial compounds or undeveloped onsite areas devoted to the continued mission of the Site. Under two of the alternatives - Regionalization by Location (at SRS) and Centralization (at SRS) - a new Expended Core Facility could be required to examine and characterize spent nuclear fuels from naval installations east of the Mississippi. Two locations have been proposed for the Expended Core Facility, one in the approximate center of the SRS and the other at the old Allied General Nuclear Services facility (or "Barnwell Nuclear Fuel Plant") that is located off Road G (and near SRS Barricade 4) just east of and adjacent to the Site.

Previously-undeveloped land committed to new spent nuclear fuel facilities (excluding the Expended Core Facility) would be limited to a maximum of approximately 100 acres (0.4 square kilometer). Depending on the location chosen, an additional 30 acres (0.1 square kilometer) could be required for a new Expended Core Facility. Thus, a maximum of 130 acres (0.5 square kilometer) could be converted from woodlands or old fields to industrial facilities and supporting infrastructure under the bounding options, Option 5a (Centralization - Dry Storage) and Option 5c (Centralization - Processing). Any site used for the support of spent nuclear fuel activities would be under government control. With the exception of the Barnwell Nuclear Fuel facility, which the Navy would purchase from Allied General Nuclear Services for an offsite Expended Core Facility, DOE would not require any additional land from the public domain for SRS spent nuclear fuel management facilities.

Ground was broken for the new Savannah River Ecology Laboratory Conference Center in May 1994. The new facility will occupy a 70-acre area, but only 5 to 10 acres will be cleared and graded for the new conference center, parking areas, and an access road. The remaining 60-65 acres will be managed as a nature study area and preserve. Thus, the Savannah River Ecology Laboratory Conference Center will require conversion of 5 to 10 acres of planted pines or pine/mixed hardwood (depending on the exact location of the building) to light-industrial/public use.

Table 5-30. Cumulative impacts associated with construction and operation of spent fuel alternatives at Savannah River Site.

ALTERNATIVE 1 - NO ACTION

	Option 1 Wet Storage
Land Use	No new land committed to new use.
Socioeconomics	A maximum of 50 new jobs created annually during construction; no new jobs created during operation.
Air Resources	Site emissions would not exceed any air quality standard. Table 5-31 lists cumulative Site nonradioactive releases at the SRS boundary.
Occupational and Public Health and Safety	Radioactive airborne releases, expressed as cumulative dose to a maximally exposed individual at the Site boundary, would be 9.0x10-5 rem.
Materials and Waste Management	High-Level: Current generation levels Transuranic: Current generation levels Low-Level: Current generation levels Mixed: Current generation levels Hazardous: Current generation levels Sanitary: Current generation levels

ALTERNATIVE 2 - DECENTRALIZATION

	Option 2a Dry Storage	Option 2b Wet Storage	Option 2c Processing
Land Use	Small amount of land (<10 acres) committed to new use.	Small amount of land (<10 acres) committed to new use.	Small amount of land (<10 acres) committed to new use.
Socioeconomics	Construction jobs: 600 peak Operation: No new jobs	Construction jobs: 600 peak Operation: No new jobs	Construction jobs: 550 peak Operation: No new jobs
Air Resources	Site emissions would not exceed any air quality standard. Table 5-31 lists cumulative Site nonradioactive releases at the SRS boundary. a. Not expected to change; no analysis conducted.
b. Not expected to change; based on projected employment levels at SRS.

Construction on the new Centralized Sanitary Wastewater Treatment Facility is scheduled to begin in 1994 and should be completed in 1995. This new facility will be built approximately 1 mile south of F-Area on Burma Road. Building the central facility will require clearing approximately 6 acres of planted pines. An 18 mile trunkline/collection system will also be required, using existing transmission line and steam line rights-of-way to the extent possible. This trunkline will be located in the northwest quadrant of the SRS, and will connect the new Centralized Sanitary Wastewater Treatment Facility to A-Area, F-/H-Areas, and C-Area.

Depending on the spent nuclear fuel management alternative chosen, a total of 150 acres of SRS land could be cleared and converted to facilities and infrastructure as a result of spent nuclear fuel management (including an Expended Core Facility), construction of the Savannah River Ecology Laboratory Conference Center, and completion of the Centralized Sanitary Wastewater Treatment Facility. This represents less than 0.1 percent of the undeveloped land on the SRS, and will have minimal cumulative impact on long-term land use locally and regionally.

5.16.2 Socioeconomics

There would be minimal cumulative impacts on the socioeconomic resources of the SRS region from any spent fuel management alternative. The greatest change in employment would occur under the Centralization Alternative, which would include construction and operation of an Expended Core Facility at SRS. Construction of an Expended Core Facility would require an estimated 850 additional employees in the peak year (1999), while operation of the facility would add a maximum of approximately 500 full-time jobs. DOE anticipates that overall employment on the Site will decline during the first 5 years of the spent fuel management period and will stabilize thereafter as the SRS mission changes. Workers who might otherwise lose their jobs could be employed by SRS in spent fuel program activities. Therefore, DOE expects little or no direct increase in employment due to the program. The Site would fill any new jobs from the existing regional labor force.

5.16.3 Air Quality

Table 5-31 compares the cumulative emissions of nonradioactive pollutants from the SRS, including those from the proposed spent nuclear fuel alternatives, to the pertinent regulatory standards. The values provided are the maximum concentrations that would occur at ground level at the Site boundary. Not all maximum concentrations would occur at the same location.

Table 5-31. Total maximum ground-level concentrations (yg/cubic meter) of criteria and toxic air pollutants at SRS boundary resulting from normal operations and spent nuclear fuel management alternatives. ,b

a. Source: WSRC (1994a).
b. Numbers in parentheses indicate the percentage of the regulatory standard that each concentration represents.
c. No standard for this chemical.
d. Measurement data currently unavailable.

The data demonstrate that, even with the emissions from the spent nuclear fuel management activities, releases of toxic air pollutants from the SRS would be only a small fraction of the regulatory standards. Therefore, DOE anticipates no cumulative impact.

The releases of some criteria air pollutants by SRS operations would approach regulatory standards. Site sulfur dioxide emissions would reach about 50 percent of both the 24-hour and 3-hour limits under all alternatives. In addition, the emissions of particulates less than 10 microns (PM10) would approach a concentration equal to about 38 percent of the standard. However, the contribution to both these pollutants concentrations made by spent nuclear fuel-related activities would be small, as explained in Section 5.7.

The SRS evaluated the cumulative impact of airborne radioactive releases in terms of cumulative dose to a maximally exposed individual at the Site boundary. Table 5-32 lists the results of this

Table 5-32. Annual cumulative health effects to workers and offsite population due to SRS radioactive releases during incident-free operations.

b. Probability of fatal cancer.
c. Dose in person-rem.
d. Incidence of excess fatal cancers.

analysis. The highest dose would be 4.7x10-1 millirem, which would occur under the processing options of Alternatives 4 and 5. This dose is below the regulatory standard (CFR 1994) of 10 millirem.

Airborne emissions from the two-unit Vogtle Electric Generating Plant (approximately 10 miles southwest of the center of the SRS near Waynesboro, Georgia) were reported to have delivered an MEI total body dose of 1.14 x 10-3 millirem during 1992 (Georgia Power Company 1993). Since the SRS and Plant Vogtle are essentially proximal to the same 80 kilometer population, the ratio of SRS population and MEI doses was used as an estimator of the population dose due to Plant Vogtle emissions. Using this approach, the population dose attributable to Vogtle was estimated to have been about 8.3 x 10-2 person-rem in 1992. Adding (1) the population dose from Plant Vogtle, (2) the total collective offsite population dose from all SRS activities in 1992 (both air and water source terms), and (3) the highest projected collective dose from spent nuclear fuel management activities (Options 4c and 5c) yields a total cumulative dose of 27.083 person-rem from all SRS sources and Plant Vogtle, which is only 0.3 percent higher than the dose from SRS alone. Note that the doses in Table 5-32 ("Total Collective Dose, Offsite Population") represent the sum of (2) and (3) above.

5.16.4 Water Resources

Approximately 82.1 million gallons per year of Savannah River water would be required for the two most water-intensive options, Option 4f (Regionalization at SRS - Processing) and Option 5c (Centralization - Processing). Because either of these options would probably require construction of an Expended Core Facility, this facility's projected surface water usage of 2.5 million gallons per year was factored into the cumulative impacts analysis. Thus, the two options with the highest surface water usage, both of which would require as much as 84.6 million gallons, represent approximately 0.4 percent of the current (baseline) SRS surface water usage of 20 billion gallons per year (see Table 5-8).

Operational impacts to surface water quality under any of the spent nuclear fuel management options examined would be minimal. Existing SRS treatment facilities could accommodate all new spent nuclear fuel-related domestic and process wastewater streams. Expected wastewater flows would be well within the design capacities of existing (or planned upgrades of) Site treatment systems. Sanitary wastewater from new spent nuclear fuel facilities would be routed to the new Centralized Sanitary Wastewater Treatment Facility. Liquid radioactive wastes would presumably be sent to the F-/H-Area Effluent Treatment Facility. Treated nonradioactive liquid releases from the new spent nuclear fuel facilities would likely be discharged to Upper Three Runs Creek or Fourmile Branch.

Water quality in the Savannah River downstream of the SRS is adequate to good, with most parameters analyzed showing values below state and Federal Maximum Contaminant Levels or DOE Derived Concentration Guides. Iron, present in soils in the region, is the only constituent of surface waters that routinely exceeds MCLs. Spent nuclear fuel management activities are not expected to result in higher concentrations of iron downstream of the SRS. As noted earlier, in Section 5.16, construction on the new Centralized Sanitary Wastewater Treatment Facility is scheduled to begin in 1994 and should be completed in 1995. The new Centralized Sanitary Wastewater Treatment Facility will replace 14 aging sanitary wastewater facilities with a single state-of-the-art facility which will treat sanitary wastes by an extended aeration-activated sludge process. Chlorine will not be used to treat sanitary wastes in the new facility. Use of non-chemical ultraviolet light disinfection systems will eliminate the use and handling of 32,000 gallons of sodium hypochlorite and 59,000 gallons of sodium sulfite per year. Eliminating these chemicals will essentially eliminate the potential for toxic chemical releases from the wastewater treatment process.

Operation of the new Centralized Sanitary Wastewater Treatment Facility and closure of the old A-, B-, S-Area, and Naval Fuel sanitary wastewater facilities would also eliminate wastewater discharges to Upper Three Runs Creek, the stream on the SRS least degraded by past operations. Treated effluent from the new Centralized Sanitary Wastewater Treatment Facility will discharge to Fourmile Branch. Overall stream quality in Fourmile Branch is expected to improve because the effluent from the new facility will be cleaner than the effluent from the old package plants in C-, F-, and H-Areas that presently discharge to Fourmile Branch. As a result, the cumulative effect of the new spent nuclear fuel management facilities (any alternative considered) and new Centralized Sanitary Wastewater Treatment Facility will probably be a net improvement in water quality in two SRS streams, Upper Three Runs Creek and Fourmile Branch, and may result in better water quality downstream in the Savannah River as well.

Sanitary wastewater from the new Consolidated Incineration Facility will be routed to the new Centralized Sanitary Wastewater Treatment Facility; there will be no direct process wastewater drains to the environment. Liquid wastes will be collected in storage tanks and periodically trucked to a permitted hazardous/mixed waste treatment and disposal facility. Sanitary wastes from the new Savannah River Ecology Laboratory Conference Center will be piped to a septic tank-drain field system and would not impact surface water in the area.

Sanitary wastes produced during construction of the Expended Core Facility would be treated through the use of portable chemical toilets or through an existing wastewater treatment facility. Depending on the location chosen by DOE and the Navy for the new Expended Core Facility, sanitary wastes from operation of the ECF would either be treated in an existing wastewater treatment facility (most likely the new Centralized Sanitary Wastewater Facility) or a new treatment facility designed to handle the facility's wastewater capacity. No process wastes from operation of the Expended Core Facility will be discharged to the environment.

5.16.5 Occupational and Public Health and Safety

Table 5-32 summarizes the cumulative health effects of incident-free SRS operations, including those projected for the spent nuclear fuel alternatives. The table lists potential cancer fatalities for workers and the public due to radiological exposures to airborne and waterborne releases from the Site. In addition, the table provides the (airborne) dose to the hypothetical maximally exposed individual in the offsite population. The evaluation used 1992 as the baseline year for normal operations, because it is the last year for which the SRS has complete information. DOE believes that this year gives a realistic depiction of current operational releases of radionuclides. The assessment added the estimated releases from each spent fuel alternative to this baseline to determine the cumulative impacts listed in Table 5-32.

5.16.6 Waste Management

The analysis of cumulative impacts of SRS waste management activities takes as its starting point the assumption that waste generation under the No Action Alternative represents the baseline condition for the entire Savannah River Site. Waste generation levels associated with the other proposed spent nuclear fuel management alternatives (see Table 5-19) thus represent positive and negative deviations from this baseline. Cumulative effects of the proposed spent nuclear fuel alternatives on the volume of low-level waste, transuranic waste, and high-level waste produced under each of the proposed alternatives are presented in Table 5-30.

In addition to baseline waste generation and wastes generated by spent nuclear fuel management activities, environmental restoration and cleanup activities are expected to become an increasingly important part of the DOE mission at the SRS in the future. These remediation activities are expected to produce large quantities of radioactive, hazardous, and mixed wastes. It is estimated that approximately 22,000 cubic meters (28,754 cubic yards) of low-level waste, 366,000 cubic meters (478,362 cubic yards) of hazardous waste, 82,000 cubic meters (107,174 cubic yards) of mixed wastes, and 900 cubic meters (1,176 cubic yards) of transuranic wastes would be produced by environmental restoration activities at the SRS over the 1995-2024 period (DOE 1995). Decontamination and decommissioning activities are expected to generate approximately 109,000 cubic meters (142,463 cubic yards) of low-level waste, 32,000 cubic meters (41,824 cubic yards) of hazardous waste, 95,000 cubic meters (124,165 cubic yards) of mixed wastes, and 4,000 cubic meters (5,228 cubic yards) of transuranic wastes over the same 30-year period (DOE 1995). High-level radioactive waste would not be generated by environmental restoration or decontamination and decommissioning activities.

5.17 Unavoidable Adverse Environmental Impacts

The construction and operation of facilities related to any of the five alternatives at the Savannah River Site (SRS) would result in some adverse impacts to the environment. Changes in project design and other measures could eliminate, avoid, or reduce most of these to minimal levels. The following paragraphs identify adverse impacts that mitigation could not reduce to minimal levels or avoid altogether.

The generation of some fugitive dust during construction would be unavoidable, but would be controlled by water and dust suppressants. This would occur under Alternatives 2 to 5, but greatest generation of dust would occur under Alternative 5 (excluding the offsite shipping option). Similarly, construction activities would result in some minor, yet unavoidable, noise impacts from heavy equipment, generators, and vehicles.

The maximum loss of habitat would involve the conversion of 70 to 100 acres (0.28 to 0.4 square kilometer) of managed pine forest to industrial land use; this would occur under Alternative 5 if DOE moved all spent nuclear fuel to the SRS.

The amount of radioactivity that normal operation of the spent nuclear fuel facilities would release under four of the five alternatives (Alternatives 1 to 4) would be a small fraction of the 1992 operational releases at the SRS and would be well below applicable regulatory standards.

For the alternative having the most impact (Alternative 5 - Centralization), DOE has calculated that the maximum probability for latent fatal cancer for the maximally exposed member of the public would be about 3 times higher than that calculated for 1992 at the SRS. For latent fatal cancer incidence in the offsite population, this comparison indicates an increase of about 2 times, but the number of cancers calculated is less than one.

The only socioeconomic impacts of the proposed spent nuclear fuel management facilities would be temporary increases in employment and expenditures in the region of influence during the construction phase. These would be unavoidable beneficial impacts.

5.18 Relationship Between Short-Term Use of the Environment and the

Maintenance and Enhancement of Long-Term Productivity

Implementation of any of the proposed alternatives would result in some short-term resource demands (e.g., fuel, construction materials, and labor) and would, under certain alternatives (notably the Centralization Alternative), reduce the natural productivity of a relatively small tract of land (less than .07 percent of total SRS area) currently committed to timber production. Depending upon the precise location selected for facility development, a small amount of marginal-to-good wildlife habitat (see Sections 4.9 and 5.9) would also be lost when the area is cleared, graded, and committed to facilities and supporting infrastructure. However, these short-term resource losses and land-use restrictions provide a basis for improved productivity and utility over the long term at the SRS because consolidating all spent nuclear fuel at a few onsite locations would free for other uses those locations presently committed to spent fuel management. On a national scale, the interim management plan described in this EIS would have the same impact of making locations throughout the DOE complex available for other long-term uses.

5.19 Irreversible and Irretrievable Commitments of Resources

The irreversible and irretrievable commitment of resources resulting from the construction and operation of facilities related to the spent nuclear fuel alternatives would involve materials that could not be recovered or recycled or that would be consumed or reduced to unrecoverable forms. The construction and operation of spent nuclear fuel facilities at the SRS would consume irretrievable amounts of electrical energy, fuel, concrete, sand, gravel, and miscellaneous chemicals. Other resources used in construction would probably not be recoverable. These would include finished steel, aluminum, copper, plastics, and lumber. Most of this material would be incorporated in foundations, structures, and machinery. Construction and operation of facilities for spent nuclear fuel management would also require the withdrawal of water from surface- and groundwater sources, but most of this water would return to onsite surface streams or the Savannah River after use and treatment.

The Centralization alternative (Option 5c - Processing) would consume the greatest amount of electricity of any of the alternatives, about 110,400 megawatt-hours. The Processing option (excluding Option 4c, Regionalization by fuel type) would have the highest requirements for coal to produce steam, approximately 2,580 metric tons (2,843 tons) annually. The Centralization alternative (except Option 5d where all spent fuel would be shipped off the site) would involve the greatest irretrievable consumption of other resources, such as construction materials, chemicals, gases, and operating supplies. However, this demand would not constitute a permanent drain on local resources or involve any material that is in short supply in the region.

5.20 Potential Mitigation Measures

This section summarizes measures that DOE could use to avoid or reduce impacts to the environment caused by spent nuclear fuel management activities at the SRS. DOE would determine the extent to which any mitigation would be necessary and the selection of which measures would be implemented during a detailed site-specific NEPA review tiered from this Programmatic EIS. Consequently, the following sections in this chapter address impact avoidance and mitigation in general terms and describe typical measures that the SRS could implement. In addition, the analyses described in this appendix indicate that the environmental consequences of spent fuel management would be minimal in most environmental media.

5.20.1 Pollution Prevention

DOE is committed to comply with Executive Order 12856, "Federal Compliance with Right-to-Know Laws and Pollution Prevention Requirements"; Executive Order 12780, "Federal Acquisition, Recycling and Waste Prevention"; and applicable DOE Orders and Guidance Documents in planning and implementing pollution prevention at the SRS. The pollution prevention program at the Site was initiated in 1990 as a waste minimization program. Currently, the program consists of four major initiatives: solid waste minimization; source reduction and recycling of wastewater discharges; source reduction of air emissions; and potential procurement of products manufactured from recycled materials. Since 1991, the waste of all types generated at the SRS has decreased, with greatest reductions in hazardous and mixed wastes. These reductions are attributable primarily to material substitutions.

All spent fuel management activities at the SRS would be subject to the Site pollution prevention program. Implementation of the program plan would minimize the amount of waste generated by these activities.

5.20.2 Socioeconomics

Spent nuclear fuel activities would have minimal impact on the socioeconomic environment in the region of influence because most employees would be drawn from the existing site workforce. The minor impacts of in-migrating construction workers could be minimized by DOE possibly informing local communities and county planning agencies as to scheduling of construction activities.

5.20.3 Cultural Resources

A Programmatic Memorandum of Agreement (SRARP 1989) between the DOE Savannah River Operations Office, the South Carolina State Historic Preservation Office, and the Advisory Council on Historic Preservation, ratified on August 24, 1990, is the instrument for the management of cultural resources at the SRS. DOE uses this memorandum to identify cultural resources and develop mitigation plans for affected resources in consultation with the State Historic Preservation Officer. DOE would comply with the terms of the memorandum for all measures needed to support spent nuclear fuel management at the Site. For example, DOE would survey sites prior to disturbance and could reduce impacts to any potentially-significant cultural resources discovered through avoidance or removal. Any artifacts discovered would be protected from further disturbance and the elements until removed.

DOE conducted an investigation of Native American concerns over religious rights in the Central Savannah River Valley in conjunction with studies in 1991 related to a New Production Reactor. During this study, three Native American groups expressed concern over sites and items of religious significance on the SRS (see Section 4.4.2). DOE has included these organizations on its environmental mailing list, solicits their comments on NEPA actions of the Site, and sends them documents about SRS environmental activities, including those related to these SNF management considerations. These Native American groups would be consulted on any actions that may follow subsequent site-specific environmental reviews.

5.20.4 Geology

DOE expects that there would be no impacts to geologic resources at the SRS under any alternative evaluated in this EIS. Potential soil erosion in areas of ground disturbance would be minimized through sound engineering practices such as implementing controls for stormwater runoff (e.g., sediment barriers), slope stability (e.g., rip-rap placement), and wind erosion (e.g., covering soil stockpiles). Re-landscaping would minimize soil loss after construction was completed. These measures would be included in a site-specific Storm Water Pollution Prevention Plan that the SRS would prepare prior to initiating any construction.

5.20.5 Air Resources

DOE would meet applicable standards and permit limits for all radiological and non-radiological releases to the atmosphere. In addition, the SRS would follow the DOE policy of maintaining radiological emissions to levels "as low as reasonably achievable" (ALARA). ALARA is an approach to radiation protection to control or manage exposures (both individual and collective) and releases of radioactive material to the environment as low as social, technical, economic, practical, and public policy considerations permit. ALARA is not a dose limit, but rather a process that has as its objectives the attainment of dose levels as far below the applicable limits as practicable.

5.20.6 Water Resources

DOE would minimize the potential for adverse impacts on surface water during construction through the implementation of a stormwater pollution prevention plan that details controls for erosion and sedimentation. The plan would also establish measures for prevention of spills of fuel and chemicals and for rapid containment and cleanup.

DOE could minimize water usage during both construction and operation of facilities by instituting water conservation measures such as instructing workers in water conservation (e.g., turn off hoses when not in use), installing flow restrictors, and using self-closing hose nozzles.

5.20.7 Ecological Resources

DOE does not anticipate that any of the spent fuel alternatives would impact any wetlands on the Site. In any case, DOE and SRS policy is to achieve "no net loss" of wetlands. Pursuant to this goal, DOE has issued a guidance document, Information for Mitigation of Wetlands Impacts at the Savannah River Site (DOE 1992), for project planners that puts forth a practical approach to wetlands protection that begins with avoidance of impacts (if possible), moves to minimization of impacts (if avoidance is impossible), and requires compensatory measures (wetlands restoration, creation, or acquisition) in the event that impacts cannot be avoided.

The analysis in this EIS indicates that there are no threatened and endangered species or sensitive habitats in the areas considered as representative of potential sites for spent nuclear fuel activities at the SRS. However, DOE would perform site-specific predevelopment surveys to ensure that development of new facilities would not impact any of these biological resources.

5.20.8 Noise

DOE anticipates that noise impacts both on and off the Site would be minimal. DOE does not foresee noise impacts from spent nuclear fuel management that would warrant mitigation measures beyond those consistent with good construction, engineering, operations, and management practices.

5.20.9 Traffic and Transportation

DOE has a system of onsite buses operating at the SRS. The Site would evaluate the need for upgrades or changes in service that might be required for the spent nuclear fuel management activities and would make changes, as necessary.

DOE would manage changes in traffic volume or patterns during construction through such measures as designating routes for construction vehicles, providing workers with safety reminders, and upgrading onsite police traffic patrols, if necessary.

5.20.10 Occupational and Public Health and Safety

The DOE program for maintaining radiological emissions to levels "as low as reasonably achievable" (ALARA) described in Section 5.20.5 above will minimize any impacts to workers and the public due to atmospheric releases. Likewise, the Site Pollution Prevention Plan and emergency preparedness measures will enhance safety both on and off the Site.

5.20.11 Utilities and Support Services

The utilities and support services at the SRS are sufficient to meet the requirements of any of the alternatives for the spent fuel management at the Site. Impacts on these services would be minimal. No mitigation measures would be required.

5.20.12 Accidents

The SRS has in place emergency action plans that would be activated in the case of an accident. These plans contain both onsite provisions (e.g., evacuation plans, response teams, medical and fire response, training and drills, communications equipment) and offsite arrangements (e.g., response plans for medical and fire agencies, coordination with local and state agencies, communication plans). The SRS plans would be updated to include any new facilities or activities related to spent nuclear fuel management that would involve the Site. The execution of the plans in response to an accident would mitigate adverse effects both on the Site and in the surrounding areas.

ATTACHMENT A: ACCIDENT ANALYSIS

ATTACHMENT A: ACCIDENT ANALYSIS

A.1 Accident Evaluation Methodologies and Assumptions

The potential for facility accidents and the magnitude of their consequences is an important factor in the evaluation of the spent nuclear fuel alternatives addressed in this EIS. There are two health risk issues:

- Would accidents at any of the Savannah River Site (SRS) facilities that the U.S. Department of Energy (DOE) could build for spent nuclear fuel management activities pose unacceptable health risks to workers or the general public?
- Could alternative locations or facilities for the spent nuclear fuel alternatives provide smaller public or worker health risks? Smaller risks could arise from such factors as greater isolation of the facility from the public, a reduced frequency of such external accident initiators as seismic events or aircraft crashes, reduced inventory, and process differences.

Guidance for the implementation of Council on Environmental Quality (CEQ) regulations (CFR 1986), as amended (51 FR 15625), requires the evaluation of impacts that would have a low probability of occurrence but high consequences if they did occur; this EIS, therefore, addresses facility accidents to the extent feasible.

A.1.1 Radiological Accident Evaluation Methodology

The alternatives considered in this EIS provide an opportunity to incorporate new features and technology in new facilities, processes, and operations that would minimize the possibility of undue risk to the health and safety of plant workers and the public. Modifications and upgrades would mitigate accident consequences from existing facilities or reduce the likelihood of occurrence.

Under normal circumstances, DOE would develop accident scenarios and calculate accident consequences using safety analyses, mitigation features, and design details on proposed facility designs. However, the preliminary design information for the proposed facilities that is available during the preparation of this EIS does not contain sufficient detail to permit quantitative safety analyses. Therefore, for each spent nuclear fuel alternative, DOE has evaluated the existing and proposed facilities for the type of radiological accidents it has determined to be reasonably foreseeable.

The radiological accident types fell into four categories: (1) fuel damage, (2) material releases, (3) nuclear criticalities, and (4) liquid spills or discharges. For each accident type, DOE determined reference accidents by examining DOE-approved safety analysis reports (SARs) and other appropriate documentation (e.g., previous EISs). In addition, DOE considered accidents from adjacent facilities for their possible impacts related to spent nuclear fuel. DOE extracted the overall frequency for each reference accident from the appropriate source, rather than attempting to calculate individual frequencies for all possible initiators; that is, DOE did not use the specific probability of a certain magnitude earthquake to determine the frequency of a criticality or spill, given the occurrence of the earthquake. If multiple initiators could lead to one of the reference accidents, or the combined frequency of the initiators could lead to one of the reference accidents, DOE used the combined frequency of the initiators, generally providing conservative results. For example, the Receiving Basin for Offsite Fuel has a number of potential release initiators that could result in an uncontrolled criticality, as listed in Table A-1. As listed, a number of incidents, all of which have their own assigned frequencies, can contribute to the initiation of an uncontrolled criticality.

Table A-1. Potential release initiators at the Receiving Basin for Offsite Fuel.

Natural Phenomena	External Events	Operations Induced Events	Criticality
Temperature Extreme	Aircraft Crash	Fuel Cutting	Fuel Bundling Error
Snow	Helicopter Crash	Spill at Hose Rack	Cask Loading Error
Rain	Surface Vehicle Crash	Fuel Rupture in Storage	Fuel Identification Problem
Lightning		Fire and Explosion	Fuel Movement Error
Tornado		Fuel Near Basin Surface	Dropped Fuel
Earthquake		Spills and Leaks	Crane or Hoist Collapse
Meteorite Impact		Resin Regeneration	Cask Immersion Error
		Facility Waste to Cell	

This evaluation results in qualitative comparisons for proposed facilities based on the assumption that the facility function is similar to one already analyzed. In addition, an identical set of initiators is not considered in each safety analysis report for existing SRS facilities because these reports were prepared over several years in accordance with requirements in effect at the time. Section A.2 includes a comparison of the similarities of possible facilities to an existing facility, the basis for the selection of reference accidents, and several tables containing data to support a comparison of point estimates of risk.

The qualitative comparison supports the National Environmental Policy Act (NEPA) process, in that the decisionmaker can assess the relative risk from each alternative at SRS and other sites.

A.1.1.1 Notable Accident Initiators. While there are many different types of accident initiators of various frequencies that could lead to an accident, three notable initiators - criticalities, earthquakes, and aircraft crashes - require additional discussion due to the public's perception of the importance of these initiators and the public's familiarity with these types of initiators.

Because there has never been an uncontrolled criticality accident at the SRS, DOE must use historic experience related to the initiators to estimate the frequency for a criticality incident in the Receiving Basin for Offsite Fuel. Storage basins for spent nuclear fuel have excellent safety histories. From 1945 through 1980, there were 40 known criticality accidents worldwide, none of which occurred in a fuel storage facility. From 1975 to 1980, there were, conservatively, 160 reactors with storage basins in operation around the world, and no criticality incidents occurred. Therefore, DOE assumes that the upper frequency limit for a criticality event is 3.1 x 10-3 per year (Du Pont 1983). This figure is applicable to the extent that the storage basins and the operations performed in them are similar to those of the Receiving Basin for Offsite Fuel. However, the frequency for a processing criticality event was determined through a detailed fault tree analysis, as referenced in the safety analysis report, to be an overall calculated limit of 1.4 x 10-4 per year. This value accounts for the implementation of new administrative controls or equipment.

The SRS is in an area that has a relatively low seismic frequency. Based on three centuries of recorded seismic activity, an earthquake with a Richter magnitude greater than 6.0, which corresponds to a Modified Mercalli Intensity Scale (MMI) of VII, would not be likely at the SRS. The design-basis earthquake for the SRS is a MMI VIII event with a corresponding horizontal peak ground acceleration of 0.2g. Based on current technology, as applied in various probabilistic evaluations of the seismic hazard in the SRS region, the 0.2g peak ground acceleration can be associated with a 2 x 10-4 annual probability of exceedance (5,000-year return period). There are four scenarios for the Receiving Basin for Offsite Fuel to which an earthquake of intensity MMI VIII or greater might contribute:

- Deformation of the storage racks leading to a criticality incident.
- Derailment of the 100-ton (91-metric-ton) crane into the storage basin with the deformation of the storage rack leading to criticality.
- Damage to the basin walls leading to the release of contaminated basin water to the subsoil.
- Rupture of a waste tank or pipe in the Resin Regeneration Facility leading to the release of contaminated liquids.

An aircraft crash into a spent nuclear fuel facility is of concern because it could result in a radioactive release of materials from the stored spent nuclear fuel. Appendix D contains an aircraft crash probability analysis based on the examination of large civilian and military aircraft crossing the airspace within a 10-mile (16-kilometer) radius of the SRS. It does not include the crash probability of general aviation aircraft because aircraft of this type generally do not possess sufficient mass or attain sufficiently high velocities to produce a serious radiological threat in the event that they crashed into an area containing spent nuclear fuel. The analysis did not evaluate crash probabilities with a likelihood of occurrence of less than 10-7 per year because they would not significantly contribute to the risk. This was the case for spent nuclear fuel facilities located at the SRS.

A.1.1.2 Use of DOE-Approved Safety Documents. The NEPA guidance issued by the

DOE Office of NEPA Oversight, dated May 1993, recommends that accident impact analyses "reference Safety Assessments and Safety Analysis Reports, if available." This guidance was the primary basis used to develop the approach used in the accident analysis section of this EIS. This Appendix uses several relevant safety analysis reports as well as a previously published EIS. Safety analysis reports are the primary source of information on reasonably foreseeable accidents with the potential to cause a release of hazardous materials. These reports are required for all reactors and nuclear materials facilities with operations that potentially pose a significant hazard to onsite personnel, offsite populations, or the environment. The referenced safety analysis reports and EIS approval/draft submittal dates encompass a range from 1983 to 1993. The 1983 safety analysis report was supplemented by a 1993 addendum; the next oldest safety analysis report was approved in 1988.

A.1.2 Chemical Hazard Evaluation Methodology

This analysis reviewed the appropriate safety analyses to assess the degree to which they addressed chemical accidents. It found that each of the safety analyses addressed chemical hazards in a qualitative manner. To provide a quantitative discussion of chemical hazards, the analysis evaluated a separate risk assessment (WSRC 1993c) for the storage risk of offsite research reactor fuel in the Receiving Basin for Offsite Fuel to determine a bounding chemical accident. The analysis determined chemical inventories (see Section A.3) for the existing spent nuclear fuel facilities at the SRS using the "Savannah River Site Tier Two Emergency and Hazardous Chemical Inventory Report" (WSRC 1994a) to determine the facilities total chemical inventory. This chemical inventory was further screened using the EPA's "List of Lists" (EPA 1990).

A.1.3 SRS Emergency Plan

The SRS emergency plan (WSRC 1993b) defines appropriate response measures for the management of emergencies (e.g., accidents) involving the Site. It incorporates into one document a description of the entire process designed to respond to and mitigate the consequences of an accident.
Emergencies that could cause activation of all or portions of this plan include:

- Events (operational, transportation, etc.) with the potential to cause releases above allowable limits of hazardous materials.
- Events such as fires, explosions, tornadoes, hurricanes, earthquakes, dam failures, etc.,

that affect or could affect safety systems designed to protect site and offsite populations and the environment.

- Events such as bomb threats, hostage situations, etc., that reduce the security posture of the Site.
- Events created by proximity to other facilities, such as the Vogtle Electric Generating Plant, a commercial nuclear powerplant located across the Savannah River from the Site.

For radiological emergencies, protective actions in this plan are designed to keep onsite and offsite exposures As Low As Reasonably Achievable (ALARA). This is accomplished by minimizing time spent in the vicinity of the hazard, keeping as far from the hazard as possible, and taking advantage of available shielding. Protective actions that could be used on the Site in the event of an emergency include remaining indoors, sheltering, evacuation, and relocation. For events that cause an actual or projected radiological release, appropriate protective actions for on- and offsite populations have been determined based on trigger points called Protective Action Guides (PAGs).

A.1.4 General Assumptions

This assessment applied the following key assumptions to examine existing accident analyses and to relate these analyses to the spent nuclear fuel alternatives.

- When a referenced accident scenario is used for a possible new facility, DOE would build the new facility close to an existing referenced facility performing a similar function, resulting in consequences and health effects similar to the existing facilities analyzed. The exception could be the proposed Expended Core Facility which Appendix D analyzes separately.
- For existing facilities to be modified, portions of the facility to be decommissioned, or new facilities to be added, potential accident initiators resulting from construction and nearby activities would be bounded by the referenced accident scenarios.
- Type 2 High Enriched Uranium fuel, the dominant type currently in storage or process at the SRS, would provide a reference source term for other fuel types (i.e., Mark-22 fuel).
- Spent nuclear fuel acceptance criteria would specify that all fuel must be capable of indefinite suspension in air with no melting.
- The total frequency of an event (e.g., criticality) could be used to determine point estimates of risk, regardless of the type or specific frequencies of the individual contributing initiators.
- Adjustment (scaling) factors could be applied to reflect a best engineering judgment in terms of relative risk between the various alternatives.
- The point estimate of risk for a given accident scenario would be representative in that it could, for the purposes of this programmatic EIS, represent a similar accident scenario at new facilities that perform similar functions.
- Reference accidents would be attributed to a facility based on its function (e.g., fuel canning or dry material storage) regardless of whether the facility currently exists, is undergoing design, or is in the conceptual design phase.
- Possible new facilities would be designed to pose no greater risk to the workers and public than existing facilities with similar functions.

This evaluation takes no credit for the upgraded design requirements for the proposed facilities. Such facilities should have improved reliability or mitigative features and, therefore, would reduce the aggregate frequency of accidents. Therefore, the application of values from existing safety analysis reports would provide conservative results. In addition, the evaluation makes no attempt to discriminate among similar existing facilities that might have slightly different frequencies of occurrence or source terms (i.e., an FB-Line event frequency was applied to HB-Line and other processing facilities).

For most accidents, the evaluation did not quantify consequences for workers. The safety analysis reports from which information was extracted for the reference accidents were written before the issuance of DOE Order 5480.23 (DOE 1992); previous applicable Orders did not require the inclusion of worker doses. The historic record indicates that DOE facilities have an enviable safety record. Figure A-1 compares the rate of worker fatalities in the DOE complex (DOE 1993) to national average rates compiled by the National Safety Council for various industry groups (NSC 1993). Because the DOE worker accident fatality rate compares favorably to rates from such industry groups as agriculture and construction and is slightly less than trade and services group rates, the absence of quantitative data regarding accident impacts to radiological workers should not impede the decisionmaking process. The discussion presented in Volume 1 adequately addresses the impacts for close-in workers (i.e., those directly involved in the activity or near the accident source) at the SRS.

A.1.4.1 Receptor Group Assumptions. To ensure comparative results, the evaluation assessed the measures of impacts among four receptor groups:

- Worker. An individual located 100 meters (328 feet) in the worst sector of a facility location where the release occurs.
- Colocated Worker. An individual located 640 meters (2,100 feet) in the worst sector of a facility location where the release occurs.
- Maximally Exposed Offsite Individual (MEI). A hypothetical resident located at the nearest Site boundary from the facility location where the release occurs.
- Offsite Population to 80 Kilometers. The collective sum of individuals located within an 80-kilometer (50-mile) radius of the SRS.

Figure A-1. Comparison of fatality rates among workers in various industry groups.

As noted above, the worker is 100 meters (328 feet) from the facility where the accident occurs. This is because information quantifying accident impacts (i.e., dose and health effects) to workers at less than 100 meters from an accidental release of radionuclides is unavailable. For each of the accident scenarios considered in Appendix C of this EIS, there is some risk of worker injury or death at distances closer than 100 meters. Furthermore, the safety analyses from which this evaluation extracted information for the accident scenarios often did not include any discussions on worker impacts as a result of potential accidents. DOE Orders published before DOE 5480.23 (DOE 1992) did not require the inclusion of worker doses. However, Section A.2.6.2 includes a qualitative discussion regarding accident impacts for the worker at less than 100 meters (328 feet) for each of the radiological accident scenarios.

A.1.4.2 Code Assumptions. DOE's application of the AXAIR and AXAIR89Q (a validated version) dose estimation models is acceptable for projecting health effects from accidents at SRS and comparing the results to results from other similar codes (RSAC-5 and GENII) used at other sites. AXAIR is a Gaussian model based on the methodology outlined in NRC Regulatory Guide 1.145 (NRC 1983). AXAIR contains a meteorological data file specific to SRS that provides conservative calculated doses for the radiological consequences of atmospheric releases. AXAIR and AXAIR89Q include the following specific functions:

- Performs both environmental transport and radiation dosimetry calculations
- Bases environmental transfer models on NRC Reg Guide 1.145 guidelines
- Includes exposure pathways for inhalation of radionuclides and gamma radiation from the radioactive plume
- Calculates gamma shine doses using a non-uniform Gaussian model
- Uses worst sector and 99.5-percentile meteorology

Doses calculated with this code should bound the radiological consequences for atmospheric releases postulated.

A.1.4.3 Criticality Assumptions. An estimate of the consequences of a criticality incident requires an estimate of the number of fissions that might occur. While U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide 3.34 specifies 1 x 1019 fissions as the upper tenth of incidence experience, the SRS analyses are based on mean values, to the extent possible, for all incidents. Criticality incidents have produced from 1014 to 4 x 1019 fissions with a mean of 2 x 1018 fissions for incidents involving fissile solutions and a mean of 5 x 1017 fissions for incidents involving solids. As a consequence, two accident scenarios (Table A-2) address criticality - the wet pool criticality scenario and the processing criticality scenario. For the wet pool criticality scenario, the mean value for solid systems (5 x 1017) is assumed to apply to the source term used to determine the accident consequences, while the processing criticality scenario assumes that the mean value for a solution

(2 x 1018) was applied to the source term to determine accident consequences.

A.2 Radiological Accident Scenarios

A.2.1 Selection of Reference Accidents

To support the examination of both existing and proposed facilities, this evaluation considered a spectrum of potential accident types. To develop a meaningful spectrum of potential accidents, the evaluation posed the following question:

> "What could be done to spent nuclear fuel that would result in a radiological consequence to the receptor groups?"

In determining the answer to this question, the following four general types of events emerged: (1) fuel damage, (2) material releases, (3) criticalities, and (4) liquid spills or discharges. A review of applicable safety analysis reports for the SRS facilities that the spent nuclear fuel alternatives would be likely to affect generated more than 20 accidents involving the transport, receipt, processing, and storage of spent nuclear fuel. A consolidation and subsequent "binning" of these accidents for each accident type reflects an appropriate range of case-specific reference accidents.

Table A-2. Reference radiological accidents considered for spent nuclear fuel activities.

Name and Reference	Reference for Source Term/Dose	Comparative Likelihood/Frequency
A1. Fuel Assembly Breach Reference Accident: RBOF fuel cutting	Tables 1-3 DPSTSA-200-10-3, Addendum 1	1.6x10-1 per year
A2. Material Release (Processing) Reference Accident: F-Canyon Uncontrolled Reaction	Meehan 1995	2.6x10-1 per year
A3. Material Release (Dry Vault) Reference Accident: PSF release	Table 5-9 DPSTSA-200-10-19	1.4x10-3 per year
A4. Material Release (Adjacent Facility) Reference Accident: Release of Waste Tank Activity to Cell	Tables 1-3 DPSTSA-200-10-3, Addendum 1	2.4x10-3 per year
A5. Criticality in Water Reference Accident: RBOF criticality	Tables 1-3 DPSTSA-200-10-3, Addendum 1	3.1x10-3 per year
A6. Criticality During Processing Reference Accident: FB-Line	WSRC-RP-93-1102	1.4x10-4 per year
A7. Spill/Liquid Discharge (External) Reference Accident: Direct discharge of water from K-Reactor disassembly basin	Figure 3 Meehan 1994	2.0x10-4 per year
A8. Spill/Liquid Discharge (Internal) Reference Accident: RBOF hose rack spill	Tables 1-3 DPSTSA-200-10-3, Addendum 1	1.1x10-1 per year

The fuel damage event (type 1 accident) considered was physical damage or breaching of a fuel assembly. Three material (type 2 accidents) releases were considered; they represent releases that could occur during processing from medium energetic events, those that could occur during dry storage of special nuclear materials, and those that could occur from an adjacent facility. Criticality (type 3 accidents) can have different dose impacts and can occur with different frequencies, depending on the physical or chemical characteristics of the material and the surroundings. Two criticality events - in water and during processing - represent these accident scenarios. The evaluation considered a dry criticality accident scenario bounded by the wet pool criticality in terms of frequency and bounded by the processing criticality accident in terms of number of fissions assumed. Two liquid discharges and spills (type 4 accidents) were considered - discharges of pool or basin water assumed to contain tritium, cesium, and other radioactive constituents from the fuel in the pool (external spill), and spills of slightly contaminated liquids inside a facility during fuel handling, spraying, or cask unloading (internal spill).

These eight typical accidents form the set of accidents for the selection of a reference accident. Each type has been assigned an alphanumeric designator, which is listed below and used throughout this document:

- Type 1 - Fuel damage
    - A1 - Fuel assembly breach
- Type 2 - Material releases
    - A2 - Processing release
    - A3 - Dry vault release
    - A4 - Adjacent facility release
- Type 3 - Criticalities
    - A5 - Criticality in water
    - A6 - Criticality during processing
- Type 4 - Liquid discharges and spills
    - A7 - External spill/liquid discharge
    - A8 - Internal spill/liquid discharge

A second review of the safety analyses and the original list of accidents confirmed that each specific accident considered in DOE-approved safety analyses could be represented or bounded by one of the eight "generic" accidents (i.e., a fire could result in material release or an earthquake could result in criticality or liquid release). The use of this approach with documented total frequencies avoids the need for unique identification of all initiating precursor events or their specific probabilities.

A.2.1.1 Externally Initiated Accidents. The accident analysis section of this EIS considered

accident scenarios from external events or adjacent facilities and their potential impacts on direct spent nuclear fuel activities and facilities. Three significant sources of externally induced accident mechanisms were identified as potentially applicable to these facilities and activities: aircraft crashes, adjacent fires, and adjacent explosions. As discussed above, an aircraft crash scenario is not a reasonably foreseeable event within the probability scope of this EIS. For the most part, a fire or explosion in a facility adjacent to the spent nuclear fuel facilities described in Figure 3-2 would not have a significant impact on spent nuclear fuel facilities. However, the screening process determined that a fire and explosion in the Resin Regeneration Facility, located immediately adjacent to the Receiving Basin for Offsite Fuel, could result in the airborne release to the shielded cell and should be included for completeness.

A.2.1.2 Nearby Industrial or Military Facility Accidents. Within a 40-kilometer

(25-mile) radius of the SRS, there are approximately 120 industrial facilities with 25 or more employees (DOE 1990). Four of these facilities are within a 16-kilometer (10-mile) radius of the SRS. Other than those on the SRS, the only major storage facilities within a 40-kilometer radius are the facilities at Chem-Nuclear Systems, Inc., Vogtle Electric Generating Station, and a cluster of natural gas storage tanks near Beech Island. The facilities within a 16-kilometer radius of the SRS boundary are still at least 10 kilometers (6 miles) from the nearest spent nuclear fuel facility, and thus present negligible risk to spent nuclear fuel activities.

A.2.1.3 Common Cause Accident. DOE considered accident scenarios based on a common

cause accident during the screening process. A severe seismic event was the only common-cause initiator identified with the potential to simultaneously impact multiple spent nuclear fuel management facilities at the SRS. A design basis earthquake, which has an estimated acceleration of 0.2g and an annual frequency of 2.0 x 10-4 per year (or one occurrence every 5,000 years), could potentially impact multiple facilities within a single facility area, resulting in the simultaneous release of radioactive and/or toxic materials from these facilities to the environment. It is also considered possible, although probably less likely, than an earthquake of the same magnitude could damage facilities in more than one facility area (e.g., F- and H-Areas; K-, L-, and P-Reactor Disassembly Basins), resulting in simultaneous releases to the environment.

A semi-quantitative evaluation of the cumulative impacts resulting from multiple releases within an area caused by a severe seismic event was performed as part of the accident selection process described in Section A.2.1. A review of the safety analysis reports for the H-Canyon, HB-Line, and Receiving Basin for Offsite Fuels was performed to determine the consequences and risks presented individually by each facility following a design basis earthquake. The risks presented in each safety analysis report were then summed to approximate the risk that would be expected if all of these releases occurred simultaneously from a single seismic initiator. The sum of these risks was compared to the risks of the other accident scenarios presented within the EIS and were found to be bounded by those accidents. A similar evaluation was performed for the spent nuclear fuel-related facilities in the F-Area, and the same conclusion was reached. For the reactor disassembly basins, multiplying the risk from a severe earthquake calculated for the K-Reactor Disassembly basin by three could be considered as the outermost bounding estimate for the three reactor disassembly basins (K-, L-, and P-Reactor Disassembly Basins). This is considered an unrealistic estimate of the cumulative risk because of the extremely conservative assumptions that were made in performing the K-Reactor Disassembly Basin analysis (Meehan 1994). However, even if the risk is increased by a factor of three, it is still considered to be bounded by other accidents already presented within the EIS. Therefore, consistent with the accident methodology described in Section A.2.1, no further analysis of this type of scenario was required. The SRS does maintain emergency plans that would provide protective actions and mitigate consequences that could occur during a common cause accident scenario.

A.2.1.4 Accidents Resulting from Terrorism. DOE considered accident scenarios based

on a terrorist attack or an act of sabotage during the screening process and concluded that any accident resulting from such initiators would be bounded by or similar to the accident scenarios already considered.

A.2.2 Reference Accident Descriptions

DOE established a reference accident for each of the eight generic or typical accidents. The following paragraphs outline the basis for selection of each reference accident by scenario. A reference accident was included if it is analyzed in an SRS safety analysis report that has been approved by the DOE or submitted to DOE for approval as part of the safety basis authorizing operation of a facility, and if the facility is to be utilized as, or is similar in function to, one of the facilities included in the five alternatives and their subordinate cases. For example, the analysis assumed that the Receiving Basin for Offsite Fuel was representative of any spent nuclear fuel wet storage pool. If an accident could occur in any pool, the analysis selected a reference scenario from the Receiving Basin for Offsite Fuel Safety Analysis Report as the reference accident, as listed in Table A-2. The following paragraphs provide the basis for each selection.

- A1. Fuel Assembly Breach - Physical damage to an assembly could occur from dropping, objects falling onto the assembly, or cutting into the fuel part of an assembly. The Receiving Basin for Offsite Fuel Safety Analysis Report (WSRC 1993a) Addendum contains a current analysis of a "fuel cutting accident." The inert, non-uranium-containing extremities of some spent nuclear fuel elements are cut off (cropped) in the repackaging basin before the bundling of the elements. The spent nuclear fuel could be inadvertently cut, causing a release of airborne or high water activity to the work area. Because of the metallic nature of SRS fuel, only a very small fraction of the gases generated in an assembly would be released to the basin water in an accident. Consistent with the safety analysis report, fuel cooled for 90 days is used in the source term for this accident. With foreign research reactor spent nuclear fuel elements, the release of fission product gases would be less than with the Mark-22 fuel assemblies previously considered. The physics of the release of gases from research reactor fuel is similar to SRS fuel because the fuel is constructed in a similar manner. Spent nuclear fuels that could release more fission gases than a Mark-22 fuel assembly would require an Unreviewed Safety Question analysis before the SRS could accept them in the Receiving Basin for Offsite Fuel. Air monitors in this area would warn personnel in the event of an airborne release. The fuel cutting operation involves only one fuel element at a time. This is representative for all cutting and dropping accidents because cracking the cladding would release less than cutting into the fuel itself.

- A2. Material Release (Processing) - The primary activities associated with processing spent nuclear fuel include dissolving the fuel in acid in the F- or H-Area Canyon, separating the radioactive and fissile isotopes, and forming those isotopes into a solid material, either metal or powder. Because of the large volumes of liquid radioactive solution generated during the dissolution process, uncontrolled reactions in the Canyons are the most rapid means of losing control of the material and inadvertently releasing potentially significant quantities of material to the environment. The most common uncontrolled reactions, and those considered in this scenario, include eructations, foaming, boilover, and gassing while dissolving spent fuel. These types of uncontrolled reactions are typically caused by chemical addition errors, procedural errors, or equipment failure. Although uncontrolled reactions can also include deflagrations and explosions (caused by excess hydrogen generation due to radiolytic decay and the presence of an ignition source), these types of events are much less common, and because of their lower frequency, typically present a lower risk to workers and members of the public. In developing this scenario, it was assumed that the uncontrolled reaction causes a large release of material within the Canyon building to the Canyon sumps which results in a greater than normal release of radioactive material through the ventilation system and Canyon exhaust stack. In addition, it was assumed that the uncontrolled reaction occurred in the F-Canyon facility since the exposures resulting from an inadvertent release of plutonium isotopes are expected to bound potential inadvertent releases of uranium isotopes from uncontrolled reactions in the H-Canyon facility.
- A3. Material Release (Dry Vault) - Accident types A1 and A2 cover material releases from fuel handling and processing. In addition, DOE considered a reference accident for vault-type storage. The Plutonium Storage Facility (PSF) Safety Analysis Report (Du Pont 1989) analyzed three medium energetic events (shipping container failure, criticality, and impact-type events) and an earthquake. As discussed above, medium energetic events are accidents that result in release of material from the primary container and have sufficient energy to penetrate the secondary confinement barriers for a short period of time. That report contains a total frequency of these four initiating events and provides one release value. Because the SRS has no long-term spent nuclear fuel dry storage facilities, this evaluation assumes that the Plutonium Storage Facility vault is representative of dry storage facilities, as are the activities and precursor events. A material release from any medium energetic event in the Plutonium Storage Facility was selected as the reference accident for nonprocessing material releases.
- A4. Material Release (Adjacent Facility) - For completeness, DOE considered a reference accident from a facility immediately adjacent to the Receiving Basin for Offsite Fuel (WSRC 1993a). This scenario includes a fire and explosion at the Resin Regeneration Facility in waste tank EP 38 during which the coolant of a received cask, when discharged to the waste tank, results in a flammable or explosive concentration of vapors in the tank. Rupture of the tank by an explosion could release airborne activity to the shielded cell if the accident occurred during one of the projected 150 times per year when regeneration of the portable columns takes place. While a fire and explosion have not occurred in waste tank EP 38, one fire and pressure surge did occur when a shipping cask was being vented. The

spent nuclear fuel remained intact and radionuclides were not released. The incident has been attributed to the ignition of a mixture of hydrogen, oxygen, and air emanating from the cask and created by reaction of hot aluminum fuel with water left in the cask by the shipper.

- A5. Criticality in Water - This scenario assumes that a wet pool storage facility is the most likely to have a criticality in water. The Receiving Basin for Offsite Fuel provides the capability for underwater receipt, handling, and storage of spent nuclear fuel. Primary radiation shielding is provided by the water covering the spent nuclear fuel. A safety analysis report determined frequency and results from many initiating events that could lead to criticality. The following activities could ultimately lead to a criticality incident: Fuel Bundling, Cask Loading, Fuel Identification and Manifest Problems, Fuel Movement, Dropped Fuel, Fuel Near Basin, Cask Immersion, and Cranes and Hoist. These events are representative for any wet storage pool.
- A6. Criticality During Processing - As noted in the discussion for accident type A2, FB-Line events are representative for SRS processing facilities. The analysis considered the total of the frequencies for criticality initiators for all processing stages, which would, therefore, be conservative because not all processing stages would necessarily be involved in a new facility and not all stages would necessarily occur simultaneously.
- A7. Spill/Liquid Discharge (External) - The reference accident selected for this type of event is the direct discharge of water (i.e., 3.4 million gallons) from the K-Reactor disassembly basin to the Savannah River and the exposure of fuel and targets in the basin to air. Analyses performed by the DOE while developing the EIS for the Interim Management of Nuclear Materials at the SRS demonstrate that this scenario could be initiated by a severe earthquake and would result in bounding airborne exposures (from exposed fuel) and liquid exposures (contaminated drinking water) to the general public. The selection of the direct-discharge event is conservative for existing or possible new facilities constructed in the F- or H-Areas because no free-flowing surface streams would be near a discharge point. The use of the source term from the reactor disassembly basin is considered to be conservative for the spent nuclear fuel storage pools since its inventory consists primarily of the fuel types with the largest source terms available for release (i.e., Mark-22 assemblies). Although the disassembly basin has water circulating systems to control radioactivity, chemistry, clarity, and temperature, these processes are less efficient than those used in the Receiving Basin for Offsite Fuel, resulting in higher concentrations of tritium, cesium, and other contaminants available for release.
- A8. Spill/Liquid Discharge (Internal) - DOE considered a second reference accident for contaminated liquids spills or discharges to ensure the appropriate onsite impacts. The discharge discussed for accident type A7 would be external to the building and would have no measurable worker impact component because the reference accident occurred outside the facility. The Receiving Basin for Offsite Fuel hose rack spill was selected as the reference accident because it is representative of small, unplanned, but relatively frequent spills in a storage facility and could impact the worker. Minor releases of contaminated water could occur at the hose rack platform during the handling of portable deionizers for the reactor areas.

A.2.3 Source Term and Frequency Determinations

Table A-2 lists source term references from existing documents approved by DOE or submitted by Westinghouse Savannah River Company to DOE for approval for each selected reference accident. The same references nominally prescribed the frequency of accidents or initiating events. If it was not directly available, the frequency was derived from information already contained in the appropriate safety analysis report or EIS (e.g., if only a risk estimate and a dose were listed, the frequency was derived by dividing the risk by the dose). These frequencies fall into ranges associated with abnormal events (more frequent than 1 x 10-3 per year), design-basis accidents (1 x 10-3 per year to 1 x 10-6 per year), or beyond-design-basis accidents (less than 1 x 10-6 per year to 10-7 per year).

This document does not analyze beyond-design-basis accidents or accidents with frequencies of less than 1.0 x 10-6 explicitly because the accident analysis source material (DOE-approved safety analysis reports) considers these accidents to be incredible events. Beyond-design-basis accidents, such as an airplane crash-induced criticality, have no different consequences (i.e., number of fissions) than the criticality estimated to occur with a frequency of 3.1 x 10-3 per year. Because of the use of aggregate frequencies in some cases, the contribution to overall risk from 1.0 x 10-7 per year events is negligible, and the higher frequency initiators dominate the point estimate of risk. Some initiating or precursor event frequencies from the safety analysis reports are at 10-7 per year or lower; thus, these reports in fact consider events beyond the 10-6 frequencies.

Frequencies for reference accidents were determined as follows:

- A1. Fuel Assembly Breach - The frequency for this reference accident was obtained from DPSTSA-200-10-3, Receiving Basin for Offsite Fuel (RBOF), Addendum 1, Tables 1-5, which lists the frequency as 1.6 x 10-1 per year (WSRC 1993a).
- A2. Material Release (Processing) - The frequency for this reference accident was obtained from DPSTSA-200-10-4, Safety Analysis - 200 Area, Savannah River Plant, F-Canyon Operations, Addendum 2, "Accident Analysis," Revision 1, Table A.5.5-7A, which lists the frequency for an uncontrolled chemical reaction (the bounding processing accident) as 2.6 x 10-1 per year (Meehan 1995).
- A3. Material Release (Dry Vault) - The frequency for this reference accident was obtained from DPSTSA-200-10-19, Final Safety Analysis Report - 200 Area, Savannah River Site Separations Area Operations, Building 221F, B-Line, Plutonium Storage Facility, July 1989, Table 5-9, which lists the frequency as 1.4 x 10-3 per year (Du Pont 1989).
- A4. Material Release (Adjacent Facility) - The frequency for this reference accident was obtained from DPSTSA-200-10-3, Receiving Basin for Offsite Fuel (RBOF), Addendum 1, Tables 1-5, which lists the frequency as 2.4 x 10-3 per year (WSRC 1993a).
- A5. Criticality in Water - The frequency for this reference accident was obtained from DPSTSA-200-10-3, Receiving Basin for Offsite Fuel (RBOF), Addendum 1, Tables 1-5, which lists the frequency as 3.1 x 10-3 per year (WSRC 1993a).
- A6. Criticality During Processing - The frequency for this reference accident was obtained from WSRC-RP-93-1102, FB-Line Basis for Interim Operation, November 1993, Figure 3, which lists a frequency of 1.4 x 10-4 per year (WSRC 1993d).
- A7. Spill/Liquid Discharge (External) - The frequency for this reference accident was derived from analyses provided in DOE/EIS-0147, Continued Operation of K-, L-, and P-Reactors, December 1990 (DOE 1990), as well as other safety analyses developed for additional SRS facilities. The initiating event is a design basis earthquake with peak horizontal ground accelerations equal to 0.2 times the force of gravity (i.e., 0.2g) which occurs with an estimated frequency of 2.0 x 10-4 per year, and results in the release of the basin water (3.4 million gallons) to the Savannah River.
- A8. Spill/Liquid Discharge (Internal) - The frequency for this reference accident was obtained from DPSTSA-200-10-3, Receiving Basin for Offsite Fuel (RBOF), Addendum 1, Tables 1 - 3, which lists the frequency as 1.1 x 10-1 per year for a representative spill at a hose rack (WSRC 1993a).

A.2.4 Applicability of Accidents to Facilities

This evaluation reviewed Section 1 of the reference document Technical Data Summary Supporting the Spent Nuclear Fuel Environmental Impact Statement (WSRC 1994b) to develop a matrix of the selected radiological accidents to the facilities (modules) being considered for the various alternatives and cases. For proposed new facilities, the analysis used best engineering judgment to extrapolate from appropriate accident scenarios based on the descriptions provided in the reference document. Table A-3 lists the connection of facilities to accident scenarios. For example, the Examination and Characterization Facility (module B) identifies a potential accident scenario, A1 (as defined in Table A-2), that should be considered when this facility is utilized to support any case.

Table A-3. Applicable accidents and facilities.

Facility	Modulea	Accidents
Spent Fuel Receiving, Cask Handling and Fuel Unloading	A	A1
Examination and Characterization	B	A1
Naval Reactor Spent Fuel Examination and Characterization	C	A1, A5, A7, A8
Spent Fuel Repackaging	D	A1, A5,

		A7, A8
Canister Loading	E	A1, A7, A8
Interim Dry Storage	F	A1, A3
Interim Spent Fuel Storage Pool	G	A1, A5, A7, A8
F-Canyon/F-Area Separations	H, I	A1, A2, A3, A6
H-Canyon/H-Area Separations	J, K, L	A1, A2, A3, A6
Reactor Disassembly Basins	M	A1, A5, A7
Receiving Basin for Offsite Fuels	N	A1, A4, A5, A7, A8

a. As defined in WSRC (1994b).

A.2.5 Facilities and Reference Accidents Associated with each Alternative Case

Table A-4 links alternatives, specific cases, supporting facilities (modules), and accident scenarios. This table identifies the facilities that could be required to support each alternative by specific case. The combined associated accident scenarios for each facility provide the accident spectrum associated with the specific cases for each alternative.

A.2.6 Impacts from Radioactive Release Accidents

This section provides a quantitative discussion of potential consequences to the receptor groups identified in Section A.1.4.1. It also provides a qualitative discussion on potential health effects and consequences for workers at less than 100 meters (328 feet) for each of the potential accident scenarios.

Table A-4. Spent nuclear fuel facilities and accident spectrum by alternatives.

Alternative	Modules[a]	Accidents
1. NO ACTION		
Option 1 - Wet Storage	M, N	A1, A4, A5, A7, A8
2. DECENTRALIZATION		
Option 2a - Dry Storage	B, D, E, F, G, M, N	A1, A3, A4, A5, A7, A8
Option 2b - Wet Storage	B, D, E, G, M, N	A1, A4, A5, A7, A8
Option 2c - Processing	G, H, I, J, K, L, M, N	A1, A2, A3, A4, A5, A6, A7, A8
3. PLANNING BASIS		
Option 3a - Dry Storage	B, D, E, F, G, M, N	A1, A3, A4, A5, A7, A8
Option 3b - Wet Storage	B, D, E, G, M, N	A1, A4, A5, A7, A8
Option 3c - Processing	G, H, I, J, K, L, M, N	A1, A2, A3, A4, A5, A6, A7, A8
4. REGIONALIZATION		
Option 4a - Dry Storage	A, B, D, E, F, G, M, N	A1, A3, A4, A5, A7, A8
Option 4b - Wet Storage	A, B, D, E, G, M, N	A1, A4, A5, A7, A8
Option 4c - Processing	A, G, H, I, J, K, L, M, N	A1, A2, A3, A4, A5, A6, A7, A8
Option 4d - Dry Storage	A, B, C, D, E, F, G, M, N	A1, A3, A4, A5, A7, A8
Option 4e - Wet Storage	A, B, C, D, E, G, M, N	A1, A4, A5, A7, A8
Option 4f - Processing	A, C, G, H, I, J, K, L, M, N	A1, A2, A3, A4, A5, A6, A7, A8
Option 4g - Ship Out	M, N	A1, A4, A5, A7, A8
5. CENTRALIZATION		
Option 5a - Dry Storage	A, B, C, D, E, F, G, H, M, N	A1, A3, A4, A5, A7, A8
Option 5b - Wet Storage	A, B, C, D, E, G, M, N	A1, A4, A5, A7, A8
Option 5c - Processing	A, C, G, H, I, J, K, L, M, N	A1, A2, A3, A4, A5, A6, A7, A8
Option 5d - Ship Out	M, N	A1, A4, A5, A7, A8

A.2.6.1 Radioactive Release Accidents and Consequences for Spent Nuclear Fuel

Alternatives. Table A-5 summarizes the information in Tables A-2 through A-4 and provides individual consequences (doses) based on accident type for each case. The table lists consequences for the four receptor groups as follows: Maximum Offsite Individual Dose, the Population to 80 kilometers (50 miles) Dose, the Worker Dose, and the Colocated Worker Dose.

Table A-5. Radioactive release accidents and consequences for spent nuclear fuel alternatives.

Description	Accident		Accident frequency (per year)	Maximally offsite individual dose (rem)	Population to 80 kilometers dose (person-rem)	Worker dose (rem)	Colocated worker dose (rem)
	1.	NO ACTION					
Option 1 Wet Storage	A1	Fuel Assembly Breach	1.6x10-1	2.0x10-3	1.7x101	(a)	1.2x10-2
	A4	Material Release (adjacent facility)	2.4x10-3	6.0x10-3	5.0x101	(a)	5.0x10-2
	A5	Criticality in Water	3.1x10-3	3.0x10-3	8.8x100	(a)	1.4x10-1
	A7	Spill/Liquid Discharge (external)	2.0x10-4	5.4x10-3	1.8x101	(a)	7.6x10-2
	A8	Spill/Liquid Discharge (internal)	1.1x10-1	2.4x10-10	2.0x10-6	(a)	2.0x10-11
	2.	DECENTRALIZATION					
Option 2a Dry Storage	A1	Fuel Assembly Breach	1.6x10-1	2.0x10-3	1.7x101	(a)	1.2x10-2
	A3	Material Release (dry vault)	1.4x10-3	2.1x10-6	6.9x10-3	(a)	(a)
	A4	Material Release (adjacent facility)	2.4x10-3	6.0x10-3	5.0x101	(a)	5.0x10-2
	A5	Criticality in Water	3.1x10-3	3.0x10-3	8.8x100	(a)	1.4x10-1
	A7	Spill/Liquid Discharge (external)	2.0x10-4	5.4x10-3	1.8x101	(a)	7.6x10-2
	A8	Spill/Liquid Discharge (internal)	1.1x10-1	2.4x10-10	2.0x10-6	(a)	2.0x10-11
Option 2b Wet Storage	A1	Fuel Assembly Breach	1.6x10-1	2.0x10-3	1.7x101	(a)	1.2x10-2
	A4	Material Release (adjacent facility)	2.4x10-3	6.0x10-3	5.0x101	(a)	5.0x10-2
	A5	Criticality	3.1x10-3	3.0x10-3	8.8x100	(a)	1.4x10-1

		in Water				
	A7	Spill/Liquid Discharge (external)	2.0x10-4	5.4x10-3	1.8x101	(a)	7.6x10-2
	A8	Spill/Liquid Discharge (internal)	1.1x10-1	2.4x10-10	2.0x10-6	(a)	2.0x10-11

	A4	Material Release (adjacent facility)	2.4x10-3	6.0x10-3	5.0x101	(a)	5.0x10-2
	A5	Criticality in Water	3.1x10-3	3.0x10-3	8.8x100	(a)	1.4x10-1
	A6	Criticality in Processing	1.4x10-4	7.0x10-3	8.6x100	(a)	2.6x10-1

Table A-5. (continued).

Description	Accident		Accident frequency (per year)	Maximally offsite individual dose (rem)	Population to 80 kilometers dose (person-rem)	Worker dose (person-rem)	Colocated worker dose (person-rem)
	2. DECENTRALIZATION						
	A7	Spill/Liquid Discharge (external)	2.0x10-4	5.4x10-3	1.8x101	(a)	7.6x10-2
	A8	Spill/Liquid Discharge (internal)	1.1x10-1	2.4x10-10	2.0x10-6	(a)	2.0x10-11
	3. PLANNING BASIS						
Option 3a Dry Storage	Same as Option 2a for Decentralization						
Option 3b Wet Storage	Same as Option 2b for Decentralization						
Option 3c Processing	Same as Option 2c for Decentralization						
	4. REGIONALIZATION						
Option 4a and 4d Dry Storage	Same as Option 2a for Decentralization						
Option 4b and 4e Wet Storage	Same as Option 2b for Decentralization						
Option 4c and 4f Processing	Same as Option 2c for Decentralization						
Option 4g Ship Out	Same as Alternative 1, No Action						
	5. CENTRALIZATION						
Option 5a Dry Storage	Same as Option 2a for Decentralization						
Option 5b Wet Storage	Same as Option 2b for Decentralization						
Option 5c Processing	Same as Option 2c for Decentralization						
Option 5d Ship Out	Same as Alternative 1, No Action						

a. The safety analysis reports from which information was extracted for these accidents were written before the issuance of DOE Orders 5480.23 (DOE 1992); previous orders did not require the inclusion of worker doses.

A.2.6.2 Impacts to Workers at Less than 100 Meters from Radiological

Releases. This section provides a qualitative discussion addressing the impacts due to potential radiological accident scenarios to workers at less than 100 meters (328 feet) involved in SRS spent nuclear fuel management. While worker fatalities may result from release initiators (i.e., plane crashes, seismic event, crane failure, etc.) and not as a direct consequence of a radiation release, this discussion considers only the radiological impacts of an accident, should it occur.

- A1. Fuel Assembly Breach - No fatalities to workers would be expected from radiological consequences because the release of the source term would be under water. Attenuation by the water would occur for most products, but the release of noble gases would cause a direct radiation exposure to workers in the area. However, because of the high metallic content of SRS spent nuclear fuel, only a very small fraction of the gases generated in an assembly would be released to the basin water. Air monitors in the area would warn personnel in the event of an airborne release. Timely evacuation would prevent substantial radiation exposures.

- A2. Material Release (Processing) - No fatalities to workers would be likely from radiological consequences (Meehan 1995). This scenario assumes that the material released from the process vessels would remain within the Canyon structure and be processed through the Canyon's ventilation and filtration system. Because of shielding effect from the thick concrete walls separating the vessels and areas occupied by workers, the exposures to workers are not expected to be significantly larger than those that would be received during routine operations.

- A3. Material Release (Dry Vault) - No fatalities to workers would be likely from radiological consequences. Medium energetic events resulting in the release of radioactive material from the Plutonium Storage Facility vault can result in the dispersal of radioactive materials. For these events, the radioactive material present would bypass the containment and disperse, but would result in a dose well below the lethal level. This assumes that a material release would be distributed into the volume of the smallest room for each unit of operation. It is further assumed that the operator is able to exit the room in 30 seconds (Du Pont 1989). This scenario presumes that the fractions of the plutonium volatized and transported are the same as those applied to the dispersal of the nonvolatile fission products of a criticality. Based on these assumptions, radiological exposure to the worker could occur.

- A4. Material Release (Adjacent Facility) - No fatalities to workers would be likely from radiological consequences. The rupture of a waste tank by an explosion could release airborne activity to the shielded cell if the accident occurred during one of the projected 150 times per year when regeneration of the portable columns took place (WSRC 1993a). Although some radiological exposure to the worker could occur, the risk to the worker from the initiating fire and explosion would predominate. Air monitors in the area would warn personnel in the event of an airborne release. Timely evacuation would prevent substantial radiation exposures.

- A5. Criticality in Water - No fatalities to workers would be likely from radiological consequences. The use of casks and the underwater handling of spent nuclear fuel greatly reduce the possibility of over-exposure of workers to radiation. The approximately 3 meters (10 feet) of water that covers all fuel provides an attenuation factor of 105 for intense gamma radiation and provides protection from direct radiation, even in the event of a criticality. However, a small chance of direct radiation exposure could result due to a floating fuel element or a fuel element inadvertently being raised too high. Strategically located radiation monitors reduce even this probability by alerting workers and sounding an evacuation alarm.

- A6. Criticality During Processing - The radiation field generated by a criticality incident could lead to fatalities among workers at the FB-Line facility. As discussed in Section A.2.2, FB-Line inadvertent criticality events are bounding for F- and H-Area spent fuel management processing facilities. This is assumed because workers involved in the FB-Line activities are in close proximity to plutonium metal. Of the 74 personnel that could be present during normal operations, 56 are expected to be within areas which the safety analysis report (WSRC 1993d) identifies as potential criticality accident locations. The shielding due to the concrete floors and walls, the distance between personnel, and the specific nature of the event reduce personnel dose so that only nearby personnel on the floor where the accident occurred would potentially receive a fatal dose. In the event of a criticality accident, DOE estimates that up to 4 deaths could occur, and as many as 50 other workers could receive non-fatal levels of direct radiation.

- A7. Spill/Liquid Discharge (External) - No fatalities to workers would be likely from radiological consequences because drainage of the water from the pool or basin would be expected to take several days, or under the most extreme circumstances, several hours, which provides sufficient time for workers to evacuate the area.

- A8. Spill/Liquid Discharge (Internal) - No fatalities to workers would be likely from radiological consequences. Minor releases of contaminated water have occurred at the Receiving Basin for Offsite Fuel hose rack platform during the handling of portable deionizers from the reactor areas. One such release was the result of an operator attempting to correct a small leak on a pressurized portable deionizer. The operator was subsequently sprayed with contaminated water, resulting in a radioactive exposure. A spill at the hose rack is not expected to release more than 378.5-liters (100 gallons) of contaminated water.

A.2.7 Point Estimates of Risk

Table A-6 lists the point estimate of risk for each reference accident considered for two receptors. The point estimate of risk is the product of frequency (in occurrences per year) and the number of potential latent fatal cancers. The number of potential latent fatal cancers is the product of dose (in rem for the individual or person-rem for the population) and the ICRP 60 risk factors (4.0 x 10-4 latent fatal cancer per rem for the worker or 5.0 x 10-4 latent fatal cancer per rem for the general public). These point estimates were used to determine the relative risk for each case and to determine the accident that becomes dominant if DOE retires specific facilities during the total period under consideration. For example, all alternatives begin with the immediate storage of spent nuclear fuel in wet pools; however, for the alternative considering interim dry storage, the accident dominating risk will change as the configuration of facilities utilized changes and as spent nuclear fuel or special nuclear material is placed in and remains in interim storage rather than being handled.

A.2.8 Fuel Transition Staging Risk

Table A-7 facilitates the examination of the dominant reference accident during the fuel handling, processing, and storage stages. The use of stages enabled a realistic comparison of risk over the evaluated period. For example, when all fuel has been unloaded, characterized, canned, and put into an interim storage position, consideration of fuel handling events is no longer meaningful.

A.2.9 Adjustment Factors for Comparison Between Alternatives

The accident scenarios described in this document (i.e., Appendix C) differ only slightly between the various alternatives. The scenarios do not account for variations in spent nuclear fuel shipments (including onsite operational transfers) and spent nuclear fuel storage inventories across the alternatives. To provide a realistic comparison across alternatives, DOE developed factors to adjust

Table A-6. Point Estimates of Risk for Reference Accident Scenarios.

Accident Scenario	Descriptions	Frequency (per year)	Potential Fatal Cancers[a]		Point Estimate of Risk[b]	
			Maximally	Population	Maximally	Population

			Exposed Individual	to 80 kilometers	Exposed Individual	to 80 kilometers
A1	Fuel Assembly Breach	1.6x10-1	1.0x10-6	8.5x10-3	1.6x10-7	1.4x10-3
A2	Material Release (processing)	2.6x10-1	3.4x10-8	2.6x10-4	8.8x10-9	6.8x10-5
A3	Material Release (dry vault)	1.4x10-3	1.1x10-9	3.5x10-6	1.5x10-12	4.9x10-9
A4	Material Release (adjacent facility)	2.4x10-3	3.0x10-6	2.5x10-2	7.2x10-9	6.0x10-5
A5	Criticality in Water	3.1x10-3	1.5x10-6	4.4x10-3	4.7x10-9	1.4x10-5
A6	Criticality in Processing	1.4x10-4	3.5x10-6	4.3x10-3	4.9x10-10	6.0x10-7
A7	Spill/Liquid Discharge (external)	2.0x10-4	2.7x10-6	9.0x10-3	5.4x10-10	1.8x10-6
A8	Spill/Liquid Discharge (internal)	1.1x10-1	1.2x10-13	1.0x10-9	1.3x10-14	1.1x10-10

a. ICRP 60 risk factor (5.0 x 10-4) latent fatal cancer per rem was used to determine potential latent fatal cancers.

b. Units for point estimates of risk are given in potential fatal cancers per year.

Table A-7. Dominant risks based on fuel transition stages.

Fuel/Material Stage	Maximally Exposed Individual Risk	Population to 80 Kilometers Risk
Wet storage	1.6x10-7 potential fatal cancer/yr based on accident scenario A1.	1.4x10-3 potential fatal cancer/yr based on accident scenario A1.
Dry storage	1.5x10-12 potential fatal cancers/yr based on accident scenario A3.	4.9x10-9 potential fatal cancers/yr based on accident scenario A3.
Processing (fuel "in-process" by DOE definition)	1.6x10-7 potential fatal cancer/yr based on accident scenario A1.	1.4x10-3 potential fatal cancer/yr based on accident scenario A1.

frequencies or consequences, depending on the specific circumstances of each alternative. This section describes the methodology and justification used to develop adjustment (scaling) factors for a relative comparison of adjusted point estimates of risk for each alternative on a case-by-case basis.

A.2.9.1 Classification of SRS Accident Scenarios for Applicability to

Adjustment Factors. This evaluation screened the SRS accident scenarios to determine which adjustment factor categories were applicable. Table A-8 lists the classification of the different SRS accident scenarios. These adjustment categories are as follows:

- Frequency sensitive due to spent nuclear fuel handling
- Frequency sensitive due to spent nuclear fuel inventories
- Consequence sensitive due to spent nuclear fuel inventories

Table A-8. Adjustment factor classification of SRS accidents.

Accident Scenarios	Accident Description	Frequency Sensitive (Handling)	Frequency Sensitive (Inventory)	Consequence Sensitive

(Inventory)

A1	Fuel Assembly Breach	X		
A2	Material Release (Processing)		X	
A3	Material Release (Dry Vault)			X
A4	Material Release (Adjacent Facility)	X		
A5	Criticality in Water	X		
A6	Criticality during Processing		X	
A7	Spill/Liquid Discharge (External)			X
A8	Spill/Liquid Discharge (Internal)			X

The following paragraphs provide the basis for each category selection:

- A1. Fuel Assembly Breach - The major initiator for this accident is the mishandling of a fuel assembly. For this reason, the accident frequency for this accident is adjusted to account for the annual number of fuel handling events. The amount of material involved in this accident is limited by the amount of damage that would occur due to the mishandling of a fuel assembly. Therefore, the bounding consequences of this accident are constant and independent of the amount of material available.

- A2. Material Release (Processing) - The probability that a release could occur during processing depends on the amount of material that would be processed. Therefore, the accident frequency for this accident is adjusted based on the spent nuclear fuel inventory. Because a maximum amount of material can be processed at any one time, the bounding consequences of this accident are independent of the amount of material on the site.

- A3. Material Release (Dry Vault) - The major contributor to the probability of occurrence for this release was external initiators that did not involve material handling. This supports using the same frequency for each alternative. The consequences of this accident are proportional to the amount of material available for release. Therefore, the bounding consequences for this accident are based on the amount of material to be stored.

- A4. Material Release (Adjacent Facility) - The initiator for this accident involves the discharge of coolant from a cask into a waste tank. The frequency of occurrence for this accident depends on the number of casks received; therefore, the frequency is adjusted to account for the annual number of fuel shipments.

- A5. Criticality in Water - The probability of occurrence of this accident was determined by considering the probability of occurrence of several initiating events. Many of these initiating events involved a criticality due to the mishandling of fuel. Therefore, the frequency for this accident is adjusted to account for the annual number of fuel handling events. The magnitude of the criticality accident is not a function of the amount of material available because the criticality is a highly unlikely, localized event. The consequences for this accident are not adjusted to account for the amount of material available.

- A6. Criticality During Processing - The probability that a criticality could occur during processing depends on the amount of material that will be processed. Therefore, the frequency for this accident is adjusted based on the spent nuclear fuel inventory. The magnitude of the criticality accident is not a function of the amount of material available because the criticality is a highly unlikely, localized event. The consequences for this accident are not adjusted to account for the amount of material available.

- A7. Spill/Liquid Discharge (External) - The major contributor to the probability of occurrence for this release was external initiators that did not involve material handling. This supports using the same frequency for each alternative. The consequences depend on the amount of fuel in the basin because an increase in the amount of fuel will increase the source term in the basin water. Therefore, the bounding consequences are adjusted for the amount of fuel to be stored.

- A8. Spill/Liquid Discharge (Internal) - The major contributor to the probability of occurrence for this release was external initiators that did not involve material handling. This supports using the same frequency for each alternative. The consequences depend on the amount of fuel in the basin because an increase in the amount of fuel will increase the source term in the basin water. For this reason the bounding consequences are adjusted for the amount of fuel to be stored.

A.2.9.2 Methodology for Determination of Onsite Shipping Frequencies.

This section discusses the methodology for determining the onsite shipping frequencies of spent nuclear fuel on a case-by-case basis for each alternative. The annual frequency of handling accidents will vary in direct proportion to the annual number of handling events. However, the consequences of the accident will not vary as a result of spent nuclear fuel handling activities because the amount of material involved in each handling event does not vary. This evaluation assumes that onsite shipments of spent nuclear fuel are near-term shipments, averaged over 5 years. Table A-9 provides a breakdown of current spent nuclear fuel inventories at SRS facilities.

Table A-9. Spent nuclear fuel inventories.

Facility	Number of Aluminum Assemblies[b]	Number of Aluminum Slugs (Buckets[c])	Number of Nonaluminum-Clad Assemblies	Number of Aluminum-Clad Assembly Shipments	Number of Aluminum-Clad Bucket Shipments	Number of Nonaluminum-Clad Assembly Shipments
Receiving Basin for Offsite Fuel (RBOF)	234	107 (2)	261	20	1	22
K-Reactor Basin	1,783	349 (7)	0	149	3	0
L-Reactor Basin	861	13,840 (256)	0	72	86	0
P-Reactor Basin	577	61 (2)	0	48	1	0
Totals	3,455	14,477 (268)	261	289	91	22

[a] Basis for inventory numbers: (WSRC 1994c).

[b] Assemblies include targets and fuel assemblies. Assembly shipments are based on 12 assemblies per shipment.

[c] Number of buckets calculated using 54 slugs per bucket. Bucket shipments are based on 3 buckets per shipment.

A.2.9.2.1 Alternative 1 - No Action - The SRS would send the

following number of shipments of aluminum-clad fuel sent to the Receiving Basin for Offsite Fuel from:

- K-Reactor Basin - 152;
- L-Reactor Basin - 158;
- P-Reactor Basin - 49;
- Total - 359 shipments.

All nonaluminum-clad fuel would be sent from the Receiving Basin for Offsite Fuel to a reactor basin (a total of 22 shipments).

The number of shipments would be 380. Because fuel handling would occur at both origin and destination, this number would double (i.e., 760 total shipments). Therefore, over 5 years, this alternative would have an average shipping rate of 152 shipments per year.

A.2.9.2.2 Alternative 2 - Decentralization

- Option 2a - Dry Storage - For this option, initial shipments would be the same as those for Alternative 1 (760 shipments at a rate of 152 per year). Subsequent shipments from all storage locations to the new dry storage facilities would total 402 shipments. Because fuel handling would occur at both origin and destination, this number would double (i.e., 804 total shipments). Because all fuel would be moved to dry storage within a 5-year period, this total would have an average rate of 161 shipments per year. Adding all shipments would produce a total of 1,564 shipments at a rate of 313 per year.
- Option 2b - Wet Storage - For this option, initial shipments would be the same as those for Alternative 1 (760 shipments at a rate of 152 per year). Subsequent shipments from all storage locations to the new wet storage facilities would total 402 shipments for existing SRS fuel. Because the receipt of offsite fuel would continue prior to the relocation of fuel to the new wet storage facilities, an additional 50 shipments would occur [assuming receipt of five shipments per year of offsite fuel (per Volume 1, Appendix I "Offsite Transportation of Spent Nuclear Fuel")] until 2005. The resulting fuel movement would total 452 shipments. Because fuel handling would occur at both origin and destination, this number would double (i.e., 904 total shipments). Therefore, over 5 years this option would have an average shipping rate of 181 shipments per year. Adding all shipments under this option would produce a total of 1,664 shipments at a rate of 333 per year.
- Option 2c - Processing - In this option, all aluminum-clad fuel would move from its present location to the process facilities. All nonaluminum-clad fuel would remain in its present storage locations. The result would be in a total of 380 shipments. As in the previous options, this number would double for a total of 760 shipments. Therefore, over 5 years this option would have an average shipping rate of 152 shipments per year.

A.2.9.2.3 Alternative 3 - Planning Basis

- Option 3a - Dry Storage - The movement of materials for this option would be identical to that for Option 2a, resulting in a total of 1,564 shipments at a rate of 313 per year.
- Option 3b - Wet Storage - The movement of materials for this option would be identical to that for Option 2b, with the exception of a delay in the receipt of foreign fuel until the new facilities are in operation. This would result in a total of 1,564 shipments at a rate of 313 per year.
- Option 3c - Processing - The movement of materials for this option would be identical to that for Option 2c, resulting in a total of 760 shipments at a rate of 152 shipments per year.

A.2.9.2.4 Alternative 4 - Regionalization

- Option 4a - Dry Storage - For this option, initial shipments would be the same as Alternative 1 (760 shipments at a rate of 152 per year). Subsequent shipments of the aluminum-clad fuel to the new dry storage facilities would total 380 shipments. (Note: Nonaluminum-clad fuel would be sent offsite from the reactor basins and would not contribute to any further onsite movements.). Because fuel handling would occur at both origin and destination, this number would double (i.e., 760 total shipments). Because all fuel would move to dry storage within about 5 years, this total would have an average shipping rate of 152 shipments per year. Adding all shipments would produce a total of 1,520 shipments at a rate of 304 per year.
- Option 4b - Wet Storage - The movement of materials for this option would be identical to that for Option 3b, with the exception of movement of the nonaluminum-clad fuel to the new wet storage facility. This fuel would move off the Site from the reactor basins and would not contribute to any further onsite movements. This would result in

a total of 1,520 shipments at a rate of 304 per year.

- Option 4c - Processing - The movement of materials for this option would be identical to that for Options 2c and 3c, resulting in a total of 760 shipments at a rate of 152 per year.
- Option 4d - Dry Storage - The movement of materials for this option would be identical to those for Options 2a and 3a, resulting in a total of 1,564 shipments at a rate of 313 per year.
- Option 4e - Wet Storage - The movement of materials for this option would be identical to that for Option 3b, resulting in a total of 1,564 shipments at a rate of 313 per year.
- Option 4f - Processing - The movement of materials for this option would be identical to those for Options 2c, 3c, and 4c, resulting in a total of 760 shipments at a rate of 152 per year.
- Option 4g - Ship Out - This option would require the shipping of all spent nuclear fuel at the SRS to a selected regional location. The movement of materials for this option would include the entire spent nuclear fuel inventory at the SRS, resulting in a total of 402 shipments at a rate of 81 per year.

A.2.9.2.5 Alternative 5 - Centralization

- Option 5a - Dry Storage - The movement of materials for this option would be identical to those for Options 2a and 3a, resulting in a total of 1,564 shipments at a rate of 313 per year.
- Option 5b - Wet Storage - The movement of materials for this option would be identical to that for Option 3b, resulting in a total of 1,564 shipments at a rate of 313 per year.
- Option 5c - Processing - The movement of materials for this option would be identical to those for Options 2c, 3c, and 4c, resulting in a total of 760 shipments at a rate of 152 shipments per year.
- Option 5d - Ship Out - This option would require the shipping of all spent nuclear fuel at the SRS to a selected central location. The movement of materials for this option would include the entire spent nuclear fuel inventory at the SRS, resulting in a total of 402 shipments at a rate of 81 per year.

A.2.9.3 Methodology for Determination of Offsite Shipping Frequencies.

This evaluation determined the total number of offsite shipments using the data contained in Volume 1, Appendix I, "Offsite Transportation of Spent Nuclear Fuel." The total number of Naval Fuel shipments was determined from Table 3 of "Methodology for Adjusting SNF Facility Accident Probabilities and Consequences For Different EIS Alternatives" (dated March 18, 1994).

Naval, foreign, and university shipments would occur throughout the interim management period and could be averaged over the 40-year period **covered by this EIS.** All other shipments would be averaged over 5 years.

A.2.9.4 Frequency Adjustment Factors for Fuel Handling. For this

analysis, DOE assumed the baseline fuel handling rate (events per year) to be the No Action alternative. For the other alternatives, this evaluation divided the expected spent nuclear fuel handling rate by the baseline spent nuclear fuel handling rate (No Action) to obtain the adjustment factor (see Table A-10).

A.2.9.5 Frequency/Consequence Adjustment Factors Due to Inventory. The

No Action alternative for the SRS would require the storage of 206 MTHM

(227 tons) of fuel. Using this amount as the baseline, this evaluation compared the amount of fuel for the other alternatives to the base number, as listed in Table A-11. These adjustment factors can be applied to either a frequency or a consequence, depending on the classification of the accident scenario as listed in Table A-8.

A.3 Chemical Hazard Evaluation

A.3.1 Selection of Reference Chemical Hazard

A review of the same safety analyses used to generate the spectrum of radiological accident scenarios failed to identify a quantitative discussion of chemical hazards. However, each of the safety analyses provided a qualitative discussion of chemical hazards. Thus, Section 5.15.3 discusses chemical hazards associated with existing spent nuclear fuel facilities qualitatively. This qualitative evaluation was determined to be appropriate based on three criteria: sliding scale in proportion to significance, public perception of severity, and long-term effects of chemicals not known. For completeness, a separate risk assessment (WSRC 1993c) provided a quantitative discussion of chemical hazards for the Receiving Basin for Offsite Fuel facility. This assessment described a bounding chemical hazard accident involving the release of nitrogen dioxide vapor.

Table A-10. Fuel handling frequency adjustment factors.

Option Number	Estimated Annual Shipping Rate	Frequency Adjustment Factor
Alternative 1 - No Action		
Option 1	152	Baseline
Alternative 2 - Decentralization		
Option 2a	316	2.08
Option 2b	333	2.19
Option 2c	157	1.03
Alternative 3 - Planning Basis		
Option 3a	375	2.47
Option 3b	375	2.47
Option 3c	216	1.42
Alternative 4 - Regionalization		
Option 4a	421	2.77
Option 4b	421	2.77
Option 4c	269	1.77
Option 4d	394	2.59
Option 4e	394	2.59
Option 4f	234	1.54
Option 4g	160	1.05
Alternative 5 - Centralization		
Option 5a	803	5.28
Option 5b	803	5.28
Option 5c	643	4.23
Option 5d	160	1.05

Table A-11. Inventory adjustment factors for each alternative.

Alternative	Inventory[a] (MTHM[b])	Adjustment Factor
No Action	206.27	Baseline
Decentralization	219.89	1.07
Planning Basis	222.76	1.08
Regionalization - A	213.09	1.03
Regionalization - B	256.62	1.24
Centralization	2,741.80	13.30

a. Source: Wichmann (1995).

b. Metric Tons Heavy Metal; to convert to tons, multiply by 1.1023.

A.3.2 Hazardous Chemical Inventories

The inventory of hazardous chemicals at each facility was determined by using the "Savannah River Site Tier Two Emergency and Hazardous Chemical Inventory Report" (WSRC 1994a) to get the facility's total chemical inventory, then listing those chemicals that also appeared on the EPA's "List of Lists"

(EPA 1990). The chemical inventories listed in Tables A-12 through A-15 represent facilities used for wet storage and/or processing of spent nuclear fuel. The SRS maintains no large-scale dry storage facilities; thus, chemical inventories for dry storage facilities are not listed.

Table A-12. Hazardous chemical inventory for the Receiving Basin for Offsite Fuel.

Chemical	Maximum Daily Amount (Kg)a	Average Daily Amount (Kg)
Ethylene glycol	2,981	23
Methyl ethyl ketone	2	2
Nitric acid	4,731	2,365
Phosphoric acid	3,953	3,953
Sodium hydroxide (caustic soda)	5,800	2,900
Sodium nitrite	3,070	1,535

a. To convert kilograms to pounds, multiply by 2.2046.

Table A-13. Hazardous chemical inventory for the reactor basins (typical).

Chemical	Maximum Daily Amount (Kg)a	Average Daily Amount (Kg)
Aluminum sulfate (solution)	570	230
Ethylene glycol (thermal arc torch coolant concentrate)	2	2
Hydrogen peroxide	1	1
Nitric acid	75	75
Sodium hydroxide	454	454
Sodium hypochlorite	11	6
Zinc	0.5	0.5

a . To convert kilograms to pounds, multiply by 2.2046.

Table A-14. Hazardous chemical inventory for H-Area.

Chemical	Maximum Daily Amount (Kg)a	Average Daily Amount (Kg)
Dichlorodifluoromethane (Freon 12)	227	68
Dichlorodifluoromethane (Racon 12)	227	0
Ethylene glycol	4.0	2.0
Hydrofluoric acid	1	0.5
Hydrogen peroxide	0.5	0.0
Mercury	4,900	4,900
Methyl ethyl ketone	3	3
Nitric acid	10	5
Nitric oxide	1,300	1,300
Phosphorus pentoxide	1	1
Potassium permanganate (Cairox)	200	100
Sodium hydroxide	1	1
Sodium hypochlorite	41	29
Sulfuric acid	1	0.5
Trichlorofluoromethane (Freon 11)	1,150	1,000
Trichlorofluoromethane (Genetron 11)	450	0

a . To convert kilograms to pounds, multiply by 2.2048.

Table A-15. Hazardous chemical inventory for F-Area.

Chemical	Maximum Daily Amount (Kg)a	Average Daily Amount (Kg)
Dichlorodifluoromethane (Freon 12)	1	0.5
Dichlorodifluoromethane (Racon 12)	1	0
Ethylene glycol	4	2
Hydrofluoric acid	1,177	1,177
Potassium permanganate	3	1
Sodium hydroxide	0.5	-
Sodium hypochlorite	7	4
Sulfuric acid	30	-
Trichlorofluoromethane (Freon 11)	900	450

a . To convert kilograms to pounds, multiply by 2.2048.

SUMMARY

INTRODUCTION

Volume 1 to the Department of Energy's Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Management Programs Environmental Impact Statement evaluates a range of alternatives for managing naval spent nuclear fuel expected to be removed from U.S. Navy nuclear-powered vessels and prototype reactors through the year 2035. The Environmental Impact Statement (EIS) considers a range of alternatives for examining and storing naval spent nuclear fuel, including alternatives that terminate examination and involve storage close to the refueling or defueling site. The EIS covers the potential environmental impacts of each alternative, as well as cost impacts and impacts to the Naval Nuclear Propulsion Program mission.

This Appendix covers aspects of the alternatives that involve managing naval spent nuclear fuel at four naval shipyards and the Naval Nuclear Propulsion Program Kesselring Site in West Milton, New York. This Appendix also covers the impacts of alternatives that involve examining naval spent nuclear fuel at the Expended Core Facility in Idaho and the potential impacts of constructing and operating an inspection facility at any of the Department of Energy (DOE) facilities considered in the EIS. This Appendix also considers the impacts of the alternative involving limited spent nuclear fuel examinations at Puget Sound Naval Shipyard. This Appendix does not address the impacts associated with storing naval spent nuclear fuel after it has been inspected and transferred to DOE facilities. These impacts are addressed in separate appendices for each DOE site.

BACKGROUND

The Naval Nuclear Propulsion Program is a joint U.S. Navy and DOE program responsible for all matters pertaining to naval nuclear propulsion. The Program is responsible for the nuclear propulsion plants aboard over 120 nuclear-powered warships powered by over 140 naval reactors and for nuclear propulsion work performed at six naval shipyards and two private shipyards. Removal of spent nuclear fuel from ships is ending at two of those shipyards as a result of recent decisions on base closures, and nuclear propulsion work at one of the private shipyards has not involved handling spent nuclear fuel for more than 15 years. The Program is also responsible for two government-owned, contractor-operated laboratories, two moored training ships, three land-based prototype reactors, and the Expended Core Facility located at the Naval Reactors Facility. The Naval Reactors Facility is located at the Idaho National Engineering Laboratory (INEL).

NAVAL SPENT NUCLEAR FUEL MANAGEMENT

Naval spent nuclear fuel is the fuel removed from naval nuclear propulsion plants. Naval fuel is designed to meet the demanding requirements needed to support long-term operation in a warship. To meet these requirements, it is designed to withstand battle shock and to retain its radioactivity so as to minimize radiation dose to the ships' operating personnel who must live and work in close proximity to the reactor. Even after decades of service, the spent nuclear fuel retains its strength and high integrity.

For nearly 40 years, naval spent nuclear fuel has been shipped by rail in shielded shipping containers from naval shipyards and prototypes to the Expended Core Facility in Idaho where it is removed from the shipping containers and placed into water pools at the Expended Core Facility. All fuel is examined for specific characteristics and for abnormalities. Selected fuel is given more detailed examination. Naval fuel examinations provide assurance that operations of shipboard reactors can continue without restriction. These examinations have significantly contributed to the longer core lives and continued safe performance of current naval reactor designs. This work has also resulted in substantial reduction in the amount of spent nuclear fuel generated by the Naval Nuclear Propulsion Program.

DESCRIPTION OF ALTERNATIVES

The EIS considers five general alternatives for spent nuclear fuel management. The general alternatives are described in Chapter 3 of Volume 1. Naval spent nuclear fuel would be managed under each of these general alternatives as follows.

No Action

Naval reactors would be refueled and defueled as planned. Naval spent nuclear fuel would be stored in transport casks at the Navy or DOE facility where defueling was conducted. (Fuel generated from ships at Newport News Shipbuilding would be transferred to Norfolk Naval Shipyard.) No further spent nuclear fuel examination would be conducted. This alternative would require a phase-in period while additional containers are procured for spent nuclear fuel storage. During an approximately 3-year period, spent nuclear fuel would be transported in shipping containers to the Expended Core Facility in Idaho. The containers would be unloaded and used to support additional refuelings and defuelings.

Decentralization

For naval spent nuclear fuel, three options are considered. Each option would require a phase-in period while facilities are developed. The length of the phase-in period would depend on the option and mode of storage selected. During the phase-in period, spent nuclear fuel would be transported in shipping containers to the Expended Core Facility in Idaho. The containers would be unloaded and used to support additional refuelings and defuelings.

a. Store naval spent nuclear fuel at the Navy or DOE facility where defueling is conducted. (Fuel generated from ships at Newport News Shipbuilding would be transferred to Norfolk Naval Shipyard.) At each storage location, dry storage in shipping containers and dry casks as well as wet storage in a water pool facility are considered.

b. Modify the existing water pool facility at Puget Sound Naval Shipyard to conduct the maximum practical amount of naval spent nuclear fuel examinations at that site. Store naval spent nuclear fuel at the Navy or DOE facility where defueling is conducted. (Fuel generated from ships at Newport News Shipbuilding would be transferred to Norfolk Naval Shipyard.) At each storage location, dry storage in shipping containers and dry casks as well as wet storage in a water pool facility are considered.

c. Ship naval spent nuclear fuel to the Expended Core Facility for examination, then return the fuel after examination to the Navy or DOE facility where defueling is conducted. (Fuel generated from ships at Newport News Shipbuilding would be transferred to Norfolk Naval Shipyard.) At each storage location, dry storage in shipping containers and dry casks as well as wet storage in a water pool facility are considered.

1992/1993 Planning Basis

The historic practice of transporting all spent nuclear fuel removed from naval reactors to the Expended Core Facility in Idaho for examination would resume. Following examination, fuel would be transferred to DOE for management at the Idaho Chemical Processing Plant pending final disposition.

Regionalization

The overall Regionalization alternative includes two options. The first option involves managing spent nuclear fuel at three DOE sites (Hanford Site, the INEL, and the Savannah River Site) based on fuel type. Under this option, the historical practice of transporting spent nuclear fuel removed from naval reactors to the Expended Core Facility in Idaho for examination would resume. Following examination, fuel would be transferred to DOE for management at the Idaho Chemical Processing Plant pending final disposition.

The second overall option involves managing spent nuclear fuel at a Western Regional Site and an Eastern Regional Site, based primarily on the originating location of the fuel. Under this option, naval fuel would be allocated to one site, either the western or the eastern site, for examination and storage. This Appendix evaluates the potential impacts of examining naval spent nuclear fuel at all of the potential sites.

Centralization

The Centralization alternative would collect all of the DOE's current and future spent nuclear fuel at one DOE site. The Hanford Site, the INEL, the Nevada Test Site, the Oak Ridge Reservation, and the Savannah River Site have been considered as candidates for this single site. If the INEL were selected, then naval spent nuclear fuel would be examined at the Expended Core Facility and would be stored at the Idaho Chemical Processing Plant. If a site other than INEL were selected, then the Expended Core Facility would be shut down and a new or modified facility for examination and additional storage facilities would be constructed at the selected site.

SITES CONSIDERED FOR NAVAL SPENT NUCLEAR FUEL MANAGEMENT

Naval Shipyards and Prototypes - The EIS evaluates four naval shipyards, Puget Sound Naval Shipyard at Bremerton, Washington; Norfolk Naval Shipyard at Portsmouth, Virginia; Portsmouth Naval Shipyard at Kittery, Maine; and Pearl Harbor Naval Shipyard at Pearl Harbor, Hawaii, for management of naval spent nuclear fuel only. The EIS also evaluates the Kenneth A. Kesselring Prototype Site at West Milton, New York. The four shipyard locations are industrial in nature and located near harbor areas. The Kesselring Site is a 3900-acre facility located in the mid-eastern sector of New York State in a wooded rural environment.

Idaho National Engineering Laboratory - This is the location of the Naval Reactors Facility which is also the present location of the Expended Core Facility. It is located in southeastern Idaho and occupies about 890 square miles of desert. The Idaho National Engineering Laboratory is presently used for industrial and support operations associated with energy research and waste management activities, grazing, recreational uses, and environmental research. It is remote from urban areas and occupies a controlled federal reservation which is largely undisturbed from its natural state.

Savannah River Site - The Savannah River Site in South Carolina is the location of one of the Department of Energy's weapons production sites. The P, K, and L Reactors at this location produced plutonium and tritium in support of the nation's nuclear weapons program. The Savannah River Site is located in the eastern United States and is in a heavily wooded environment which is returning to a more natural state from its previous agricultural uses. It is 310 square miles in area.

Hanford Site - The Hanford Site in the State of Washington is the location of one of the Department of Energy's weapons production sites. The N-Reactor at this site was used by the DOE through the years for the production of plutonium in support of the nation's nuclear weapons program. The Hanford Site is in the western United States on open, vacant desert land. It is 560 square miles in area which is largely undisturbed from its original state.

Oak Ridge Reservation - The Oak Ridge Reservation in Tennessee is the location of one of the Department of Energy's facilities which was primarily used to support the nation's nuclear weapons program. The Y-12 Plant at this location was used for processing highly enriched uranium for fuel elements used in the Savannah River reactors. The Oak Ridge Reservation is located in the eastern United States and is in a heavily wooded environment. It is 55 square miles in area, and consists of three industrialized areas separated by undeveloped forest land.

Nevada Test Site - The Nevada Test Site in Nevada has been a location for performing nuclear weapons testing. This site has been used by the DOE for activities in support of the national nuclear weapons program. The Nevada Test Site is in the western United States and is located in open, vacant desert land. It is 1350 square miles in area.

ANALYSES

This EIS evaluates the potential environmental impact of each alternative, including both the construction of new facilities and management operations at those facilities (transport, receipt, handling, examination, and storage of naval spent nuclear fuel). In general, accident analyses focus on accidents which have the probability to occur at least once every 10 million years. The range of accidents considered includes those resulting from human errors or mechanical failure such as airplane crashes into storage facilities and improper spent nuclear fuel handling, as well as natural disasters such as earthquakes and tornadoes. Both radiological and non-radiological impacts were considered.

The cumulative impacts of spent nuclear fuel management and other operations at these facilities have also been evaluated.

RESULTS AND COMPARISON OF ALTERNATIVES

Implementation of some of the alternatives would require construction or modification of facilities for storage of naval spent nuclear fuel at naval sites or a replacement for the Expended Core Facility at a DOE site. The locations for any new facilities would be selected from space already available on existing federally owned property, so no additional land would be withdrawn from public use at any site. The only exception to this might occur if the Barnwell Nuclear Fuel Plant at Savannah River were to be purchased and removed from the public domain. New facility locations would be chosen to avoid impacts on the cultural, archaeological, aesthetic, or scenic values of the area and to ensure that the rights or interests of Native American or Native Hawaiian groups would not be infringed. No site listed in the National Register of Historic Places would be affected. Ecologically sensitive areas, such as those in the vicinity of any threatened or endangered species, would be avoided. Construction activities associated with any naval spent nuclear fuel storage or examination facility would comply with all applicable laws and regulations, using established procedures for preserving air and water quality and previously unknown archaeological or cultural artifacts encountered and for minimizing such impacts as noise and disturbance or destruction of habitat.

No new naval spent nuclear fuel storage or examination facility would release water carrying radioactive or hazardous material to the environment. In 40 years of receipt, transportation, handling, and examination of naval spent nuclear fuel, the Naval Nuclear Propulsion Program has never had a release of radioactivity that has had a significant effect on the environment. Based on the operations that would be performed and the controls that would be in place, the impacts on air, water, ecological, or geological resources of any naval facility considered would be negligible. Furthermore, experience has shown that since naval spent nuclear fuel management is a low-intensity industrial activity, its contributions to noise and traffic would be inconsequential and its utility needs would generally be within the capabilities of the candidate sites. The Hanford Site and Nevada Test Site are possible exceptions to this because they are already operating at or near their electrical utility capacities and may require additional capacity to accommodate a new Expended Core Facility.

In the unlikely event of any accident involving naval spent nuclear fuel, it is estimated that no more than 210 acres of land would be affected for the most severe case, and in the other accidents analyzed, smaller areas of land would be affected. The affected area would require decontamination and during this cleanup, access controls would have to be established. However, due to the limited land area affected, it is judged that these restrictions would only be temporary and the impact on issues such as economics, treaty rights, tribal resources, ecology, and land use would be small and limited in time. The remediation actions would be simpler in rural areas than in urban areas, but, provided that prudent controls and remediation operations were promptly implemented, the affected land and buildings could be recovered in either case. As demonstrated in the accident analyses in this appendix, the human health effects would not be large and the effects on wildlife and other biota would also not be large, partly due to the relatively small area affected and partly because of the limited effects of the accident.

The radiological and non-radiological impacts of all the alternatives considered would be small. After consideration of the full range of environmental impacts and other effects associated with the management of naval spent nuclear fuel, it is judged that for all of the alternatives considered, the impacts on the ecology, cultural and aesthetic values, air and water resources, geology, and such areas as noise, traffic, and utilities, normally associated with most daily activities, would be so small and differ so little among alternatives for naval spent nuclear fuel that they would be of little assistance in differentiating among the alternatives.

The areas of impact which are of special interest to the public or which provide the most distinct contrasts among the alternatives are public health, socioeconomics, cost, and the Naval Nuclear Propulsion Program mission.

Public Health Impacts

A primary concern for most people is the risk to the public from exposure to radiation or radioactive material for each of the alternatives. The exposure could be a result of normal operations or an accident. A practical method often used to characterize the public risk resulting from federal actions such as these is to estimate the number of prompt fatalities or cancer fatalities that might result.

The analyses in this EIS show that there would be no prompt fatalities from the radiation exposure associated with accidents (or normal operations) for any of the alternatives considered and that there would be no latent cancer fatalities under any of the alternatives. However, for the No Action and Decentralization alternatives, under which naval spent nuclear fuel would be stored at a naval shipyard, the risks to a member of the public would be higher than for other alternatives.

Figure S-1 provides an overall comparison of the alternatives in terms of the calculated increase in the number of cancer fatalities that might occur in the general population over 40 years of operation for each alternative. It is important to emphasize that these cancer fatalities are calculated results rather than actual expected fatalities. This is because the expected number of such fatalities during normal operations is so small as to be indistinguishable relative to the larger number of such deaths expected from naturally occurring conditions and other man-made effects not related to naval spent nuclear fuel operations. This is not meant to trivialize the importance of radiation-induced cancer fatalities but, rather, is meant to put the issue in perspective. In all the alternatives, thousands of years of facility operation and transportation of naval spent nuclear fuel would be required before a single additional fatal cancer might be expected to occur. To provide some perspective, the naturally occurring radioactive materials in fertilizer used to produce food crops contribute about 1 to 2 millirem per year to an average American's exposure to radiation. Using the same calculational method used to determine the cancer fatality risk for the Naval Nuclear Propulsion Program alternatives, the exposures from consuming food grown with fertilizer result in 125 to 250 cancer fatalities annually in the United States.

Figure S-1. Risk from normal operations by alternative (fatal cancers to the general population over 40 years from facility operations and transportation).

The most severe risks for a facility accident were determined to be from an airplane crash into a dry storage container at the Pearl Harbor Naval Shipyard. This accident was calculated to result in 26 cancer fatalities and had a probability of occurring about once every 100,000 years. This accident has been calculated to produce a risk of less than 0.0003 additional cancer fatalities per year. The risks from all other accidents associated with examination or storage of naval spent nuclear fuel were much less than this. In general, the risks from facility accidents tended to be worse for the No Action and Decentralization alternatives, because for these alternatives fuel would be stored at sites which are located close to large population centers. For transportation accidents, the potential risks varied with the distances to be traveled, being least for the No Action and the Decentralization - No Examination alternatives which would involve transportation over short distances to storage locations near where the fuel is removed from reactors.

Socioeconomic and Cost Impacts

The socioeconomic impacts of implementing each of the alternatives would differ somewhat and are summarized in Table S-1. The primary socioeconomic impact of the alternatives considered would be on employment. Nation-wide employment levels would not vary significantly among alternatives for managing naval spent nuclear fuel and therefore do not provide a basis to distinguish among the alternatives. The maximum impact on local employment levels would be caused by alternatives requiring development of new naval spent nuclear fuel examination capability at a DOE facility other than INEL while terminating these activities at INEL. Continuing current practices of transporting naval spent nuclear fuel to the Expended Core Facility at INEL for examination followed by transfer to the DOE for storage would result in the minimum disruption of employment levels.

As shown in Figure S-2, there are large differences in the costs associated with all alternatives. These costs include the costs that would be incurred from construction of new facilities and containers, naval spent nuclear fuel transportation, and facility operation. In general, lower costs are associated with those alternatives that support examination of naval spent nuclear fuel with existing facilities and those alternatives that terminate or severely curtail spent nuclear fuel examination. The higher costs are associated with those alternatives that require construction of a new Expended Core Facility and those alternatives that use shipping containers for storage.

Table S-1. Summary of potential socioeconomic impacts.

Alternative	Long-term Impacts at INEL	Long-term Impacts at Other Sites
1. No Action	Lose 500 jobs	Add 50-100 jobs at naval sites
2. Decentralization		
- No Examination	Lose 500 jobs	Add 50-200 jobs at naval sites
- Limited Examination	Lose 500 jobs	Add 110-260 jobs at naval sites
- Full Examination	No change	Add 50-200 jobs at naval sites
3. 1992/1993 Planning Basis	No change	No change
4/5. Regionalization or Centralization		

- Idaho National Engineering Laboratory	No change	No change
- Hanford Site	Lose 500 jobs	Add 500 permanent jobs and some construction jobs at Hanford
- Savannah River Site	Lose 500 jobs	Add 500 permanent jobs and some construction jobs at Savannah River
- Nevada Test Site	Lose 500 jobs	Add 500 permanent jobs and some construction jobs at NTS
- Oak Ridge Reservation	Lose 500 jobs	Add 500 permanent jobs and some construction jobs at ORR

Figure S-2. Summary of costs by alternative (facility and transportation costs over 40 years).

Mission Impacts

Two important components of Naval Nuclear Propulsion Program operations are the safe management of naval spent nuclear fuel and support of the Navy's fleet of nuclear-powered warships.

Based on the analyses in this EIS, all alternatives considered would allow safe storage of naval spent nuclear fuel until a permanent repository becomes available. However, some of the alternatives would not provide equal levels of Fleet support. Alternatives which limit or terminate naval spent nuclear fuel examination would severely impact ongoing research and development work. Naval spent nuclear fuel examination results are used to confirm the adequacy of design features, explore material performance, and confirm or adjust computer predictions of fuel performance. This information contributes to the design and manufacturing of new naval reactor cores as well as the safe operation of nuclear-powered warships. Of the alternatives allowing full examination at the INEL, Hanford Site, Savannah River Site, Oak Ridge Reservation, or Nevada Test Site, examination at the INEL would have the smallest mission impact due to the presence of existing facilities and equipment for performing this work, and the presence of a highly skilled work force, all of which would need to be relocated or reassembled if a new examination site were selected.

CONCLUSION - PREFERRED ALTERNATIVE

The Navy's preferred alternative for the management of naval spent nuclear fuel would continue the historic, technically sound and safe practice of conducting refueling and defueling of nuclear-powered warships and prototypes as planned, transporting naval spent nuclear fuel to the Expended Core Facility at INEL for full inspection and examination, and transferring naval spent nuclear fuel to the DOE facility for storage pending availability of a method for permanent disposition. This preferred alternative is based on consideration of environmental, socioeconomic, cost, and mission impacts of each alternative.

The analyses contained in this EIS demonstrate that the environmental impacts of implementing any of the alternatives would be very small for normal operations and accident conditions. The analysis results do not provide a basis to distinguish among the alternatives in most of these areas. The socioeconomic impacts of the alternatives also do not provide a basis to distinguish among the alternatives.

The Navy's preferred alternative is, therefore, based on impacts to the Navy's mission and on cost. Alternatives that limit or terminate naval spent nuclear fuel examination would adversely affect Fleet support and the development of new naval reactors. Primarily because of the existing infrastructure, examination followed by storage at INEL would best support the Naval Nuclear Propulsion Program mission and would be the least cost alternative allowing for full examination of naval spent nuclear fuel.

The alternatives which involve the Navy's preferred alternative are: 1992/1993 Planning Basis alternative and the Regionalization and Centralization alternatives that include the use of the Expended Core Facility at INEL.

1. INTRODUCTION

This appendix describes the alternatives which have been evaluated for the examination and storage of spent nuclear fuel from U. S. naval nuclear shipboard and prototype reactors. The spent fuel is removed during reactor refuelings and defuelings at naval and commercial shipyards and at the prototype sites. The alternatives include a range of options for managing naval spent fuel through the year 2035. The options for spent fuel examination include ceasing all examinations, examining a limited amount of fuel at a naval shipyard, and performing a full range of examinations at the current facility (Idaho National Engineering Laboratory) or at another Department of Energy (DOE) facility. The options for naval spent fuel storage include storage at the refueling and defueling sites (in some cases, it is necessary to move the fuel to the closest acceptable Navy shipyard), storage at the current facility, or storage at another DOE facility. Spent fuel transportation aspects will depend on the examination and storage alternatives selected.

Naval spent fuel examination, whether at a naval or DOE site, will remain the responsibility of the Naval Nuclear Propulsion Program. This appendix therefore addresses the environmental impacts of naval spent fuel examination. This appendix also addresses the environmental impacts of long-term storage of spent fuel at naval shipyards and prototype sites. The environmental impacts of long-term spent fuel storage at DOE facilities are addressed in the Environmental Impact Statement appendices applicable to those sites.

2. BACKGROUND

2.1 NAVAL NUCLEAR PROPULSION PROGRAM OVERVIEW

The Naval Nuclear Propulsion Program is a joint Navy/Department of Energy (DOE) organization responsible for all matters pertaining to naval nuclear propulsion pursuant to Presidential Executive Order 12344, enacted as permanent law by Public Law 98-525 (42 USC 7158). The Program is responsible for:

a. The nuclear propulsion plants aboard over 120 warships powered by over 140 naval reactors.
b. Moored Training Ships located in Charleston, South Carolina used for naval nuclear propulsion plant operator training.
c. Nuclear propulsion work performed at eight shipyards (six public and two private).
d. Two DOE government-owned, contractor-operated laboratories devoted solely to naval nuclear propulsion research, development, and design work.
e. Three land-based prototype naval reactors used for research and development work and training of naval nuclear propulsion plant operators.
f. The Expended Core Facility, located at the Naval Reactors Facility which is a part of the Idaho National Engineering Laboratory.

More detailed discussion is available in the references listed in Section 2.6 (DOE/DOD 1994; Duncan 1990; Hewlett and Duncan 1974).

2.2 HISTORY AND MISSION OF THE PROGRAM

In 1946, at the conclusion of World War II, Congress passed the Atomic Energy Act, which established the Atomic Energy Commission (AEC) to succeed the wartime Manhattan Project, and gave it the sole responsibility for developing atomic energy. At that time, Captain Hyman G. Rickover was assigned to the Navy Bureau of Ships, the organization responsible for naval ship design. Captain Rickover recognized the military implications of successfully harnessing atomic power for submarine propulsion, and that it would be necessary for the Navy to work with the AEC to develop such a program. By 1949, Captain Rickover had forged an arrangement between the AEC and the Navy that led to the formation of the Naval Nuclear Propulsion Program. In 1954, the nuclear submarine USS NAUTILUS put to sea and demonstrated the basis for all subsequent U.S. nuclear-powered warship propulsion designs. In the 1970's, government restructuring moved the AEC part of the Naval Nuclear Propulsion Program from the AEC (which was disestablished) to what became the Department of Energy. Although the Naval Nuclear Propulsion Program grew in size and scope over the years, it retained its dual responsibilities within the Department of Energy and the Department of the Navy, and its basic organization, responsibilities, and technical discipline have remained much as when it was first established.

By eliminating altogether the need for oxygen for propulsion, nuclear power offered a way to drive a submerged submarine without the need to resurface frequently. In addition, nuclear power offered a way to drive a submerged submarine at high speed without concern for fuel consumption.

Nuclear propulsion, though originally developed for submarines, significantly enhances the military capability of surface ships. Nuclear propulsion provides virtually unlimited high-speed endurance without dependence on tankers and their escorts. Moreover, the space normally required for propulsion fuel in oil-fired ships can be used for weapons and aircraft fuel in nuclear-powered ships.

Naval fuel is designed to meet the very stringent operational requirements for naval nuclear propulsion reactors. Because of its military design, it will maintain its integrity indefinitely under the far less demanding conditions encountered during land-based storage. Naval fuel is designed to operate in a high-temperature and high-pressure environment for many years. Current designs are capable of over 20 years of successful operation. Measurements of the corrosion rates for current naval fuel designs have shown that naval spent nuclear fuel could be safely stored for periods far, far longer than the 40 years considered in this Environmental Impact Statement (EIS) in the cool water or air used for storage. Naval fuel uses highly corrosion-resistant materials for fuel and cladding which can withstand high-intensity radiation and harsh environments. As a result, the fuel is very strong and has very high integrity. The fuel is designed, built, and tested to ensure that the fuel construction will contain and hold the radioactive fission products. Naval fuel totally contains fission products within the fuel - there is no fission product release from the fuel in normal operation. Since the nuclear reactor core contains a large quantity of fission products, it is essential to contain them within the nuclear fuel in order to minimize radiation exposure to a ship's crew. Naval fuel is extremely rugged. It can withstand combat shock loads which are well in excess of 10 times the seismic loads for which commercial nuclear power plant fuel is designed. It routinely operates with rapid changes in power level since naval ships must be able to change speed quickly in operational situations. Naval fuel consists of solid components which are non-explosive, non-flammable, and non-corrosive. The ruggedness of naval fuel is demonstrated by the fact that two nuclear-powered ships were lost at sea in the 1960's, and subsequent environmental monitoring shows no release of fission products from the fuel despite the catastrophic nature of the loss of the ships (NNPP 1994a). Also, naval spent nuclear fuel examined after 28 years of storage in a water pool exhibited no detectable deterioration. Although spent nuclear fuel is highly radioactive, it is not regarded as "waste"; it requires special handling procedures, shielding, and other measures to isolate it from people and the environment.

The integrity of naval nuclear fuel is due in part to a long-standing program of examination of spent fuel after it has been removed from prototype reactor plants and operating ships. These examinations have been conducted at the Idaho National Engineering Laboratory (INEL) since the beginning of the Naval Nuclear Propulsion Program. Construction and early operation of the original INEL Expended Core Facility (ECF) occurred between 1957 and 1962. The original building contained a water pool and nine shielded cells connected to the water pool by a transfer tunnel. As examination requirements changed, the ECF underwent several expansion programs.

The first and second expansions, in 1962 and 1963, were prompted by the initiation of irradiated test specimen examinations at ECF. In the 1970's, the third expansion occurred with the addition of new, larger hot cells. The fourth expansion (1979-1987) included the extension of the ECF building and water pools for the addition of the Breeding Nondestructive Assay Facility. This addition was for the receipt and examination of the Light Water Breeder Reactor nuclear fuel following its operation in the former PWR Shippingport Atomic Power Station. The work at ECF has continued at or near capacity, receiving, handling, and examining spent fuel from naval reactor plants.

The examinations of naval spent nuclear fuel are essential to meeting the goals of the Naval Nuclear Propulsion Program. The primary goals that are supported by examinations are:

- Continued safety of naval reactors
- The design of new reactors having extended lifetimes
- Improvements in nuclear fuel performance
- Demonstration of satisfactory operation of existing naval reactors by providing confirmation of their proper design and allowing maximum depletion of their fuel
- Validation of design models for new core types.

The goal of the extended lifetime reactor design is to have the reactor core last for the life of the ship. Such a design would eliminate the need to refuel the reactor during its useful lifetime. It would also reduce the cost of fueling the ship, and would increase the time that such a ship would be in active service rather than being refueled.

This EIS assumes that the extended-lifetime goal is partially achieved. Based on current technology, the EIS assumes that each of the three SEAWOLF submarines will need to be refueled once during the period to the year 2035. Based on anticipated developments supported by new data from the examinations of naval spent nuclear fuel, this EIS also assumes that each of the New Attack Submarine Class will not need to be refueled during the period to 2035.

If the examinations of naval spent nuclear fuel are terminated and the goal of a life-of-the-ship core is not achieved, more naval spent nuclear fuel will be created than is otherwise anticipated. The number of shipments of naval spent nuclear fuel during the period from 1995 to 2035 would increase from about 580 to about 630 and the corresponding amount of naval spent nuclear fuel would increase from 65 metric tons of heavy metal (MTHM) to about 70 metric tons of heavy metal.

Similarly, the goals for safety, improved fuel performance, and satisfactory operation of naval reactors will depend on continuing the examinations of naval spent nuclear fuel.

2.3 REGULATORY FRAMEWORK

The Naval Nuclear Propulsion Program includes activities conducted by both the U.S. Navy and the Department of Energy. Executive Order 12344, enacted as permanent law by Public Law 98-525, and the Atomic Energy Act of 1954 establish the responsibility and authority of the Director of the Naval Nuclear Propulsion Program (who is also the Deputy Assistant Secretary for Naval Reactors within the Department of Energy) for all facilities and activities that comprise the Program. These executive and legislative actions establish that the Director is responsible for all matters pertaining to naval nuclear propulsion, including direction and oversight of environmental, safety, and health matters for all program facilities and activities.

The federal permits, licenses, and other entitlements listed below may need to be obtained to implement the alternative selected. Existing federal permits, licenses, and entitlements will be modified as required. Applicable state and local permits, licenses, and entitlements will be obtained or modified, as necessary.

- National Pollutant Discharge Elimination System (NPDES) Permit as required by the Federal Water Pollution Control Act (FWPCA), 33 U.S.C. - 1251 et seq.
- NPDES General Permit for Stormwater Discharges from Construction Sites as required by the FWPCA, 33 U.S.C. - 1251 et seq.
- Permit to emit hazardous air pollutants (radionuclides) under the Clean Air Act (CAA), 42 U.S.C. - 7401 et seq., as amended by the Clean Air Act Amendments of 1990.
- Department of Energy Certificate of Compliance for Radioactive Materials Packages in accordance with the Atomic Energy Act (AEA), 42 U.S.C. - 2011 et. seq.

2.4 NAVAL SPENT NUCLEAR FUEL

2.4.1 Summary of Naval Spent Nuclear Fuel Operations

For approximately 40 years, naval spent nuclear fuel has been shipped by rail to the Naval Reactors Facility at the INEL, where it is removed from the shielded shipping containers and placed into the water pools at the ECF. All spent fuel received at the ECF is visually examined externally for evidence of any unusual condition such as unexpected corrosion, unexpected wear, or structural defects. After the fuel assembly structural components have been removed, the interior of the assembly is examined for the conditions discussed above. In addition, the assembly is examined for distortions from irradiation, heat, or the fission process which could interfere with the even distribution of primary coolant and consequent heat removal. The inspection also checks for possible flow obstructions due to foreign material or excessive corrosion product buildup. About 10 to 20 percent of the spent naval reactor cores are given more detailed examinations for such purposes as confirming the adequacy of new design features, exploring materials performance concerns, and obtaining detailed information to confirm or adjust computer predictions of neutron physics, heat transfer, or hydraulic flow and distortion. These detailed examinations may include metallography to determine corrosion film thicknesses, dimensional measurements to determine fuel assembly distortion, and radiochemical analysis to determine core depletions, as well as other inspections. As discussed below, the examination program is essential in supporting the Navy's continued safe operation of naval reactors and design of new, improved fuel having a longer lifetime.

Examination of all spent naval fuel is essential to the mission of the Navy for three reasons: to provide data on current reactor performance, to validate models used to predict future performance, and to support research to improve reactor design.

Naval fuel examinations provide real data on reactor cores installed in ships currently operating in the fleet. This information is essential to validate calculational models and analyses. Through the years, the Naval Nuclear Propulsion Program has built a substantial technical database from examinations of earlier reactor core types. The Program predicts the performance of current core types with calculational models supported by this database. Essentially no information exists yet on core types that will form the backbone of the nuclear fleet for the foreseeable future (Trident class submarines, LOS ANGELES class submarines, and NIMITZ class aircraft carriers). Data from these reactor core types are necessary to validate basic assumptions of current models, provide a measure of variability which exists between individual cores and within a single core, and identify any unanticipated effects of operation that have not been evaluated or accounted for in current models.

Confidence in the validity of engineering models is essential for assurance that ship operations can continue without restriction. Since reactors operating in the fleet are not taxed to the limits of their design during peacetime operations, the Program requires a technically sound basis for continuing to conclude that we have a robust design. Prototype reactors cannot by themselves provide this information, as their operation is not identical to that of a warship. The fact that a core operated satisfactorily with no indication of a problem during a normal shipboard lifetime does not guarantee that the core would have been acceptable under the worst case conditions for which it was designed. The examination of spent nuclear fuel from each core provides the assurance needed that there are no unexpected technical issues not evaluated and addressed in the models that would affect continued unrestricted operation.

Data from examinations also contribute significantly to improvements in reactor design. Improvements in calculational models and analyses have enabled the Program to increase both the lifetime and the performance of reactor cores. For example, the reactor cores installed in the USS NAUTILUS in the 1950's operated for 2 years. Current reactor cores are designed to last over 20 years, a significant technical accomplishment unique to naval fuel. The Navy is seeking to develop a life-of-the-ship (30-year) core for the New Attack Submarine which is still in the design stages. This core will further reduce the amount of spent fuel generated in the long-term, as ships will not require refueling during their lifetime. Continuing data from current core types are essential if this effort is to succeed.

In the final analysis, examination of naval spent nuclear fuel absorbs considerable resources. In a time of extremely tight budgets, the Navy would not be performing such examinations unless they were judged to be necessary to support the conduct of technical work. Examinations done over the last 37 years have played a key role in achieving over 4500 reactor-years of safe nuclear reactor operations, having nuclear-powered warships steam over 100,000,000 miles, and increasing core lifetimes from 2 years to over 20 years. The record shows there is no reason for reducing the technical basis upon which safe naval reactor design and operation are founded, and that basis includes, as a key cornerstone, the examination of naval spent nuclear fuel.

A limited quantity of naval fuel is retained following examination for reference and further study. After examination, most spent fuel is loaded into shielded containers and transferred to the DOE's Idaho Chemical Processing Plant (ICPP) at the INEL for storage. The transportation of naval spent nuclear fuel from shipyards and prototypes is described in Attachment A. The receipt and handling at ECF of the spent fuel from naval reactors is described in Attachment B.

The Naval Nuclear Propulsion Program evaluates small samples of both fuel and non-fuel materials for possible use in naval reactor systems. The samples are irradiated at the INEL Test

Reactor Area and then examined at ECF. A typical sample undergoes several cycles of irradiation and examination over several months or years.

The basic process for managing naval spent nuclear fuel starts with the spent fuel from the reactor plant loaded in a container. There are many stringent control steps in the actual process that are necessary to ensure the safety and health of the workers, the public, and the environment. These controls have been established by the conservative philosophy of the Naval Nuclear Propulsion Program and, as a minimum, meet the applicable regulations of federal and state agencies. Those controls will also apply to any and all of the alternatives that are being considered for the management of naval spent nuclear fuel.

Historically, the main steps that have been used for many years for managing spent fuel consist of the following:

Step 1. The process starts with spent fuel that has been removed from the reactor and loaded in a shielded shipping container at a prototype site or shipyard authorized to perform naval reactor refuelings or defuelings.
Step 2. The loaded shipping container is transported by rail to the ECF at the INEL.
Step 3. The spent fuel is received at ECF.
Step 4. The spent fuel is separated from structural material and examined in the ECF water pool.
Step 5. The spent fuel is transferred, in a shielded container, to the ICPP.

At the ICPP, naval spent nuclear fuel is stored in water pools to shield workers from radiation. Naval nuclear fuel is designed to operate for decades in high-temperature water without substantial corrosion. This means that it can be stored in the cool water in storage pools with very, very little corrosion for centuries because the rate of corrosion, which is very slow at the temperatures inside naval reactors, decreases rapidly as the temperature of the water around the fuel decreases. Experience at the Expended Core Facility and the Idaho Chemical Processing Plant has shown that naval spent nuclear fuel has not degraded during many years in water pools.

2.4.2 Facilities Related to Naval Spent Nuclear Fuel

The shipyards that perform the refueling and defueling operations are also responsible for shipping the naval spent nuclear fuel to the facility where structural material is removed and examinations are conducted. Since 1957, these operations have been conducted at the ECF at INEL. After the specified operations and examinations are complete, ECF is responsible for transferring the spent fuel to ICPP, the storage location.

The operations at the shipyards for removing the spent fuel from the ship require the use of special, heavily shielded equipment to remove the spent fuel from the reactor to the shipping container (which is also heavily shielded) while protecting the workers from the radiation from the spent fuel. The shipping containers are designed and tested to transport the spent fuel by rail while protecting the workers and any nearby persons from the radiation of the spent fuel. At ECF, the spent fuel is unloaded from the shipping containers with special, heavily shielded transfer casks to protect the workers from radiation. The spent fuel is removed from the transfer cask in the water pool where the depth of the water is sufficient to shield the workers from the radiation of the exposed spent fuel modules. The subsequent machining operations and examinations of the spent fuel are performed in the water pool under the required depth of water, or in a heavily shielded cell where certain operations and examinations can be performed safely. After the work on the spent fuel is completed, the spent fuel is loaded into a shielded transfer cask (under water) for transit to the storage location, such as the ICPP. These are the main pieces of special equipment and facilities that are required to perform the necessary operations with naval spent nuclear fuel. There are many other pieces of equipment and apparatus that are also used along with the main equipment to do the necessary work safely and efficiently.

2.5 PLANNED REDUCTIONS IN THE NUMBER OF NUCLEAR-POWERED NAVAL VESSELS

Following the successful operation of the USS NAUTILUS in 1954, the number of nuclear-powered submarines and surface ships in the U.S. Navy grew steadily until it reached a peak of just over 150 ships in 1987. Report NT-94-2 provides a graph of the total number of nuclear-powered vessels in the U.S. Navy over the years since the beginning of the Naval Nuclear Propulsion Program

(NNPP 1994b). Since 1988, the number of nuclear-powered vessels in the U.S. Navy has decreased. The Navy has been able to accomplish its mission with fewer ships, partly because the ships and crews became more capable over the years and partly because the development of longer-lived nuclear reactor cores makes it possible for nuclear-powered ships to spend more time on duty and less time in shipyards being refueled. A major factor in the reduction in the number of nuclear-powered vessels is that, since the end of the Cold War, the Navy has embarked on a program to reduce the number of warships in its fleet. With the Navy downsizing from a fleet of almost 600 warships to a fleet of just over 300, the number of nuclear-powered warships is also diminishing. The actual size of the nuclear-powered fleet by the year 2000 is expected to be between 80 and 90 vessels having between 95 and 110 reactors (since surface ships have two or more reactors).

Figure 2-1 shows the peak number of nuclear-powered naval vessels in 1987 and the number of nuclear-powered ships in the fleet for each of the next 10 years under current planning. This planned reduction reflects the most recent changes in the mission of the U.S. Navy, including the effects of the end of the Cold War. Under this plan, the number of nuclear-powered naval vessels will be reduced by the end of the next 10 years to approximately one-half the number at its peak. The Navy is moving ahead with this plan, but it should be remembered that such plans may change in the future if Congress alters the Navy's mission in the light of world developments.

This plan for reducing the number of nuclear-powered naval vessels was used in the development of environmental impacts in this Environmental Impact Statement (EIS). For example, the planned reduction in the number of ships in future years is incorporated into all of the impacts associated with examination or storage of naval spent nuclear fuel reported in this EIS. Similarly, the timing and number of naval spent nuclear fuel shipments used in the calculation of impacts associated with transportation are based on this plan.

3. ALTERNATIVES

This section describes the alternatives which were evaluated for the management of naval spent nuclear fuel removed during reactor refuelings and defuelings at naval and commercial shipyards and at the prototype sites. Since Chapter 3 of Volume 1 provides a complete description of the Department of Energy's alternatives for all types of spent nuclear fuel under its cognizance, the descriptions in this section are limited to aspects of the alternatives related to naval spent nuclear fuel.

1. No Action: Spent fuel from naval reactors at naval shipyards and prototype sites would be stored in shielded containers at facilities close to the refueling and defueling sites. There would be no spent fuel examinations.

2. Decentralization: There are three different variations to this alternative. The first is similar to the No Action alternative except that additional spent fuel storage options would be pursued. In the second variation, a limited amount of spent fuel would be examined in detail at Puget Sound Naval Shipyard to provide information on nuclear fuel performance. This limited amount of fuel would be stored at the examination site and the remainder would be stored at or near the refueling

and defueling sites. In the third variation, all spent fuel would be shipped to the Idaho National Engineering Laboratory (INEL) Expended Core Facility (ECF) and examined as it has been in the past, then returned for storage to facilities at or near the refueling and defueling sites; all planned ECF improvements, including the dry cell expansion (Attachment B), would be completed.

3. 1992/1993 Planning Basis: Spent fuel would continue to be received, examined, and stored at INEL as it has been in past years. All planned ECF improvements, including the dry cell expansion (Attachment B), would be completed.

4. Regionalization: Current and future naval spent nuclear fuel would be received, examined, and stored at the Hanford Site, INEL, the Savannah River Site, the Nevada Test Site, or the Oak Ridge Reservation. If INEL were the site selected for Regionalization of naval spent nuclear fuel, then this alternative would be essentially the same as the 1992/1993 Planning Basis alternative.
5. Centralization: Current and future spent fuel would be collected and stored at one Department of Energy (DOE) site. Examination and storage facilities would be constructed, as necessary. All examinations would be performed at that one site. There would be no difference between the Regionalization and the Centralization alternatives for naval spent nuclear fuel.

This section also describes other alternatives which were considered and then eliminated from detailed analysis.

3.1 NO ACTION

This alternative is restricted to the minimum actions deemed necessary for continued safe and secure handling and storage of naval spent nuclear fuel. It is important to note that this alternative is not a status quo condition. Naval reactors would be refueled and defueled as planned. Naval spent nuclear fuel would be stored in shipping containers at a Navy or DOE facility. These shipping containers would be modified and recertified as discussed in Section D.1.2.1 of Attachment D. No further naval spent nuclear fuel examination would be conducted and research and development activities associated with examination of the spent fuel would not be performed. The Expended Core Facility at INEL would be shut down.

Under this alternative, the transportation of naval spent nuclear fuel to INEL would be ended after about 3 years, during which additional shipping containers would be purchased and actions to prepare naval sites to serve as storage locations would be completed (see Section 3.8). The spent fuel from naval reactors at naval shipyards or active prototype sites would be stored at a naval shipyard or prototype, in most instances where it was removed from the reactor during servicing. The spent fuel would be removed from the reactors and placed directly into shipping containers for storage without detailed examination.

Newport News Shipbuilding, a private shipyard located in Newport News, Virginia, does refueling and defueling work for the Navy. Spent fuel removed from ships refueled or defueled at Newport News Shipbuilding would be transported to the nearest naval site, Norfolk Naval Shipyard, in Portsmouth, Virginia. Norfolk Naval Shipyard is about 10 miles (about 250 miles by rail) from Newport News Shipbuilding. The spent fuel would be stored in such a way that it would be protected from damage or intruders and that workers, the public, and the environment would be protected. The fuel would remain in storage until the DOE is prepared to take receipt of the fuel.

Since no additional spent fuel examinations would be performed at ECF, the work associated with examination of test specimens irradiated in the Advanced Test Reactor at INEL would be transferred to another site at INEL. The selected site might require modifications to accommodate this work.

If this alternative and its minimum actions were selected, it would be necessary to construct and certify approximately 500 additional shipping containers and to construct the associated rail spur tracks for the naval sites to be able to store the spent fuel from all of the nuclear-powered ships that will be refueled or defueled until the time that a permanent disposal facility becomes operational. During the period of time when containers would not yet be available, naval spent nuclear fuel would be transported in shipping containers to the Expended Core Facility at INEL. These containers would be unloaded and used to support additional refuelings and defuelings.

A major result of this and any other alternative which precludes detailed examination of naval spent nuclear fuel is that the further development of improved nuclear fuel for U.S. Navy ships would be hindered. Examination of spent fuel provides useful information on the performance of existing fuel system designs. Without a continuing flow of such information, eventually confidence in the ability of naval nuclear fuel to perform satisfactorily under design conditions would decrease. This information is also important in developing improvements in future fuel designs.

In this context, an alternative which would leave the spent nuclear fuel onboard nuclear-powered warships was considered. Under such an alternative, refueling and defueling operations would cease and the nuclear-powered warships would be retired in place at piers at Navy facilities. As discussed in Section 3.6.3 of this Appendix, it was determined that this approach to a "no action" alternative would actually involve many actions, including a large expansion of pier space, with the resultant ecological impacts, an increased number of naval personnel assigned to monitoring the retired nuclear-powered ships, a large reduction in work force at several shipyards, and a reduction in the number of operating nuclear-powered warships beyond that planned. Consequently, it was concluded that this could not be considered a "no action" alternative and a more appropriate, and feasible, approach for the No Action alternative was used as a basis for this Environmental Impact Statement.

Attachment D contains a more detailed description of storing naval spent nuclear fuel at or close to its removal location.

3.2 DECENTRALIZATION

Under this alternative, DOE would maintain existing naval spent nuclear fuel in storage at INEL, and new naval spent nuclear fuel would be stored at or near the sites where it was removed from reactors. Three different variations of this Decentralization alternative have been considered. In general, these variations are similar to the No Action alternative with regard to their location and method for long-term storage of spent nuclear fuel. At each storage location under all three options, storage in shipping containers, dry storage casks, and wet storage in water pools has been considered. All of them would require a transition period while facilities are developed (see Section 3.8).

3.2.1 Store Naval Spent Nuclear Fuel at or Close to Locations Where

Removed Without Examination

Similar to the No Action alternative, this alternative would include storage of the spent fuel from reactors at naval shipyards or active prototype sites close to the locations where it was removed during refueling or defueling. The spent fuel would be placed directly into storage without detailed examination. Storage would be in water pools, dry casks, or shipping containers. The spent fuel would be protected from damage or intruders, and workers, the public, and the environment would be protected. The fuel would remain in storage until a permanent disposal site became available.

No further naval spent nuclear fuel examination would be conducted. Without this examination program, further development of improved nuclear fuel for U.S. Navy ships would be hindered. Naval spent nuclear fuel examination provides useful information on the performance of existing fuel system designs. A continuing flow of such information is needed to prevent confidence in the ability of naval nuclear fuel to perform satisfactorily under design conditions from decreasing over time. Information from examination of naval spent nuclear fuel is also important in developing improvements in future designs. In addition, the work associated with examination of irradiated test specimens, which is also essential to the development of advanced designs, would no longer be performed at the Expended Core Facility at INEL and would have to be relocated to other facilities at INEL. The Expended Core Facility at INEL would be shut down.

The environmental effects associated with this alternative would be determined primarily by the choice among water pool, dry storage casks, or shipping container storage. The shipping containers could be mobile storage casks, which could also be used for shipping. Like the other options under this alternative, a transition period would be required during which it would be necessary to design, construct, and certify enough shipping containers or dry storage casks to store the spent fuel from all nuclear-powered ships being refueled or defueled or to design, construct, and certify water pools for fuel storage at naval sites. During this transition period, naval spent nuclear fuel would continue to be shipped to the Expended Core Facility at INEL where the shipping containers would be unloaded and used to support additional refuelings and defuelings.

Attachment D contains a more detailed description of storing naval spent nuclear fuel at or close to its removal location.

3.2.2 Examine a Limited Amount of Naval Spent Nuclear Fuel in the

Puget Sound Naval Shipyard Water Pit Facility and Store All Naval Spent Nuclear Fuel at Navy Facilities

Under this alternative, the existing water pool facility at Puget Sound Naval Shipyard, originally built to support the refueling of nuclear-powered aircraft carriers, would be modified to conduct the maximum amount of naval spent nuclear fuel examinations practical at that site. The difference between this alternative and the one described in the preceding section is that only a small amount of spent nuclear fuel could be examined to provide information on nuclear fuel performance for use in the development of improved nuclear fuel.

The only existing facility available within the Naval Nuclear Propulsion Program, other than the facility at ECF, which could be used to examine spent fuel from naval reactors is the water pool at the Puget Sound Naval Shipyard at Bremerton, Washington. However, the use of this facility for visual and dimensional examinations of high-priority spent fuel assemblies would require removal of the presently installed aircraft-carrier refueling equipment. As a result, Puget Sound would no longer have the capability to refuel nuclear-powered aircraft carriers. This facility has no shielded cells for performing destructive examinations of spent fuel. Although this alternative would provide a limited capability for examination and analysis of spent fuel, the ability to sustain further development of the advanced nuclear reactors needed to ensure the safety and performance superiority of U.S. Navy ships would be jeopardized. Continuous performance of naval spent nuclear fuel examinations at Puget Sound Naval Shipyard would preclude the performance of aircraft-carrier refuelings at Puget Sound because the needed water pit would no longer be available.

The limited amount of spent fuel examined in the modified facility and all naval spent fuel removed from reactors at Puget Sound Naval Shipyard would be stored at that shipyard. The naval spent fuel removed at other naval shipyards or active prototype sites would be stored at a site close to the location where it was removed during refueling or defueling. The limited amount of fuel to be examined would be transported from the originating site to Puget Sound Naval Shipyard in the shipping containers currently used for naval spent nuclear fuel.

Like the other options under this alternative, a transition period would be required for development of facilities utilizing shipping containers, dry storage casks, or water pools for fuel storage at naval sites. During this transition period, naval spent nuclear fuel and test specimens would continue to be shipped to the Expended Core Facility at INEL where the shipping containers would be unloaded and used to support additional refuelings and defuelings.

Under this option, the Expended Core Facility at INEL would be shut down after the end of the transition period. The examination of irradiated test specimens would be performed as discussed under the No Action alternative (Section 3.1).

Attachment D contains a more detailed description of the examination and storage of naval spent nuclear fuel for this alternative. The transportation of fuel to be inspected at Puget Sound Naval Shipyard is described in Attachment A.

3.2.3 Examine All Naval Spent Nuclear Fuel at the INEL and Return to

Naval Facilities for Storage

Under this option, all naval spent nuclear fuel would be shipped to the Expended Core Facility at the INEL for examination. After examination, this fuel would be returned to a naval or DOE facility for long-term storage near the location where the fuel was removed from a reactor. The examination of spent fuel under this alternative would be performed at the INEL Expended Core Facility as has been done in past years. As with other options under this alternative, the naval spent nuclear fuel would be stored in shipping containers, dry storage casks, or water pools. All planned improvements to the Expended Core Facility, including the dry cell expansion, would be completed.

The receipt, examination, and preparation for storage for this alternative would be the same as described in more detail in Attachment B, and the storage would be the same as that described in Attachment D for shipyard and prototype storage. Transportation of the spent fuel would be accomplished in the same manner as described in Attachment A.

3.3 1992/1993 PLANNING BASIS

The practice of transporting spent nuclear fuel removed from naval reactors to the Expended Core Facility in Idaho for examination would be resumed. Following examination, the spent nuclear fuel would be transferred to DOE for management at the Idaho Chemical Processing Plant pending final disposition. All planned improvements in fuel examination capability for naval spent nuclear fuel at INEL, including the ECF dry cell expansion, would be completed. Operation of an ECF Dry Cell Facility is included in the supporting analysis and the assumptions of this Environmental Impact Statement.

The shipment of naval spent nuclear fuel from shipyards and prototypes to INEL is described in Attachment A, and receipt and handling at INEL of the spent fuel from naval reactors and active prototypes is described in Attachment B. Attachment B also includes a description of the ECF Dry Cell Facility.

3.4 REGIONALIZATION

Two options have been considered under this alternative. Under the first Regionalization option considered, DOE would manage all spent nuclear fuel at the Hanford, INEL, and Savannah River sites, allocating each type of spent nuclear fuel to one of these sites according to its characteristics, such as the type of cladding. Under the second option, spent nuclear fuel under DOE cognizance would be managed at one DOE site in the eastern portion of the United States and one DOE site in the western part of the United States, with all spent nuclear fuel assigned to one of these two sites on the basis of its point of origin. The eastern site would be either the Savannah River Site or the Oak Ridge Reservation, and the western site would be the Hanford Site, INEL, or the Nevada Test Site. The Expended Core Facility at INEL would be shut down in all cases where INEL would not be used for naval spent nuclear fuel examination and storage.

3.4.1 Regionalization Using Storage at Three Sites (Hanford, INEL,

and Savannah River)

This option under the Regionalization alternative would result in all naval spent nuclear fuel being managed at the INEL in the same manner as the 1992/1993 Planning Basis alternative because all naval nuclear fuel has similar characteristics and would be managed at a single site. Under DOE plans, all Zircaloy-clad fuel would be managed at the INEL and since naval fuel is Zircaloy-clad, it would be assigned to INEL. The practice of transporting spent nuclear fuel removed from naval reactors to the Expended Core Facility in Idaho for examination would be resumed. Following examination, the fuel would be transferred to DOE for management at the Idaho Chemical Processing Plant pending final disposition. All planned improvements in fuel examination capability for naval spent nuclear fuel at INEL would be completed.

3.4.2 Regionalization Using Storage at Only Two Sites

Under this option, DOE would collect all spent nuclear fuel at one existing large DOE site in the eastern United States (either the Oak Ridge Reservation or the Savannah River Site) and at one existing large DOE site in the western part of the country (either the Hanford Site, INEL, or the Nevada Test Site). Spent nuclear fuel would be collected at one or the other of these two sites, based on its original location. Only one of the two locations would be used for examination and storage of naval spent nuclear fuel under this option, but the impacts of managing naval spent nuclear fuel at all of the possible sites have been evaluated because the site for naval spent nuclear fuel has not been chosen.

A new naval spent nuclear fuel examination facility would have to be constructed at the site selected if it were other than INEL, and the Expended Core Facility at INEL would be shut down. The new facility would have capabilities equivalent to those of the existing Expended Core Facility at INEL and would support all examinations and experimental work required for the development of naval reactors. The new examination facility would be operated by the Naval Nuclear Propulsion Program.

Naval spent nuclear fuel would be removed from naval reactors and transported by rail to the new examination facility, as described in Attachment A. The fuel would be unloaded and examined in the water pools and shielded cells constructed for this purpose, in a manner similar to that described in Attachment B. After completion of all examination work, the naval spent nuclear fuel would be transferred to storage facilities operated by the DOE at the same site. None of the DOE sites considered in this alternative, other than INEL, currently has facilities adequate to store the amount of spent nuclear fuel involved in this option. Therefore, the DOE would have to construct new storage facilities suitable for spent nuclear fuel, including naval spent nuclear fuel, if this option were selected.

It should be understood that the Navy would operate only one facility for examination of all naval spent nuclear fuel, and all naval spent nuclear fuel examined during the period covered by this Environmental Impact Statement would be stored at the same DOE site where the examinations would be performed. Therefore, there are no differences for management of naval spent nuclear fuel between the Regionalization alternative and the Centralization alternative (described in the next section) for the same site.

3.5 CENTRALIZATION

As implied by its name, this alternative would collect all current and future DOE spent nuclear fuel at one DOE site. The sites analyzed include the Hanford Site, INEL, the Savannah River Site, the Oak Ridge Reservation (ORR), and the Nevada Test Site (NTS). As in the Regionalization alternative, the Navy would operate a facility for examination of naval spent nuclear fuel at only one DOE site, and all naval spent nuclear fuel examined during the period evaluated would be stored at the DOE site where it was examined, so there are no differences between the Regionalization alternative and the Centralization alternative for management of naval spent nuclear fuel.

If INEL were chosen as the DOE site for centralized long-term storage of naval spent nuclear fuel, the Expended Core Facility would continue to operate. After examination at the Expended Core Facility, naval spent nuclear fuel would be transferred to the Idaho Chemical Processing Plant. There would be no need to modify the Expended Core Facility since it is a safe, modern facility providing all the capabilities needed for naval spent nuclear fuel examinations. However, any planned facility changes to provide improved or additional fuel handling and examination capability, such as the ECF Dry Cell Facility, would be completed.

If a DOE site other than INEL were chosen for the centralized long-term spent nuclear fuel storage facility, then the Expended Core Facility at INEL would be closed. A new naval spent nuclear fuel examination facility would need to be constructed at the selected site, or an existing facility would have to be modified to perform the needed examinations of naval spent nuclear fuel. This facility would provide capabilities equivalent to those of the existing Expended Core Facility at INEL. Similarly, additional spent nuclear fuel storage facilities would have to be constructed at the selected site since there are insufficient facilities at other sites suitable for storage of spent nuclear fuel from INEL.

Adjacent to the Savannah River Site is the site of the Barnwell Nuclear Fuel Plant. This privately owned facility is not being used currently. It could be purchased at an undetermined price, annexed to the Savannah River Site, and subsequently modified to provide capabilities equivalent to those at the Expended Core Facility. Similarly, at Hanford there exists the Fuels and Materials Examination Facility (FMEF) that could be modified to provide capabilities equivalent to those at the Expended Core Facility. It is expected that the modifications to either of these two facilities would cost less than the construction of a new Expended Core Facility.

Shipments of naval spent nuclear fuel to the Expended Core Facility in Idaho would resume during the first 3 years of the time required to construct a new naval spent nuclear fuel examination facility at the selected location (see Section 3.8). All naval spent nuclear fuel would be transferred to the central site after the new facilities were placed into operation.

The receipt, handling, and storage of naval spent nuclear fuel for this alternative are described in

Attachments B and E, and transportation of the spent fuel is described in Attachment A.

3.6 ALTERNATIVES ELIMINATED FROM DETAILED ANALYSIS

Several other alternatives were considered in addition to those described above. However, these other alternatives were not analyzed to the same depth as those described above. These alternatives and the reasons for not analyzing them in detail are discussed in this section.

3.6.1 Use Other Combinations of Sites for Examination and Storage

of Naval Spent Nuclear Fuel

Some variations of alternatives can be conceived in which spent fuel would be shipped from the site at which it was removed from a reactor to some other facility for examination or preparation for storage and subsequently shipped to another facility for storage. Evaluating all such combinations for examination, treatment, and storage as separate alternatives would be complicated because of the large number of alternatives which could result. Furthermore, detailed treatment of such a large number of alternatives would complicate the evaluation of environmental effects.

However, it is not necessary to consider each of these combinations individually because the processes involved and the possible environmental effects generally can be represented by combinations of the effects of alternatives already discussed. For example, the impacts of examining spent fuel at a DOE site other than INEL followed by shipment back to a shipyard for storage would be essentially the same as those for examination of fuel under the alternative of examination and storage of the fuel at the alternate DOE site, described in Section 3.5, except for transportation. Continuing the example, the effects of storing the naval spent nuclear fuel at a shipyard as part of such an alternative would be the same as those for storing spent fuel at the shipyard without inspection, described in Section 3.2.1. The effects of shipping the fuel back and forth between the DOE site and a shipyard for such an approach would be approximately double the effects of shipment to the DOE site for inspection and storage because the same sites are involved but a second trip would be required to return the fuel from the inspection site to the storage site.

In a similar fashion, the effects of other possible combinations of inspection and storage sites can be deduced from combinations of the alternatives discussed in earlier sections. In order to avoid complication and confusion, these alternative combinations were not explicitly analyzed in this statement.

3.6.2 Examine or Store Spent Nuclear Fuel from Naval Reactors in

Foreign Facilities

It would be physically possible to examine and store spent nuclear fuel from naval reactors in foreign countries. The naval spent nuclear fuel could be shipped safely to a foreign country and safe storage could be established. However, the characteristics of naval fuel are classified pursuant to the requirements of the Atomic Energy Act of 1954, as amended. Such characteristics include the fuel's geometry, what requirements govern its design, how it is manufactured, and how it operates in a naval reactor. These characteristics can be deduced from physical nondestructive examination of the fuel and from more intrusive means of inspection.

Information classified under the Atomic Energy Act may not be provided to foreign governments or foreign interests unless the President determines that such access is in the defense interests of the United States, a government-to-government agreement allowing such access is reached, and proper Congressional review is afforded to ensure acceptance by the legislative branch.

Characteristics of long-lived U.S. naval fuel, which constitutes virtually all of the naval spent nuclear fuel evaluated in this Environmental Impact Statement, have never been provided to any foreign country. It has been long-standing U.S. policy not to provide such information and there is no agreement currently in existence with any foreign country providing for such access.

U.S. naval fuel also utilizes highly enriched uranium suitable for use in nuclear weapons. Naval spent nuclear fuel remains highly enriched even after it has completed use in a naval reactor. As such, the Nuclear Non-Proliferation Act, implementing requirements of the Treaty for the Non-Proliferation of Nuclear Weapons, imposes severe restrictions on the transfer of such material to foreign countries. These restrictions are in addition to those arising from the classified nature of the fuel described above.

Foreign nations provide no unique capabilities or advantages for examination or storage of naval spent nuclear fuel. In fact, only four other countries (the United Kingdom, France, Russia, and the Peoples Republic of China) build and operate nuclear-powered warships, and none has naval reactor fuel having the long-lived performance characteristics of U.S. naval reactor fuel. Thus, U.S. capabilities for the examination of such long-lived fuel are unique and special.

There are also technical and environmental reasons why processing of naval spent nuclear fuel in foreign facilities is unreasonable. As is discussed in this Environmental Impact Statement, naval spent nuclear fuel is not expected to require any processing or stabilization - it will likely be suitable for direct emplacement in a geologic repository owing to its inherent structural strength and integrity, made necessary by its military application. Processing naval spent nuclear fuel is more difficult than commercial or DOE fuel for those same reasons, and doing such reprocessing abroad would result in the production of highly enriched uranium in a foreign country, creating concerns over non-proliferation and nuclear material safeguards.

Based on these considerations, the alternative of processing or storing naval spent nuclear fuel in foreign countries is not a reasonable alternative, and thus was eliminated from detailed analysis.

3.6.3 Do Not Remove Naval Spent Nuclear Fuel from Nuclear-powered Ships

Nuclear-powered warships represent about 40 percent of the Navy's major combatants. The size of the Navy fleet is based on ensuring that the Navy has sufficient ships in active service at all times to meet the country's defense commitments, as established by Congress and the President.

It is physically possible to retain spent fuel in the reactors in nuclear-powered vessels and moor the ships at shipyards until a decision on the ultimate disposition of spent nuclear fuel is reached, making those ships for which refueling was planned unavailable for further service. However, this approach would result in these ships being unavailable once their currently installed reactor fuel reaches the end of useful life. This is impractical because the ships would have to be replaced (a process that of necessity takes many years and in most instances requires ships that have not been designed) or the Navy would be forced to operate without the full complement of ships required to execute national policies. Since the entire submarine fleet is nuclear-powered, including the fleet of ballistic missile submarines which comprise the least vulnerable part of the nation's strategic deterrent, and our attack submarines which seek out opposing ballistic submarines as well as play a crucial role in littoral warfare, failure to refuel these units would result in a unilateral decrease in the nation's strategic deterrent.

Also of particular importance in this regard is the commencement of refueling NIMITZ Class aircraft carriers which form the backbone of the Navy's fleet. Of twelve operating carriers, six are NIMITZ Class, with three more under construction to replace older, conventionally powered carriers scheduled for retirement. Refueling of the USS NIMITZ is scheduled to begin in 1998, but refueling preparations are already underway for this first-of-a-kind effort. These preparations entail emptying, by late 1995, spent nuclear fuel from the earlier refueling of the USS ENTERPRISE and defueling of the USS LONG BEACH. This spent nuclear fuel is at Newport News Shipbuilding and Drydock Co. in a special support facility which is required for the NIMITZ Class refuelings. Once the facility is emptied, it would then be reconfigured for use, including refurbishment, maintenance, and extensive training of refueling personnel.

If the facility cannot be emptied, the USS NIMITZ and subsequent NIMITZ Class carriers (USS DWIGHT D. EISENHOWER, USS CARL VINSON, USS THEODORE ROOSEVELT, US ABRAHAM LINCOLN, and others) which are scheduled for refueling in succession after the US NIMITZ could not be refueled to rejoin the fleet at the time they would be required for service. In effect, the Navy would have far fewer carriers than would be needed to fulfill national security requirements. These requirements include maintaining continued forward presence in peacetime (which is essential to deter aggression, encourage global stability, and promote interoperability with our allies) and timely crisis response. National security requirements also include ability to field forces sufficient to engage in two simultaneous regional conflicts (such as Operation Desert Storm), as well as operations other than war, such as Somalia and Haiti. The national security need to ensure that the USS NIMITZ is refueled and returned to service in the fleet on schedule was certified by the Secretary of Defense in October 1994 and accepted by the Governor of Idaho in January 1995, when he allowed shipment of naval spent nuclear fuel from the Newport News Shipbuilding and Drydock Co. to continue. Additional shipments would be required after the Record of Decision is issued on this EIS in June 1995 to complete unloading the facility by late 1995.

Additionally, implementing this alternative would require extensive modifications to facilities at shipyards, including increasing the number of piers and the availability of waterfront utilities to support the ships at their moorings. Other shipyard facilities also might have to be modified or replaced as a result of the use of waterfront space to moor the numbers of ships involved during the 40-year period. The construction of piers and other needed facilities would cause impacts on the waterfronts and harbors and could affect the local ecology. For example, dredging would be required along with disposal of dredge spoils; such activities have been an environmental concern at several Navy facilities.

While this method for storing naval spent nuclear fuel would cause some increase in construction activities, in the long run it would result in the idling of skilled workers as the shipyards ran out of room and work schedules were disrupted by the loss of ship servicing work. Mooring the ships without removing the naval spent nuclear fuel would also utilize highly trained Navy nuclear ship operators in the unproductive task of watching over shutdown ships. The resources dedicated to providing the additional moorings would produce no improvements in a shipyard's ability to perform its mission and would actually decrease its capabilities. The radiological effects on the environment or people in the vicinity would be negligible as long as the nuclear-powered vessels and propulsion plants were maintained under the same procedures and discipline used for operating ships, since the environmental effects of operating U.S. Navy nuclear-powered vessels are well documented and known to be negligible.

Separately, the costs of maintaining the ships with spent nuclear fuel remaining installed under Navy operating procedures and providing the additional piers and waterfront services and utilities would be large. The costs of this approach would be high both for ships which are to be decommissioned and for ships which would normally be refueled and returned to duty. One cost would result from the need to assign qualified nuclear operators to monitor vessels awaiting refueling or defueling. In the case of ships which are being decommissioned at the end of their life, the primary cost of this alternative would be the cost to maintain qualified nuclear operators, shipboard equipment, and associated shipyard support, including security, to ensure nuclear and radiological safety for the workers and the public. This would be more expensive than removal of the spent fuel for storage.

Thus, in summary, this alternative would be costly and would involve extensive actions which would have an effect on the environment due to construction activities. This alternative would also not permit continued service of many Navy ships and only postpone decisions on a satisfactory storage location. As a result of these considerations, this alternative was eliminated from detailed analysis.

3.7 COMPARISON OF ALTERNATIVES

This section provides a comparison of the alternatives as they relate to the activities which fall under the Naval Nuclear Propulsion Program (NNPP). The comparison focuses on those areas which are projected to have the most significant impacts. As discussed in Sections 5.1 through 5.6, the impacts projected for most impact categories are very small or nonexistent. Such impact categories include: land use, cultural resources, aesthetic and scenic resources, geology, water resources, ecological resources, noise, utilities and energy, waste management, and irreversible and irretrievable commitment of resources. Consequently, the impacts in these areas provide no basis for distinguishing among alternatives.

It is important to note that in the No Action alternative and in two of the options of the Decentralization alternative, examination of naval spent nuclear fuel would cease or be seriously reduced and important scientific information would be lost. Beyond this issue, the principal differences among the alternatives occur in the categories of occupational and public health and safety (including normal operations and accidents for facility operations and transportation operations), cumulative impacts, and socioeconomics. Even in these areas, the overall impacts and the differences are small and represent the few unavoidable adverse effects that remain after the years of experience have been factored into the operations and the necessary mitigative measures have been applied.

DOE has adopted two quantitative safety goals to limit the risks of fatalities associated with its nuclear operations. The goals are:

- The risk to an average individual in the vicinity of a DOE nuclear facility for prompt fatalities that might result from accidents should not exceed one-tenth of one percent (0.1%) of the sum of prompt fatalities resulting from other accidents to which members of the population are generally exposed.

- The risk to the population in the area of a DOE nuclear facility for cancer fatalities that might result from operations should not exceed one-tenth of one percent (0.1%) of the sum of all cancer fatality risks resulting from all other causes.

A comparison of the calculated risks associated with each of the Naval Nuclear Propulsion Program alternatives indicates that the implementation of any of these alternatives would be well within the DOE facility safety goals.

3.7.1 Summary of Impacts

The most salient of the environmental impacts are summarized below. These impacts are presented under two categories:

- Human Health Impacts
- Other Impacts.

3.7.1.1 Human Health Impacts. Table 3-1 provides an overall comparison of the alternatives. This comparison is presented in terms of the increase in the number of cancer fatalities that could occur in the general population for any given year after an alternative has been implemented and has achieved a stable level of operation. This increase in the risk of developing fatal cancers is broken down to show how much risk increase is associated with normal operations, the highest risk facility accident, and transportation operations. For example, it is calculated that for the 1992/1993 Planning Basis alternative in which naval spent nuclear fuel would continue to be received, examined, and prepared for storage at the ECF at INEL, there would be:

- an increase of about 0.0000009 cancer fatalities per year for the general population around INEL (i.e., about one additional cancer fatality nationwide in 1,000,000 years among the 116,000 people who live within a 50-mile radius of INEL) due to normal ECF operations.
- an increase of 0.000026 cancer fatalities per year for the general population along the transportation routes due to normal transportation of naval spent nuclear fuel from the shipyards to the ECF.
- an increase of 0.00000017 cancer fatalities per year for the general population due to the facility accident with the highest risk (in this case it would be the accidental draining of a water pool used for examination and storage of naval spent nuclear fuel).

Table 3-1. Risk (fatal cancers to the general population per year) by alternative.

Alternative	Normal Operations Risk: Storage at NNPP Sites	Normal Operations Risk: Examination	Transportation Incident-Free Risk	Most Severe Facility Accident	Risk from a Transportation Accident Risk(3)
1. No Action	2.2 x 10-5	N/A	4.3 x 10-6	2.6 x 10-4	1.1 x 10-7
2. Decentralization					
- No Exam	2.2 x 10-5	N/A	4.3 x 10-6	2.6 x 10-4	1.1 x 10-7
- Dry Storage	3.4 x 10-4	N/A	4.3 x 10-6	1.1 x 10-5	1.1 x 10-7
- Water Pool Storage					
- Limited Exam	2.2 x 10-5	6.5 x 10-5	1.1 x 10-5	2.6 x 10-4	2.2 x 10-7
	2.7 x 10-4	6.5 x 10-5	1.1 x 10-5	1.1 x 10-5	2.2 x 10-7
- Dry Storage					
- Water Pool Storage					
	2.2 x 10-5	8.5 x 10-7	4.1 x 10-5	2.6 x 10-4	1.5 x 10-6
- Full Exam	3.4 x 10-4	8.5 x 10-7	4.1 x 10-5	1.1 x 10-5	1.5 x 10-6
- Dry Storage					
- Water Pool Storage					
3. 1992/1993 Planning Basis(1)		8.5 x 10-7	2.6 x 10-5	1.7 x 10-7	1.0 x 10-6
4/5. Regionalization or Centralization(1)(2)					
	-	8.5 x 10-7	2.6 x 10-5	1.7 x 10-7	1.0 x 10-6
- INEL	-	4.0 x 10-6	6.0 x 10-5	4.7 x 10-7	1.7 x 10-6
- Hanford	-	1.8 x 10-5	1.5 x 10-4	9.6 x 10-6	1.1 x 10-5
- S. River	-	9.0 x 10-8	7.5 x 10-5	7.2 x 10-8	7.5 x 10-6
- NTS	-	5.0 x 10-5	1.4 x 10-4	8.4 x 10-6	3.6 x 10-6
- ORR					

(1) For alternatives 3, 4, and 5, the risk due to storage of naval spent nuclear fuel is not included in

this evaluation. It is included in the evaluation of the individual DOE sites.

(2) Both the Regionalization and Centralization alternatives would locate an ECF at one of the five DOE sites. For this reason, the risk is the same for these alternatives.

(3) Some of the alternatives would involve a limited number of shipments by sea from Pearl Harbor to Puget Sound. Even though the probability of a severe accident involving a shipboard fire and release of radioactivity would be less than 10(-7) per year, the risk of such an accident has been calculated and is discussed in Attachment F, Section F.1.4.4. The risk of such an accident has been calculated to be 3.5 x 10(-6) per year.

- an increase of 0.000001 cancer fatalities per year for the general population due to risks of transportation accidents.

Table 3-1 shows that the cancer risks due to Naval Nuclear Propulsion Program activities for any of the alternatives are small. In all of these cases, thousands of years of repetition of the alternate action would be required before a single additional fatal cancer would occur. Risk is defined as the product of the probability of occurrence of an event leading to radiation exposure and the level of impact of exposure to radiation in terms of the increased number of fatal cancers that would result. A discussion of the key points in the development of an estimate of cancer fatalities is provided below; more detailed discussions of the parameters, analyses, and results are provided in Attachments A and F.

The increased number of fatal cancers is based on the calculated increase in exposure to radiation that would be seen by the general public as a result of each of the alternatives. The average annual exposure to a member of the population in the U.S. from background radiation is approximately 0.3 rem (300 millirem). The average annual collective exposure to all of the population in the U.S. from background radiation is approximately 69 million person-rem. When people are exposed to additional radiation, the number of additional radiation-induced cancer and other health effects needs to be considered. An estimate for radiation-induced cancer can be briefly summarized as follows:

- In a typical group of 10,000 persons who do not work with radioactive material, a total of about 2000 (20 percent) will normally die of cancer.

- If each of the 10,000 persons received an additional 1 rem of radiation exposure (10,000 person-rem) in their lifetime, then an estimated 5 additional cancer deaths (0.05 percent) might occur.

- Therefore, the likelihood of a person contracting fatal cancer during their lifetime could be increased nominally from 20 percent to 20.05 percent by exposure to 1 additional rem of radiation.

The "factor" for such a person to contract a fatal cancer, considering all possible organs, can be expressed as 0.0005 fatal cancers per rem of exposure. This is mathematically equivalent to 5.0 fatal cancers from 10,000 person-rem of collective exposure to a large group of persons.

Further, a collective exposure of 10,000 person-rem would be expected to produce, on the average, approximately 7.3 health detriments due to non-fatal and fatal cancers and severe genetic defects. These are two of the factors for the health detriments that may result from exposure to additional radiation. The results in this section are given in terms of fatal cancers. The total number of health detriments is the ratio 7.3/5.0 or 1.46 times these values.

The number of detrimental health effects which might result from exposure of a large group of people to low levels of radiation has been the subject of debate for many years. The calculations of health effects performed in this Environmental Impact Statement use the relation recommended by the International Commission on Radiological Protection because it is well-documented and kept up-to-date by the council. It also is widely accepted by the scientific community as representing a method which produces estimates of health effects that will not be exceeded. However, there are others who believe that exposure to low levels of radiation produces more health effects than would be estimated using the International Commission on Radiological Protection relation. On the other hand, a growing number of researchers believe that the International Commission on Radiological Protection relation overestimates the number of detrimental health effects produced by low levels of radiation. In fact, the possibility of no risk from the levels of radiation resulting from routine naval spent nuclear fuel management cannot be excluded (CIRRPC 1992). Clearly, using a relation developed by one or the other of these groups would produce a larger or smaller estimate of the number of health effects than the values presented in this statement. All of the results of analyses of normal operations and hypothetical accidents in Appendix D include the calculated exposure in addition to the number of health effects in order to permit independent calculations using any relation between radiation exposure and health effects judged appropriate.

The risks associated with all of the alternatives are low compared to the risks encountered in daily life. The risks of normal operations may be placed in perspective by considering other commonly encountered risks. For example, the average American is exposed to approximately 0.5 millirem each year from the radioactivity released from combustion of fossil fuels (NCRP 1987), which produces a lifetime risk of an average individual dying from cancer of about 1 chance in 50,000. As a further comparison, the naturally occurring radioactive materials in fertilizer used to produce food crops contribute about 1 to 2 millirem per year to an average American's exposure to radiation (NCRP 1987). This results in a risk of death from cancer between 1 chance in 12,500 and 1 chance in 25,000.

A frame of reference for the risks from accidents associated with spent nuclear fuel management alternatives can be developed by comparing them to the risks of death from other accidental causes. For example, the risk of death in a motor vehicle accident is about 1 chance in 80 (NSC 1993). Similarly, the risk of death for the average American from fires is approximately 1 chance in 500 and the risk of death from accidental poisoning is about 1 chance in 1000 (NNPP 1994b).

It must be remembered that no member of the public will receive as much as one one-thousandth of a rem from 40 years of the normal operations associated with any of the alternatives considered. Examining the results shown in the tables of radiation exposures (Attachments A and F) shows that the principal source of the difference in the exposures associated with radiation and radioactive materials released from normal operations and from hypothetical accidents for the alternatives is the number of people who live in the vicinity of the alternative sites and where they live relative to the facility itself. When the emissions from the sources are essentially the same, the resulting impacts depend directly on the size of the surrounding population, on the way the population is distributed around the site in terms of the distances and directions from the particular facility, and on the characteristics of the local meteorology.

3.7.1.2 Other Impacts. The principal impact in the employment portion of the socioeconomics

category is the number of jobs created by the construction and operation of a new (or modified) facility. The magnitude of the effect is relatively small in populations of the sizes under consideration, except to those people who benefit either directly or indirectly from the jobs. The creation of the jobs has some negative impacts: the jobs may be created at a distant location, or the jobs created locally may cause some small but adverse effect on the local community in terms of additional people and an increased need for additional public services.

The cost of operating and constructing new facilities or modifying existing ones to achieve the necessary capabilities for handling and storing spent fuel is an important economic impact. Depending on the site affected and the alternative under consideration, the cost may be as much as 5.7 billion dollars for construction and 40 years of operation.

In the unlikely event of a serious accident involving naval spent nuclear fuel, it is estimated that only about 210 acres of land would be affected for the most severe case (this is described in more detail in Attachment F), and in the other accidents analyzed, smaller areas of land would be affected. The affected area would require decontamination, and during this cleanup access controls would have to be established. However, due to the limited land area affected, it is judged that these restrictions would only be temporary and the impact on issues such as economics, treaty rights, tribal resources, ecology, and land use, would be relatively small and limited in time. The remediation actions would be simpler in rural areas than in urban areas; however, provided that prudent controls and remediation operations were promptly implemented, the affected land and buildings could be recovered in either case. As demonstrated in the accident analyses in Attachments A and F and summarized above, the human health effects are not large and the effects on wildlife and other biota would also not be large, partly due to the limited area affected.

Examination of naval spent nuclear fuel and irradiated test specimens has been conducted at the ECF at INEL since 1957. This program has made and continues to make important contributions to the safety, cost, and operational performance of naval nuclear propulsion plants. However, the No Action alternative and two of the Decentralization alternatives would result in substantial curtailment of this program. The Centralization, Regionalization, 1992/1993 Planning Basis, and the Decentralization - Full Examination alternatives would maintain the needed examination capability.

The safety of operating naval reactor plants has benefitted directly from the ECF examination programs. The result has been the construction of rugged reactor cores that are more tolerant of extreme conditions (such as corrosion, high temperatures, and intense radiation) without release of any fission products. The Naval Nuclear Propulsion Program's commitment to improved safety continues to be driven by two major issues:

- Protection of the Environment - In more than 40 years of operating and maintaining reactors in very demanding conditions, the Naval Nuclear Propulsion Program has never experienced a reactor accident, criticality accident, or a release of radioactivity that has had a significant effect on the environment.

- Personnel Safety - The importance of ensuring the integrity of the fuel is emphasized by the fact that the sailors onboard the ships live in very close proximity to an operating reactor 24 hours a day. Any release of radioactivity from the fuel into the reactor coolant would increase the radiation exposure of the ship's crew.

Since the inception of the Naval Nuclear Propulsion Program, the useful lifetime of naval reactors has been extended by more than a factor of 10. The examination programs at ECF played a major role in making this improvement possible. As a result of the extended reactor lifetimes, billions of dollars in ship refueling costs and spent nuclear fuel storage costs have been saved. In addition, longer reactor lifetimes permit the ships to spend a larger fraction of their lifetime on sea duty rather than in the shipyards, thus saving costs by reducing the number of ships required. Further reductions in nuclear propulsion plant costs are being pursued through improvements in many areas of nuclear fuel systems.

The improvements in nuclear fuel performance that have been developed in part through the knowledge gained from the examination program have contributed to improved ship operational characteristics. Major improvements have been made in power density, maneuverability, stealth, and simplicity. These improvements translate into important tactical advantages for our ships. Maintaining this advantage with ever improving technologies elsewhere in the world is vitally important to the safety of our sailors and to protecting our national interests.

In the final analysis, the most important differences are:

- The transfer of jobs associated with the Expended Core Facility among the alternative sites considered for locating the examination facility, or the outright loss of these jobs at INEL.
- The costs if new facilities are required.
- The loss or maintenance of naval spent nuclear fuel examination capability.

Sections 3.7.2, 3.7.3, and 3.7.4 provide additional summary information on the principal areas of impact.

3.7.2 Impacts Due to Normal Operations

During normal operations, there are public impacts due to direct radiation or due to the release of radioactive materials to the environment. These impacts are presented in the form of potential cancer fatalities due to exposure to the small amounts of radiation involved or radioactive materials released. It is important to emphasize that these cancer fatalities are calculated results rather than actual expected fatalities. This is because the expected number of such fatalities during normal operations is so small as to be unmeasurable and indistinguishable relative to the larger number of such deaths expected from naturally occurring conditions and other man-made effects not related to naval spent fuel operations. This is not meant to trivialize the importance of radiation-induced cancer fatalities but, rather, is meant to put the issue in perspective.

Table 3-2 presents a summary comparison of the calculational prediction of the number of fatal cancers per year that might be expected due to normal operations within each of the alternatives under consideration for naval spent nuclear fuel handling. This table provides the calculated impacts to the entire population. The impacts to selected individuals including workers are provided in Attachments A and F. Table 3-2 reflects the two possibilities (water pool and dry storage) for storing naval spent nuclear fuel at **the Navy sites.** In the case of dry storage at Navy sites, the impact from normal operations is due to calculated levels of direct radiation from storage casks at the shipyards. The environmental releases that were used to calculate the water pool values in the table are based on measured releases from the existing Expended Core Facility at the INEL. Also, the way in which direct radiation or environmental releases impact the population would be a function of the population distribution and the meteorological conditions present at the release location. To account for these differences, actual data on the population and meteorology for the various specific sites were used. The data in Table 3-2 are for a typical year in the future when the situation has stabilized at each location (that is, capabilities consistent with those described for the stated alternative have been achieved and are in operation at a facility at the indicated site).

All alternatives have some estimated number of fatalities, albeit a very small fraction. The lowest estimated number of cancer fatalities is associated with the 1992/1993 Planning Basis, Regionalization at INEL, and Centralization - INEL alternatives. The largest single estimate for the total number of cancer fatalities is only 0.00038 per year for the Decentralization - Full Examination alternative. Another way to view this is that if this alternative is selected and operations continue for

Table 3-2. Fatal cancers per year to the general population from normal operations.

10,000 years, between three and four extra cancer fatalities might be expected in that entire time period due to normal operations.

3.7.3 Impacts Due to the Most Severe Accidents

Accidents may occur during operation of naval spent nuclear fuel handling and storage facilities and during transportation of naval spent nuclear fuel. Specific accidents considered to be more severe than all other reasonably foreseeable accidents were analyzed to determine their potential impacts on the general population. For sites with spent fuel storage in water pools, the facility accident analyzed was a drained water pool or an accidental criticality since these produced the greatest consequences. For sites with dry spent fuel storage, the facility accident analyzed was an airplane crash if its probability was greater than 1 x 10-7 per year (1 chance in 10 million per year); otherwise, a wind-driven missile was the accident analyzed. Details of analyses of foreseeable accidents which might occur during fuel handling and storage are described in Attachment F. Details of the transportation accident analyses are described in Attachment A.

In Table 3-3, the potential impacts of facility and transportation accidents with the greatest consequences are expressed in terms of fatal cancers per accident. These are calculated by using the relation that 0.0005 cancer fatalities could occur for each person-rem of exposure for the general population. The impacts are based on hypothetical occurrences of the accidents and do not reflect the very low probabilities of the accidents actually occurring. For each alternative, the maximum impact of either a facility or transportation accident is listed rather than a total of the individual impacts since it is reasonable that only one severe accident would occur at one time.

For facility accidents, the greatest potential impact is associated with dry spent fuel storage at the Pearl Harbor Naval Shipyard. This is due to an airplane crash into a dry storage container. For transportation accidents, the risks vary with the distances to be traveled, being least for the No Action and the Decentralization - No Examination alternatives which involve only minimal transportation to local storage.

Table 3-4 lists the most severe risks (probability of occurrence times the number of fatal cancers) from facility accidents in terms of potential cancer fatalities per year.

\+ Based on accidents with a probability of occurrence of 1 x 10-7 or greater.

* Dry storage is the only option considered under the No Action alternative.

(1) The most severe accident is a drained water pool.

(2) The most severe accident involving storage or examination in a water pool is a drained water pool.
For the dry storage alternatives, the most severe accident is mechanical damage from a wind-driven missile.
The limited exam - dry storage option at Puget Sound also includes examination in a water pool; the consequences
shown for this option are due to accidents occurring during dry storage operations only.

(3) The most severe accident is from a plane crash for dry storage and a drained water pool for water pool storage.

(4) The most severe accident is from a plane crash.

(5) Some of the alternatives would involve a limited number of shipments by sea from Pearl Harbor to Puget Sound.
Even though the probability of a severe accident involving a shipboard fire and release of radioactivity would be
less than 10-7 per year, the risk of such an accident has been calculated and is discussed in Attachment F,
Section F.1.4.4. The most severe consequences of such an accident have been calculated to be 51.5 cancer fatalities.

Table 3-4. Most severe risk to the general population from a facility accident.

* Dry storage is the only option considered under the No Action alternative.

(1) The most severe accident is from a drained water pool.

(2) The most severe accident involving storage or examination in a water pool is a drained water pool. For the dry storage alternatives, the most severe accident is mechanical damage from a wind-driven missile. The limited exam - dry storage option at Puget Sound also includes examination in a water pool; the risks shown for this option are due to accidents occurring during dry storage operations only.

(3) The most severe accident is from a plane crash for dry storage and a drained water pool for water pool storage.

(4) The most severe accident is from a plane crash.

3.7.4 Cumulative, Socioeconomic, and Cost Impacts

A summary of the estimated cumulative impacts from the radiological operations associated with each of the alternatives evaluated in detail is presented in Table 3-5. It is based on achieving a stable level of operation by 1995 for any given alternative. The impacts are expressed as fatal cancers to the population within 80 kilometers (50 miles) and apply to the reasonably foreseeable impacts for the 40-year period ranging from 1995 to 2035. The impacts were based on annual results for normal operations multiplied by 40. The impacts due to both wet and dry storage are presented. For the cumulative effect of storage at Navy shipyards and prototypes, the sum over all the Navy sites was used to provide a comparison for the same amount of fuel. The total for each alternative was then calculated by summing the fatal cancers for transportation, receipt and examination operations, and storage. The results show that the impacts for all alternatives would be negligible.

The historical impact of transportation and ECF operations for the period ranging from 1958 to 1995 was calculated to be about 0.001 fatal cancers. This is the total number of fatal cancers that are estimated among the several million people along transportation routes coupled with the 116,000 people located within 50 miles of INEL. This estimate was based on the calculated incident-free transportation results from Attachment A, and the calculated results of normal operations and storage from Attachment F. The calculated results from Attachment F were adjusted from an annual basis (1995) to the historical basis by multiplying by 38 years and by a factor of 1.7 to take into consideration the variations in the number of ships and operations. No extra factor was applied to the estimates of the historical impact or the future impact to account for the vulnerabilities that might be associated with facility or spent fuel aging because naval spent nuclear fuel is very strong and has very high integrity (Section 2.2), and historical experience has disclosed no important vulnerability. The factor of 1.7 represents the ratio of the average to the current radiation exposures received by all military and civilian personnel in the Naval Nuclear Propulsion Program during the historical period (NNPP 1994a). In the case of the Limited Examination alternative, the analysis includes both the material shipped to Puget Sound for examination and storage, as well as the material stored there and at other sites from defuelings without examination.

Table 3-6 presents the cumulative impact from the radiological operations to a hypothetical maximally exposed worker and a hypothetical maximally exposed individual at the site boundary. The impacts are presented in terms of the likelihood of fatal cancer for the affected individual. These

- Oak Ridge Reservation	3.4	0.0014	0.0040	2.0 x 10-6

values were determined based on a projected 40-year exposure at the location of the affected individual.

The radiological doses for workers represent the largest average dose from the particular facilities involved in an alternative. The average radiation dose for workers was selected by using the 1993 annual average shipyard or DOE site radiation exposure summaries (NNPP 1994b; NNPP 1994c). The radiological doses for maximum off-site individuals are the largest values calculated for a person located at the site boundary, closest to any facility involved under an alternative. These doses are based on the values for these individuals presented in Attachment F.

Employment impacts were determined from the nature of each alternative based on the experience at INEL. Table 3-7 presents a summary of potential socioeconomic impacts at each of the various sites for each of the alternatives evaluated in detail. The results indicate that as many as 500 long-term jobs and several hundred shorter-term construction jobs might be lost or gained at an affected site depending on the alternative selected.

Cost impacts were estimated from the nature of each alternative based on experience at INEL. **Table 3-8 presents a summary of the cost impacts for each of the alternatives evaluated in detail.** The summary provides the costs which would be incurred from construction as well as transportation and operation costs over the next 40 years. In all alternatives, there would be large costs, ranging up to $5.7 billion. For three of the alternatives involving continued operation of the ECF at INEL (1992/1993 Planning Basis, Regionalization at INEL, and Centralization at INEL), there would be only minor construction cost impact; however, the cost of continued ECF operation for an additional 40 years would be $2.6 billion. The cost values considered in preparing Table 3-8 include facility construction costs ranging from zero for alternatives involving no new facilities to a high of $800 million for those requiring a new facility with full examination capability. The transportation costs depend on destination and logistics and range from a low of $10 million to a high of $110 million. Fuel storage container costs range from a low of zero for those alternatives utilizing water pool storage to a high of $3.2 billion for shipping containers on railcars for the No Action alternative. Also included are operating costs over 40 years ranging up to $2.6 billion for the various alternatives, and Idaho ECF shutdown costs for those alternatives in which the present ECF is shut down.

- Hanford	3.4
- Savannah River	3.5
- Nevada Test Site	3.5
- Oak Ridge Reservation	3.5

---

* The cost varies under this alternative depending on the mode of storage. The most expensive options are those that use shipping containers for storage; the least expensive options are those that use immobile dry storage containers.

The largest cost ($3.8 to $5.7 billion) would be needed for new storage facilities or containers in addition to the ECF operational costs under the Decentralization - Full Examination alternative. Approximately $0.8 billion would be needed for the construction of new receipt, handling, and examination facilities at the alternative site if a Regionalization or Centralization alternative other than INEL were selected, thereby resulting in a cost of $3.5 billion over 40 years of operation. Somewhat less than $800 million would be needed for modifications to existing facilities if either of those options at Hanford or Savannah River were selected. Also, if the alternative involving the Barnwell Nuclear Fuel Plant at Savannah River were selected, additional funds would be needed to buy the Barnwell Plant as well as to modify it to meet the Program needs.

A hidden cost associated with the No Action alternative and two of the Decentralization alternatives is the loss or major reduction in the capability to examine naval spent nuclear fuel. Full examinations of naval spent nuclear fuel at the Expended Core Facility at INEL have been conducted since 1957. The examinations are a critical aspect of the Naval Nuclear Propulsion Program's ongoing advanced fuel research and development program. The information derived from the examinations at ECF provides engineering data on nuclear reactor environments, material behavior, and design performance. These data contribute to the Naval Nuclear Propulsion Program in two very significant ways.

First, this information is used to support the design of new reactors having extended lifetimes. For example, such examinations have contributed to extending the life of naval fuel from 2 years for the first reactor core in USS NAUTILUS to over 20 years for the latest nuclear-powered warships. The ultimate goal is to develop naval nuclear fuel that lasts the life of the ship; this would mean that no refuelings would be needed. Longer-lived fuel allows fewer refuelings, saves money in the costs of fuel and in the costs of work on ships, makes ships available for longer periods of service, and creates less spent nuclear fuel.

Second, information from these examinations has supported the operation of existing naval reactors by providing confirmation of proper design and allowing the fuel they contain to be used for the longest possible time.

Thus, the examinations of naval spent nuclear fuel are an integral part of the outstanding record of nuclear safety of the Naval Nuclear Propulsion Program. In over 4500 reactor-years of operation and more than 300 refuelings and defuelings of naval reactors, there has never been a nuclear reactor accident, criticality accident, or any release of radioactivity that has had a significant effect on the environment.

Preventing release of radioactivity from the fuel is extremely important to the safety of the

Navy personnel who operate the nuclear-powered warships since they must live aboard ship in close proximity to the reactor 24 hours a day.

While it is difficult to quantify the benefits of an outstanding safety record, increased core life yields an understandable economic gain. The gain is in a reduction in the number of reactor cores that must be procured and in the number of refuelings. Another gain is the increased on-line availability of nuclear-powered warships which is reflected in a decreased number of ships required. It is estimated that by achieving life-of-the-ship fuel and thus eliminating the need for any refuelings, a savings of approximately $5 billion will accrue for a force structure of less than 100 ships. The improvement in life from 2 years to 20 years has already avoided the need to perform 15 refuelings over the lifetime of each ship and reduced that to a single refueling.

3.8 TRANSITION PERIOD

A transition period would be required before any of the alternatives considered for naval spent nuclear fuel management could be fully implemented, except for those which would resume the historical practice of shipping naval spent nuclear fuel to the Expended Core Facility at INEL, followed by transfer to the Idaho Chemical Processing Plant for storage. This transition period would be needed to obtain the necessary additional funding and to build the necessary facilities and equipment.

For example, if the Record of Decision were to identify that the alternative of Centralization at Savannah River had been selected, a new Expended Core Facility would have to be funded and built at the Savannah River Site before shipments of naval spent nuclear fuel from shipyards could be directed to Savannah River. Similarly, if the No Action alternative were selected, additional shipping containers would have to be built since the available shipping containers for naval spent nuclear fuel will all be filled and waiting at the shipyards in June 1995.

Impacts of all alternatives evaluated for naval spent nuclear fuel management are low. Thus, the impacts of combinations of alternatives would also be low. The Environmental Impact Statement focuses on impacts at the time of full implementation in order to simplify the discussion and to calculate ceilings for the impacts. By doing so, it assures that impacts greater than those analyzed would not occur if one alternative were used for a small fraction of the 40-year period followed by a shift to another alternative for the remainder of the 40 years. This section discusses a transition period which is believed to represent a rapid but practical shift from the situation in June 1995 to full implementation of the ultimate alternative selected in the Record of Decision. This transition period would be about the same length for any alternative.

It is expected that the transition period would consist of 3 years of shipments of containers from the shipyards or prototypes to ECF at INEL beginning with issue of the Record of Decision in June 1995, and include approximately 80 total shipments. This would result in shipping to INEL the containers which had been filled and at the shipyards at that time. Many of the containers would then be emptied at ECF and returned to the shipyard where they would be reloaded. During this 3-year period, some of these containers would make a second trip to ECF at INEL for unloading after being returned to the shipyard. After these 3 years of shipments, no further shipments to INEL would be made, and the Expended Core Facility at INEL would be shut down. The shipping containers would then be refilled during the next 3 years, but kept at the shipyards or shipped to the location of the new examination or storage facilities.

If an alternative which does not continue storage of naval spent nuclear fuel at INEL were selected, procurement and contract actions to implement the course of action selected in the Record of

Decision would be initiated during these two 3-year periods. In accordance with the course of action selected in the Record of Decision, additional shipping containers or immobile dry storage casks would be built or construction of water pools would be initiated at shipyards or a new ECF at a DOE site would be started. It is assumed that these procurements or construction would have proceeded sufficiently that the shift to the selected option would be in full swing at this time.

3.9 PREFERRED ALTERNATIVE FOR NAVAL SPENT NUCLEAR FUEL

The specific elements discussed in each category of environmental impacts have been evaluated to determine the Navy's preferred alternative for managing naval spent nuclear fuel until means for permanent disposition become available. The costs and mission impacts have also been considered in selecting a preferred alternative.

Environmental Impacts: This Environmental Impact Statement (EIS) documents the potential environmental impacts of each alternative for naval spent nuclear fuel management. It considers environmental impacts under normal operations and hypothetical accident conditions on resources such as water quality and wetlands, air quality, land use, and public health. This EIS considers a range of potential accident initiators, such as natural hazards, transportation, and fuel handling.

The analyses demonstrate that the environmental impacts of implementing any of the alternatives would be very small for both normal operations and accident conditions. All alternatives would result in radiological impacts well below established DOE safety performance goals (SEN-35-91) of one tenth of one percent of the risk of fatal cancers from all sources (including natural causes). The impacts from any of the alternatives in non-radiological areas would also be extremely small. The analysis results do not provide a basis to distinguish among the alternatives in most of these areas.

Socioeconomic Impacts: The socioeconomic impact of implementing each of the alternatives would differ somewhat. The primary determinant of socioeconomic impact of the alternatives considered is employment. Total nation-wide employment levels would not vary significantly among alternatives for managing naval spent nuclear fuel, and therefore do not seem to provide a basis to distinguish among the alternatives. The maximum impact on existing employment levels would arise from alternatives requiring development of new naval spent nuclear fuel examination capability at a DOE facility other than INEL while terminating these activities at INEL. Resuming current practices of transporting naval spent nuclear fuel to the ECF at INEL for examination followed by transfer to the DOE for storage would result in the minimum disruption of employment levels.

Mission Impacts: Two important components of Naval Nuclear Propulsion Program operations are the safe management of naval spent nuclear fuel and support of the Navy's fleet of nuclear-powered warships. Based on the analyses in this EIS, all alternatives considered would allow safe storage of naval spent nuclear fuel until permanent disposition. However, some of the alternatives would not provide equal levels of Fleet support. Alternatives which limit or terminate naval spent nuclear fuel examination would severely impact ongoing research and development work. Naval spent nuclear fuel examination results are used to confirm the adequacy of design features, explore material performance, and confirm or adjust computer predictions of fuel performance. This information contributes to design and manufacturing of new naval reactor cores as well as understanding of operating ships. Each spent naval reactor core has its own unique manufacturing and operating history. Consequently, examination of each reactor core provides an opportunity to obtain new information relevant to reactor core performance. As discussed in Section 2.4.1 of this Appendix, the technical feedback obtained through this examination program is essential to extending the lifetime of naval reactor cores and assuring their operational safety. It is also important to understand that because of their long service lives, the first of the naval cores currently being used in LOS ANGELES Class submarines are just now being removed from operating reactors and becoming available for examination. The first cores from NIMITZ Class aircraft carriers and OHIO Class submarines have yet to be removed. These cores are the basis for all of the current fleet designs and are the starting point for new designs. Of the alternatives allowing full examination at the INEL, Hanford Site, Savannah River Site, Oak Ridge Reservation, or Nevada Test Site, examination at the INEL would have the smallest mission impact due to the presence of existing facilities and equipment for performing this work, and the presence of a highly skilled work force, all of which would need to be relocated or reassembled if a new examination site were selected.

Cost Impacts: There are large differences in the costs associated with all alternatives. Few additional costs would be associated with continuing the historic practice of shipping naval spent nuclear fuel to INEL for examination, followed by transfer to the DOE for storage pending permanent disposition. Alternatives involving developing facilities for storage of naval spent nuclear fuel at naval shipyards or developing examination facilities at a DOE site other than INEL would involve billions of dollars in additional costs, relative to historic practices, without any discernible improvement in safety or reduced environmental impacts.

Based on the analyses presented in this EIS, the Navy prefers an alternative which resumes the historic, technically sound, and safe practice of conducting refueling and defueling of nuclear-powered warships and prototypes as planned, transporting naval spent nuclear fuel to the Expended Core Facility at the INEL for full inspection and examination, and transferring naval spent nuclear fuel to the DOE for storage at that site. As summarized above, this preferred alternative avoids disruption of research and development work, minimizes disruption to existing employment levels and infrastructure, represents the lowest cost, and does not involve appreciable environmental impact. This preferred alternative can be accommodated under the 1992/1993 Planning Basis, Regionalization, or Centralization at Idaho.

4. AFFECTED ENVIRONMENT

4.1 NAVY AND PROTOTYPE SITES FOR NAVAL SPENT NUCLEAR

FUEL

4.1.1 PUGET SOUND NAVAL SHIPYARD: BREMERTON, WASHINGTON

4.1.1.1 Overview

The Puget Sound region lies in the northwest corner of Washington State as shown on Figure 4.1.1-1. The region is defined by the Olympic Mountain Range to the west and the Cascade Mountain Range to the east. The lowlands contrast dramatically with the mountains, with numerous channels, bays, and inlets on the inland sea that is Puget Sound. The Puget Sound Naval Shipyard is located inside the city limits of Bremerton, Washington at 47y 33' 30" north latitude and 122y 38' 8" west longitude. Bremerton is located in Kitsap County on the Sinclair Inlet 14 miles across Puget Sound west of Seattle and about 20 air miles northwest of Tacoma. Topography in the Bremerton area is characterized by rolling hills with an elevation range from sea level to +200 feet above mean sea level (msl) in West Bremerton and ranging up to y300 feet above msl in East Bremerton (area east of Port Washington Narrows). The predominant native vegetation in the area are douglas fir, cedar, and hemlock. Within a distance of 25 to 40 miles in a westerly direction from Bremerton, the Olympic Mountains rise to elevations of 4,000 to 7,000 feet. The higher peaks are covered with snow most of the year and there are several glaciers on Mount Olympus (elevation 7,954 feet). In an easterly direction and within a distance of 60 miles, the Cascade Range rises to average elevations of 5,000 to 7,000 feet with snowcapped peaks in excess of 10,000 feet.

Puget Sound Naval Shipyard is the largest activity of the Bremerton Naval Complex, which also includes the Fleet and Industrial Supply Center, Puget Sound and Naval Sea Systems Command Detachment, and Planning and Engineering for Repair/Alteration of Aircraft Carriers. Tenant activities include Naval Inactive Ship Maintenance Facility, Naval Reserve Center, and the Defense Printing Service. Figure 4.1.1-2 provides a shipyard vicinity map, and Figure 4.1.1-3 illustrates the Puget Sound Naval Shipyard.

4.1.1.2 Land Use

Kitsap County has historically been a semi-rural county. Roughly 80 to 85 percent of Kitsap County's total area is either forest, farmland, or undeveloped. The city of Bremerton and the surrounding vicinity is the largest population and economic center in the county and therefore has a lower percentage of agriculture and undeveloped land. Most development in Kitsap County is clustered around the commercial nodes of Bremerton, Port Orchard, Bainbridge Island, Kingston, Poulsbo, Silverdale, and Gorst, and near the shorelines.

The second largest land use category is residential, which is further broken down into low and medium density housing. More land area is devoted to single-family (low density) residential than to multi-family (medium density) development in this area.

Other land use delineations are parks and open space; commercial, which includes industry; mining; and much of the Navy buildings. The nearby land uses are typical of an area developed to a moderate intensity. The area contains residential, commercial, industrial, educational, and recreational facilities. The local waters support recreational and commercial activities including regularly scheduled ferry traffic.

Bremerton Naval Complex includes a total of approximately 1,347 acres consisting of uplands and submerged lands. Puget Sound Naval Shipyard has 327 acres of upland and is highly developed. Puget Sound Naval Shipyard also owns about 338 acres of submerged tidelands. The waterfront dry dock area is the high-security portion of the shipyard where most production takes place. It includes production shops, administration, and some public works and supply functions. The upland area of the shipyard is the military support area which provides services to military personnel, including housing, retail goods and services, recreation, counseling, dental care, and other support services.

The industrial support area in the southwestern portion of the shipyard includes several piers for homeported ships and inactive fleet, the power plant, warehouses, steel yard, public works shops, and parking.

Figure 4.1.1-1. Location of Puget Sound Naval Shipyard within Washington. Figure 4.1.1-2. Puget Sound Naval Shipyard vicinity map. Figure 4.1.1-3. Puget Sound Naval Shipyard site map.

4.1.1.3 Socioeconomics

Bremerton is the largest city within Kitsap County. The major population centers in Kitsap County other than Bremerton include Port Orchard, Poulsbo, Silverdale, Bainbridge Island, and Kingston. Kitsap County also has two reservations: the Port Madison Indian Reservation governed by the Suquamish Tribe, and the Port Gamble Indian Reservation governed by the S'Klallam Tribe.

The region surrounding the shipyard, within 50 miles, contains a population of approximately 3 million. Figure 4.1.1-4 provides a population distribution rose centered on the shipyard and covering a 50-mile radius. During 1989, Kitsap County ranked 7th as the most populous county in the state (Washington SESD 1990). According to the 1990 census, Kitsap County was the fifth fastest growing county in the state with a 28.9% growth rate for the decade for a total population of 189,731. The most recent estimate (April 1992), puts Kitsap's population at 205,600. The Kitsap Regional Planning Council projects the number of inhabitants to reach 280,985 by the year 2010, an increase of 48.10% over the 1990 figure.

Kitsap County's economy is largely affected by the federal government. Government is Kitsap County's largest employment sector, with the federal government having the greatest impact. As of 1993, Puget Sound Naval Shipyard was the largest employer in the county, employing about 10,200 civilian personnel. In 1990, the government sector's share of county employment was approximately 45 percent. The retail trade and services sectors are the county's next highest employers. Many of the service industries, such as the growing number of engineering and management firms, directly or indirectly support the military. By 1989, the services sector accounted for 21 percent of employment in the county and the retail trade sector accounted for 20.5 percent (Navy 1991a).

The majority of the labor force that would be employed at the shipyard for construction and operation of the naval spent nuclear fuel area would be expected to reside within about 20 miles from the shipyard. The calculated total population, labor force, and employment within this region for the base year (1995) are presented in Table 4.1.1-1. Projections of employment and population for the years beyond 1995 have not been presented because, as discussed in Section 5, the number of additional jobs that might be created at the shipyard under any alternative could be small.

Table 4.1.1-1. Regional employment factors at Puget Sound Naval Shipyard.

Regional Employment	Regional Labor Force	Regional Population
492,900	527,000	979,070

There are seven port districts in the county. The Port of Bremerton is the largest, with Bremerton and Port Orchard within its boundaries. The Port of Bremerton owns Bremerton National Airport, Olympic View Industrial Park, marinas in downtown Bremerton and Port Orchard, and the First Street Dock in Bremerton. Kitsap County is governed by a Board of Commissioners and is divided into three districts. Bremerton is split between the three districts. Regional planning is the responsibility of the Kitsap Regional Planning Council, and the Puget Sound Regional Planning Council, which is made up of elected officials from King, Kitsap, Pierce, and Snohomish counties and cities, and from the Indian tribal councils. Land use outside the shipyard is regulated by the city of Bremerton Comprehensive Plan and Zoning Ordinance. The Bremerton Area Council of Neighborhoods is made up of nine neighborhoods. The group was established to encourage citizen participation in Bremerton city planning (Navy 1991a).

Agencies responsible for environmental protection are the U.S. Army Corps of Engineers, U.S. Coast Guard, the Environmental Protection Agency (EPA), and the United States Fish and Wildlife Service (USFWS). The Washington State Department of Ecology and the city of Bremerton are responsible for the Coastal Zone Management Plan. The Department of Natural Resources has jurisdiction over marine lands management, and the Department of Fisheries and Department of Game protect wildlife resources. Washington's system of freeways, highways, and ferries is the responsibility of the Washington State Department of Transportation. Historic preservation programs for the state are administered by the Office of Archaeology and Historic Preservation.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms.

A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the Puget Sound Naval Shipyard, consistent with the population data provided in Figure 4.1.1-4.

Figure 4.1.1-4. 50-mile population distribution around Puget Sound Naval Shipyard.

Figure 4.1.1-5 shows the locations of populations in which minority membership exceeds the average within the 50-mile radius by more than 20 percentage points and populations which have more than 50 percent minority members. These populations have been identified following an approach developed by the Environmental Protection Agency which, for purposes of environmental justice evaluation, defines minority communities as those which have percentages of minorities greater than the average in the region analyzed (EPA 1994).

Figure 4.1.1-6 shows the locations of populations which have more than 25 percent of their members living in poverty, reflecting a common definition of low-income communities (EPA 1993). The U. S. Census Bureau characterizes persons in poverty as those whose income is less than a "statistical poverty threshold." For the 1990 census, this threshold was based on a 1989 income of $12,500 per household.

4.1.1.4 Cultural Resources

Until the mid 1880s, Kitsap County was inhabited by several Native American tribes of the Salish language group who lived on the shores of Puget Sound. For about 100 years, the principal settlement of the Suquamish Tribe lay along the west shore of Agate Passage.

Congressional funding in 1891 led to the purchase of 190 acres of land on Sinclair Inlet for the construction of a dry dock, repair, and overhaul base for the U.S. Navy. This base was called the Puget Sound Naval Station.

No prehistoric archaeological sites have been identified at the Puget Sound Naval Shipyard. In addition, no submerged cultural resources have been recorded in the immediate vicinity of the shipyard. There are no Native American properties or ceremonial sites in the areas where spent nuclear fuel would be stored.

There is one National Historic Landmark and four National Registered Historic Districts within the shipyard. The east industrial portion of the shipyard was designated as a National Historic Landmark in 1992 as a part of the "World War II in the Pacific" group and contains buildings, piers, dry docks, and equipment that were used in World War II warship repairs. The four Historic Districts are: Officer's Row, Old Puget Sound Radio Station, Old Naval Hospital, and the Old Marine Reservation.

Figure 4.1.1-5. Minority population distribution within 50 miles of the Puget Sound Naval Shipyard.

Figure 4.1.1-6. Low-income population distribution within 50 miles of the Puget Sound Naval Shipyard.

4.1.1.5 Aesthetic and Scenic Resources

The Puget Sound region offers a striking contrast in terrain, with mountains; low, rolling hills; flat-topped ridges; and plateaus. These areas are separated by numerous channels, bays, inlets, lakes, and valleys. The shoreline along the county is characterized by moderate to steep irregular cliffs. The county has large areas of farmlands and forest.

The city of Bremerton and the Puget Sound Naval Shipyard are urbanized areas. The shipyard has an industrialized character along the shoreline, with parking areas, dry docks, warehouses, and ship traffic along Sinclair Inlet. The upland section of the shipyard contains housing, recreational facilities, and retail businesses. Chainlink fences mark the shipyard boundaries.

The area within the shipyard where the naval spent nuclear fuel would be stored has low visual sensitivity since the area is an industrial site.

4.1.1.6 Geology

4.1.1.6.1 General Geology.

The Kitsap Peninsula consists of several geological phenomena which have occurred over the past 60 million years. The upper layers of rock are generally underlain by hard, dense, fine-grained lava with an accumulation of several thousand feet (in most places) of marine sedimentary rocks above the lava flows. Uplifting of the Cascade and Olympic Mountain ranges caused the Kitsap Peninsula and other Puget Trough lowlands to become sites of deposition for sedimentary materials washed down from the surrounding ranges. More recently, glaciation, as well as erosion, have been responsible for carving the low, hilly, rolling topography of the area (Navy 1991a). The following geological discussion was obtained from "Site Inspection Report Puget Sound Naval Shipyard" (URS 1992).

Puget Sound Naval Shipyard is within the Puget Sound Lowland between the Olympic Mountains and the older Cascade Mountains to the east. Before the glaciation which occurred up to 1.7 to 2.2 million years ago, the Puget Sound Lowland probably contained a large river valley draining to the north and west into what is now the Strait of Juan de Fuca. Glaciation of the Puget Sound Lowland produced the arms and embayments of Puget Sound.

4.1.1.6.2 Geologic Resources.

Geological materials found in Puget Sound include hard, dense volcanic rock formed up to 63 to 65 million years ago, and fragmented sedimentary rocks, as well as unconsolidated sediments deposited by glaciers up to 1.7 to 2.2 million years ago. At least four separate glacial advances and accompanying periods between glaciers have been hypothesized for the Puget Sound Lowland. Soil layers deposited by glaciers are generally coarse sand and gravel, sand, silt from lakes, and low-permeability deposits left by glaciers. The soils from the periods between glaciers are generally fine-grained silts and sands deposited by rivers or lakes, interbedded with lenses of sand and gravel.

Most of the geologic material in Kitsap County is glacial deposits. The Kitsap Peninsula is the remnant of a plain formed from the debris deposited by glaciers. Volcanic bedrock outcrops near the south end of Sinclair Inlet and at Gold Mountain south and west of Bremerton. Sedimentary bedrock outcrops on the south end of Bainbridge Island and at the adjacent tip of the peninsula east of Bremerton.

Kitsap County has four basic soil types: soils underlain by cemented hard-packed subsoil or bedrock substrate; soils with permeable, distinctly stratified sublayers which are coarse and have good internal drainage; the organic soils represented by small, widely scattered areas of peat and muck; and soils having little or no agricultural or building potential. Typical landforms include rough mountainous land, steep broken land, coastal beaches, and tidal marshes.

The natural topography of the shipyard has been altered substantially from its original condition. Portions of the upland areas of the complex were cut to fill marshes and create level land. The resulting fill material was predominantly a silty, gravelly sand with occasional pockets of silts and clays. The surface of the filled areas is a solid layer of earth. The remaining areas of natural soils vary from dense deposits from glaciers to soft bay mud and peat. The upland soil is a stiff hard-packed clay soil with low permeability. (URS 1992)

There are no economic geologic resources at the shipyard.

4.1.1.6.3 Seismic and Volcanic Hazards.

Seismic risk related to structural damage may be represented in the United States by a relative scale of 0 through 4, with Zone 0 not expected to encounter damage and Zone 4 expected to encounter the greatest seismic risk. The Puget Sound Naval Shipyard is located in Zone 3. (UBC 1991) The Uniform Building Code seismic classification provides a means for a comparable assessment of the seismic hazard between the alternate sites.

If the Record of Decision identifies this site for the interim storage of naval spent fuel, then a detailed seismic evaluation would be conducted. More detailed information regarding the design basis considerations for storage of naval spent nuclear fuel at the shipyard is provided in Attachment D.

There have been approximately 200 earthquakes in the Pacific Northwest since 1840, most of which caused little or no damage. The most recent earthquakes of high magnitude in the region were near Olympia (approximately 40 miles from Bremerton) in 1949 (moment magnitude 7.1) and near Seattle in 1965 (moment magnitude 6.5). There has recently been speculation by some seismologists that earthquakes in the Puget Sound area might produce moment magnitudes as high as 8.2 to 8.8. On the other hand, some seismologists believe that earthquakes with moment magnitudes exceeding 7.0 are unlikely in this region. There is also some disagreement at present on the nature of fault movements that might occur in this area.

There is no known fault line within 3000 feet of the Bremerton Naval Complex; however, two known fault traces have been identified in Kitsap County. The Kingston-Bothell trace, in the northern portion of the county, and the Seattle-Bremerton trace, located a few miles north of Bremerton. There has been no known surface faulting in conjunction with earthquakes in the shipyard region.

Potential hazards from volcanism are minimal and limited to wind-borne volcanic ash. Both the distance of the shipyard from the Cascade vents and the configuration of the intervening topography exclude other volcanic hazards. Only ash from a "large" or "very large" eruption would reach the shipyard. The 1980 eruption of Mount St. Helens, Washington, approximately 120 miles south of the shipyard, resulted in a very slight coating of ash at the shipyard.

The potential hazard from large waves generated by volcanoes or earthquakes is minimal. The system of straits and inlets surrounding Puget Sound provides a natural barrier for the Puget Sound Area, which effectively dampens the propagation of distantly generated large waves. The risk of a local large wave generated by seismic events occurring that would affect the shipyard is small; however, seismologists have found evidence of a large, shallow focus earthquake near Seattle about 1300 years ago. This earthquake was most likely in excess of moment magnitude 7. In the event that a shallow focus earthquake such as this were to occur beneath Puget Sound, a tsunami could result which might cause flooding in the Puget Sound area. Because the largest earthquakes of record in the area are deep seated (more than 60 kilometers (37 miles)), and no major surface rupture is known to have occurred, the hazard of generation of a large wave by a local earthquake is minimal. The potential for landslide-generated waves is controlled by the geologic conditions; however, development of an earthquake-induced landslide of sufficient size to create a large wave is not expected.

A more detailed description of the regional geology and seismicity is documented in "Seismic Design Study - Water Pit Facility, Puget Sound Naval Shipyard, Bremerton, Washington" (Navy 1978).

4.1.1.7 Air Resources

4.1.1.7.1 Climate and Meteorology.

The general meteorological conditions of the Puget Sound area are typical of a marine climate, since the prevailing air currents at all elevations are from the Pacific Ocean. The relatively cool summers, mild winters, and wetness characteristic of a marine climate are enhanced by the presence of Puget Sound. The area tends toward damp, cloudy conditions much of the year. The Cascade Range to the east serves as a partial barrier to the temperature extremes of the continental climate of eastern Washington.

The normal annual precipitation near Bremerton is 38.33 inches. The rainy season extends from October to March and accounts for more than 75 percent of the yearly precipitation.

The mean annual temperature is 51.4yF. Normally, January is the month with the lowest average temperature of 39yF and July is the month with the highest average temperature of 64.5yF.

The average annual mean wind speed at the Seattle-Tacoma Airport is 9.0 miles per hour (mph), with a recorded maximum speed of 1-minute duration of 49 mph. Prevailing winds are from the southwest.

The mean annual relative humidity at the Seattle-Tacoma Airport at 4:00 a.m. (PST) is 83 percent, decreasing to 62 percent by 4:00 p.m. There is an average of 43.4 days per year that fog reduces visibility to 0.25 mile or less. The mean annual percent of possible sunshine is 46 percent. The month with the greatest mean percent of possible sunshine is July with 65 percent and the month with the least is December with 21 percent (Navy 1991a).

4.1.1.7.2 Air Quality.

An area can be designated by the Environmental Protection Agency as having air quality that is better than defined by the National Ambient Air Quality Standards (attainment) or as exceeding one or more of those standards (nonattainment for one or more pollutants). The Code of Federal Regulations, Title 40, Part 81, states that the Air Quality Control Region for the shipyard is better than national standards for total suspended particulate matter and SO2. The area has no specific classification for ozone, carbon monoxide, and NO2. The nearest Class I Area is the Olympic National Park, approximately 24 kilometers (15 miles) from the shipyard.

4.1.1.7.3 Existing Radiological Conditions.

Radiological facilities at all naval shipyards are designed to ensure that there are no uncontrolled discharges of radioactivity in airborne exhausts. Radiological controls are exercised to preclude exposure of working personnel to airborne radioactivity exceeding federal limits. Air exhausted from radiological work facilities is passed through high-efficiency particulate air filters and monitored during discharges. The annual airborne radioactivity emissions from the shipyards do not result in any measurable radiation exposure to the general public. Calculations of site radioactive airborne emissions for 1992 have been performed as described in Attachment F. These calculations have shown that emissions of radionuclides from each shipyard result in an effective dose equivalent of less than 0.1 mrem per year to any member of the general public.

4.1.1.8 Water Resources

4.1.1.8.1 Surface Water.

Numerous freshwater sources are found in Kitsap County, with numerous lakes dotting the county's landscape. Kitsap Lake, in west Bremerton, is one of the largest at 238 acres. Lakes and reservoirs are used for recreation and other public uses. Water for the city of Bremerton comes from surface and groundwater supplies.

Freshwaters in the Bremerton area are monitored by the Washington State Department of Ecology. Puget Sound Naval Shipyard has no important surface freshwaters.

Sinclair Inlet is located in Puget Sound. It is a narrow body of marine water approximately 1.1 miles wide at its widest point and approximately 3.5 miles long. A majority of the shoreline of Sinclair Inlet has been developed. The dominant feature is the shipyard, lying on the northern shore. The city of Port Orchard borders the southern shore. Localized areas of Sinclair Inlet contain toxic chemicals as a result of historic urban and industrial activities. Contaminants of concern include polychlorinated biphenyls (PCBs); polycyclic aromatic hydrocarbons (PAH); and toxic metals, such as chromium and mercury (PTI 1990). Fish taken from these localized areas show elevated concentrations of PCBs, mercury, and chromium.

Puget Sound tides are of the twice-daily, mixed type with two unequal highs and two unequal lows per day. Tides in the inlet are similar to those in Seattle, the primary reference station. The principal forces that produce currents in Sinclair Inlet are tidal. Generally, weak currents oscillate in direction moving water in and out of the inlet. The flushing capacity of the inlet is low due to low freshwater input (Navy 1991a).

Based on Flood Insurance Rate Map (FIRM) COMMUNITY-PANEL No. 530093 0015 and topographical maps, the Puget Sound Naval Shipyard is not in the 100 or 500 year floodplain.

4.1.1.8.2 Groundwater.

Groundwater is generally found within 100 feet of the ground surface in sand and gravel layers caused by material from receding glaciers. The rate of groundwater recharge in Kitsap County is estimated to be approximately 12 inches annually, equating to approximately 0.5 million gallons per day per square mile. The nature of the geology in the area is such that a well in almost any location can tap a number of aquifers at different depths. The quality of most groundwater near Bremerton is good. Groundwater is used for approximately 35 percent of the public water supply for Bremerton. Groundwater at Puget Sound Naval Shipyard is poor due to salinity caused by intrusion from Sinclair Inlet. (Navy 1991a).

4.1.1.8.3 Existing Radiological Conditions.

The normal activities associated with current naval nuclear operations at all naval shipyards do not result in the intentional discharge of any radioactive liquid effluent. However, there were occasions, primarily in the early 1960's, when measurable levels of radioactivity were discharged with liquid effluent. In all cases, effluent releases were less than permitted under the then current limits imposed by state and federal agencies.

The United States Environmental Protection Agency Office of Radiation Programs has performed monitoring of the water, plant life, aquatic life, and sediment in the vicinity of Puget Sound Naval Shipyard. The purpose of the survey was to determine if operations related to U.S. Navy nuclear warship activities resulted in releases of radionuclides which could contribute to significant population exposure or contamination of the environment. "Radiological Surveys of Naval Facilities on Puget Sound" (Lloyd and Blanchard 1989) discusses the most recent Environmental Protection Agency monitoring data. Pertinent conclusions are as follows:

1. "A trace amount of cobalt-60 (0.04 pCi/g+/-0.01 pCi/g) was detected in one sediment sample at PSNS. All other radioactivity detected in the 80 sediment samples is attributed to naturally occurring radionuclides or fallout from past nuclear weapons tests and the Chernobyl reactor accident in 1986."
2. "Results of core sampling did not indicate any previous deposit of cobalt-60 in the sediment."

3. "Water samples contained no detectable levels of radioactivity other than those occurring naturally."
4. "External gamma-ray measurements did not detect any increased radiation exposure to the public above natural background levels."
5. "Based on the current radiological surveys, shipyard and nuclear-powered warship operations have resulted in no increases in radioactivity that would result in major population exposure or contamination of the environment."

Environmental monitoring is conducted by the shipyard. The results of this monitoring program corroborate the Environmental Protection Agency's conclusions.

4.1.1.9 Ecological Resources

4.1.1.9.1 Terrestrial Ecology.

Vegetation and wildlife on Puget Sound Naval Shipyard are limited to "open spaces," noncontiguous, undeveloped areas which comprise approximately 46 acres of the entire Bremerton Naval Complex (Navy 1991a). Most of these areas have been previously disturbed and are currently landscaped with native and ornamental trees and shrubs.

Tree species include Douglas fir (Pseudotsuga menziesii), vine maple (Acer circinatum), big leaf maple (Acer macrophyllum), western red cedar (Thuja plicata), madrone (Arbutus menziesii), and western hemlock (Tsuga heterophylla). There are various types of thick underbrush present such as salal (Gaultheria shallon), sword fern (Polystichum sp.), Oregon grape (Berberis nervosa), and rhododendron (Rhododendron spp.) (Navy 1986).

Because of its location on the Pacific flyway, Puget Sound exhibits a diverse avifauana from an influx of seasonal migrants. Many of the migrants, particularly waterfowl, remain and overwinter in the sound because of the mild climate, abundance of bays and coves, and the availability of food. Due to the extensive industrial nature of the shipyard, its resident bird community is characterized by "urban species." Resident bird species include Stellar's jay (Cyanocitta stelleri), starling (Sturnus vulgaris), flicker (Colaptes spp.), American crow (Corvus brachyrhynchos), black-capped chickadee (Parus atricapillus), goldfinch (Spinus tristis), pigeon (Columba fasciata), robin (Turdus migratorius), golden-crowned kinglet (Regulus satrapa), evening grosbeak (Hesperiphona vespertina), and ring-necked pheasant (Phasianus colchicus) (Navy 1986). In addition, numerous glaucous-winged gulls (Larus glaucescens) inhabit the waterfront areas.

Although abundant mammal populations originally existed in the Puget Sound area, the current populations of mammals at the shipyard are extremely limited. The only mammals currently reported at the shipyard are gray squirrels (Sciurus griseus), mice, and shrews (Navy 1990a).

With few exceptions, reptiles and amphibians are not particularly abundant in the Puget Sound area. The lack of suitable habitat restricts the population of reptiles and amphibians at the shipyard to garter snakes, salamanders, newts, and frogs (Navy 1990a).

No environmental concerns associated with vegetation or wildlife have been identified at the shipyard.

4.1.1.9.2 Wetlands.

There are no freshwater wetlands on the shipyard. There are no streams, rivers, ponds, or lakes located on the shipyard (Navy 1986). The majority of the shipyard is developed and covered with an impervious surface. The shipyard does own 338 acres of water area (deep-water tidal property) along the waterfront.

4.1.1.9.3 Aquatic Ecology.

Salt marsh and brackish marsh communities formerly existed along much of the shoreline of Puget Sound. For a number of years, these areas were perceived as swampy wastelands and thousands of acres were diked, drained, and reclaimed.

The original landform of the shipyard has been greatly altered to accommodate its continuing development. Projects have increased the usable land by filling in the marsh area in the northwest corner and by extending the shoreline with quaywalls and landfill. The shoreside of the shipyard consists primarily of riprap, concrete bulkheads, and old wooden piers. Marine vegetation along the shipyard shoreline consists primarily of sea lettuce (Ulva lactuca), rockweed (Fuchus distichus), and debris of algae that have been dislodged from their subtidal moorings and carried inshore. There are no waterfront areas at the shipyard that have clam beds, eelgrass, kelp beds, or similar habitat (Navy 1986).

Resident fish populations inhabiting the shipyard intertidal shoreline include sculpins (Cottidae), surf perch (Embiotocidae), and flatfish (Pleuronectidae). Migratory fish species include Pacific salmon (Oncorhynchus spp.), sea-run cutthroat trout (Oncorhynchus clarki), Pacific tomcod (Microgadus proximus), Pacific cod (Gadus macrocephalus), Pacific herring (Clupea harengus pallasii), rockfish (Sebastes spp.), and two or three species of migratory smelt (Osmeridae) (Navy 1986). There is near-shore migration of juvenile salmon and other fish species annually, from March 15 to June 15. Herring mill in the vicinity of the shipyard from January 20 through April 15 (Navy 1991a). No recreational or commercial fishing is allowed within the confines of the shipyard.

4.1.1.9.4 Endangered and Threatened Species.

As required under Section 7 of the Endangered Species Act of 1973, the responsible agency of a major federal action must conduct a biological assessment to identify any endangered or threatened species which are likely to be affected by such action. The United States Fish and Wildlife Service had previously provided a list of endangered and threatened species that may be in the Bremerton area (Navy 1991a). The list included one species, the bald eagle (Haliaeetus leucocephalus). Wintering bald eagles may occur in the Bremerton area from about October 31 through March 31.

Bald eagles are regularly seen along most of the inland waters of Puget Sound. Eagles are active during the day and feed on a variety of animals (preferring fish or waterfowl) and carrion. They nest and rest most often in conifers, choosing large, open-crowned trees near water (Navy 1991a). Eagles are capable of tolerating a certain amount of intrusion and change; however, they tend to seek privacy for rearing their young.

Although no eagles have been reported nesting on the shipyard, there are several active nests within 1 mile of the shipyard (Navy 1991a). Trees suitable for perching and roosting are found in the non-industrialized area at the shipyard, but not near the waterfront. Bald eagles may feed within Sinclair Inlet anywhere and at any time. It is not likely that eagles feed on fish near the shipyard on a regular basis because of the high level of human activity and the variability of fish populations. Eagles in this area feed primarily on seagulls and other birds (Navy 1991a).

Marine mammals are afforded full federal protection under the Marine Mammal Protection Act of 1972. Pinnipeds (seals and sea lions) and cetaceans (whales, dolphins, and porpoises) that regularly or occasionally are found in central Puget Sound include the Pacific harbor seal (Phoca vitulina), California sea lion (Zalophus californianus), killer whale (Ordinus orca), Dall porpoise (Phocoenoides dalli), and harbor porpoise (Phocoena phocoena) (Navy 1991a).

The National Marine Fisheries Service had previously provided a list of endangered and/or threatened species under its jurisdiction that may occur in Puget Sound waters in support of the "Final Programmatic Environmental Impact Statement Fast Combat Support Ship (AOE-6 Class) U.S. West Coast Homeporting Program" (Navy 1991a). The list included two endangered mammals, the gray whale (Eschrichtius robustus) and the humpback whale (Megaptera novaeangliae); one threatened mammal, the Steller sea lion (Eumetopias jubatus); and one endangered turtle, the leatherback sea turtle (Dermochelys coriacea).

None of the sensitive, threatened, or endangered species are represented in the aquatic life of the shipyard (Navy 1991a).

4.1.1.10 Noise

Puget Sound Naval Shipyard is an existing industrial-type environment characterized by noise from truck and auto traffic; ship loading cranes and related diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related compressors for those and other liquids. In addition, new construction of buildings, reconstruction and rehabilitation activities for streets, buildings, parking lots, and ships all contribute to an industrial environment. Primary noise sources are located along the naval shore support facilities (piers and associated land-side facilities) and are dampened to the residential areas by the hills adjacent to the industrial area.

4.1.1.11 Traffic and Transportation

Primary regional land access to the Seattle/Tacoma/Bremerton area is achieved via two interstate highways, I-90 and I-5. Major transportation corridors in Kitsap County are based upon a network of state routes. The county's municipalities and population centers are accessed by State Routes (SR) 104, 303, 304, 305, and 308. The major thoroughfare in south Kitsap County is SR 16, which runs south from Bremerton to Tacoma and connects with I-5 in Tacoma.

Bremerton's primary access routes include SR 3, which is a major north-south thoroughfare that travels through western Bremerton; SR 303, which originates within Bremerton as Warren

Avenue and continues through eastern Bremerton to Silverdale; SR 304, which travels through Bremerton as Callow Avenue, Burwell Street, and Washington Avenue; Kitsap Way, which turns into 6th Street within the city; 11th Street, which provides local east-west circulation; and Wycoff, Montgomery, and Naval avenues, which provide local north-south circulation. The proposed Gorst to Bremerton Connector is a road-widening project that will improve accessibility to downtown Bremerton from SR 3 and SR 16.

Kitsap Transit provides transportation service to various areas of Kitsap County including population centers, ferry docks, and other activity centers, through a Public Transit Benefit Authority. In addition, tours and charters are available locally through Cascade Trailways which also offers a twice daily scheduled run to Tacoma. Taxi service is also available throughout the Kitsap County area.

Bremerton National Airport, used for general aviation, is the largest of three airfields located in Kitsap County and is located near SR 3 south of Bremerton. The other two airfields in the county are Port Orchard Airport and Apex Airpark near Silverdale.

Two ferry systems provide services to the Bremerton area. The Washington State Ferry System provides numerous daily runs from Bremerton, Kingston, Bainbridge Island, and Southworth to the Seattle area. There is also a state ferry run in the northern part of the county connecting Kingston to Edmonds, Washington, north of Seattle. In addition to the cross sound service provided by the Washington State Ferry System, Horluck Transportation Company runs a passenger-only service connecting downtown Port Orchard to Bremerton.

Burlington Northern Railroad provides scheduled and on-demand freight rail service to a number of locations in the southern and central portions of Kitsap County. A Navy-owned spur line from Shelton, Washington, provides additional rail service to the shipyard and Bangor Naval Submarine Base.

Naval spent nuclear fuel has been removed from Navy nuclear-powered ships and transported to the Idaho National Engineering Laboratory Expended Core Facility (ECF) for examination and evaluation as a routine part of their operating cycle. Starting in 1962, the naval spent nuclear fuel originating at Pearl Harbor Naval Shipyard was transported by ocean vessel to Puget Sound Naval Shipyard for subsequent rail shipment to ECF. From 1962 to the present, a total of 20 naval spent nuclear fuel shipments have been made from Pearl Harbor Naval Shipyard to Puget Sound Naval Shipyard, then on to ECF. In 1966, Puget Sound Naval Shipyard began removing naval spent nuclear fuel from Navy nuclear-powered ships and transporting it by rail to ECF. From 1966 to the present, a total of 115 shipments of naval spent nuclear fuel originating at Puget Sound Naval Shipyard have been made to ECF. Attachment A provides a list of the spent nuclear fuel shipments made to date by year and by originating shipyard. Attachment A also contains detailed descriptions of the shipping containers used for naval spent nuclear fuel shipments from shipyards.

Puget Sound Naval Shipyard has 23 miles of railroad tracks, 8 piers, 4 mooring sites, and 6 large dry docks.

4.1.1.12 Occupational and Public Health and Safety

4.1.1.12.1 Occupational Radiological Health and Safety. The Navy has well established and

effective Occupational Safety, Health, and Occupational Medicine programs at all of its shipyards. In regard to radiological aspects of these programs, the Naval Nuclear Propulsion Program policy is to reduce to as low as reasonably achievable the external exposure to personnel from ionizing radiation associated with naval nuclear propulsion plants. These stringent controls on minimizing occupational radiation exposure have been successful. No civilian or military personnel at Navy sites have ever exceeded the federal accumulated radiation exposure limit which allows 5 rem exposure for each year of age beyond age 18. Since 1967, no person has exceeded the federal limit which allows up to 3 rem per quarter year and since 1980, no one has received more than 2 rem per year from radiation associated with naval nuclear propulsion plants. The average occupational exposure of each person monitored at all shipyards is 0.26 rem per year. The average lifetime accumulated radiation exposure from radiation associated with naval nuclear propulsion plants for all shipyard personnel who were monitored is 1.2 rem. (NNPP 1994a) This corresponds to the likelihood of a cancer fatality of 1 in 2083.

The Navy's policy on occupational exposure from internal radioactivity is to prevent radiation exposure to personnel from internal radioactivity. The limits invoked to achieve this objective are one-tenth of the levels allowed by federal regulations for radiation workers. As a result of this policy, no civilian or military personnel at shipyards have ever received more than one-tenth the federal annual occupational exposure limit from internal radiation exposure caused by radioactivity associated with naval nuclear propulsion plants.

For work operations involving the potential for spreading radioactive contamination, containments are used to prevent personnel contamination or generation of airborne radioactivity. The controls for contamination are so strict that precautions sometimes have had to be taken to prevent tracking contamination from fallout and natural sources into radiological areas because the contamination control limits used in these areas were well below the levels of fallout and natural contamination occurring outside in the general public areas. A basic requirement of contamination control is monitoring all personnel leaving any area where radioactive contamination could possibly occur. Workers are trained to survey themselves (i.e., frisk), and their performance is checked by radiological control personnel. Frisking of the entire body is required, normally using sensitive hand-held survey instruments. Major work facilities are equipped with portable monitors, which are used in lieu of hand-held friskers. These stringent controls to protect the workers and the public from contamination have proven effective in the past.

In 1991, researchers from Johns Hopkins University, Baltimore, Maryland, completed a very comprehensive epidemiological study of the health of workers at the six naval shipyards and two private shipyards that service the Navy's nuclear-powered ships (Matanoski 1991). This independent study evaluated a population of 70,730 civilian workers over a period from 1957, beginning with the first overhaul of the first nuclear-powered submarine, USS NAUTILUS, through 1981, to determine whether there was an excess risk of leukemia or other cancers associated with exposure to low levels of gamma radiation.

The Johns Hopkins study found no evidence to conclude that the health of people involved in work on U.S. naval nuclear-powered ships has been adversely affected by exposure to low levels of radiation incidental to this work. Additional studies are planned to investigate the observations and update the shipyard study with data beyond 1981.

The radiation exposure during normal operations at each shipyard for workers who have their radiation levels monitored is determined based on the annual radiation exposure of 0.26 mrem per worker for all shipyards based on Naval Nuclear Propulsion Program Report NT-94-2 (NNPP 1994a). The total number of shipyard personnel monitored for radiation exposure associated with the Naval Nuclear Propulsion Program has been about 164,000.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population.
Under the limiting assumption that the same worker is associated with every shipment for the entire historical period, this person would receive a total exposure of 7.5 rem over the approximately 40-year period, or about 0.19 rem per year, which is within DOE standards for occupationally exposed individuals. The radiation exposures to workers correspond to much less than one incident cancer, which means that it is unlikely that there have been any past health impacts due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.1.12.2 Occupational Non-radiological Health and Safety.

The shipyard has an occupational health/preventive medicine unit and a branch clinic (industrial dispensary) which are run by Naval Hospital Bremerton. Personnel may also be taken to Harrison Memorial Hospital as needed.

The shipyard maintains two fire stations with approximately 50 personnel. The shipyard has a fire department that is fully equipped for structural and industrial firefighting and hazardous material spill response.

The shipyard has a security force of approximately 177 personnel providing law enforcement services, emergency services, security clearances, and parking and traffic control for the Bremerton Naval Complex.

In the non-radiological Occupational Safety, Health, and Occupational Medicine area, the Navy complies with the Occupational Safety and Health Administration regulations. The Navy policy is to maintain a safe and healthful work environment at all naval facilities. Due to the varied nature of work at these facilities, there is a potential for certain employees to be exposed to physical and chemical hazards. These employees are routinely monitored during work and receive medical surveillance for physical hazards such as exposure to high noise levels or heat stress. In addition, employees are monitored for their exposure to chemical hazards such as organic solvents, lead, asbestos, etc., and where appropriate are placed into medical surveillance programs for these chemical hazards.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact due to the historical shipment of naval spent nuclear fuel over the entire history of such shipments.

4.1.1.12.3 Public Radiological Health and Safety.

In order to quantify the exposures resulting from normal shipyard radiological releases to the general public, detailed analyses were performed based on very conservative estimates of radioisotopic releases since releases began. Attachment F provides detailed annual release values used in the analyses.

The GENII computer code (Napier et al. 1988) was used to calculate exposures to human beings due to the estimated radionuclide releases from normal operations at the shipyards.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from stored fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F.

The hypothetical exposures calculated in Attachment F for the period 1995 through 2035 were adjusted from an annual basis (1995) to the historical basis by multiplying by 38 years and by a factor of 1.7 to take into consideration variations in the number of ships and operations.

The calculated accumulated exposures through 1995 to the general population within 50 miles of the site (about 3 million people) are 1.3 person-rem. To provide perspective, the exposures received due to natural radiation sources through 1995 are approximately 34 million person-rem, based on 0.3 rem per person per year.

The results of environmental monitoring as described in Naval Nuclear Propulsion Program Report NT-94-1 show that Naval Nuclear Propulsion Program activities had no distinguishable effect on normal background radiation levels at site perimeters (NNPP 1994b).

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities.

All of the radiation exposures to the general population correspond to much less than one incident cancer, which means that it is unlikely that there has been any past health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.1.12.4 Public Non-radiological Health and Safety.

Kitsap County has two hospitals, Harrison Memorial Hospital in East Bremerton and the Naval Hospital Bremerton.

Fire protection in Kitsap County is administered by local fire departments and fire districts. The Bremerton Fire Department has three stations. Police protection services in Kitsap County are provided by the County Sheriff's Office, the city of Bremerton, and other local jurisdictions providing mutual aid.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.1.13 Utilities and Energy

Public water systems supply the majority of Kitsap County's water requirements. Wells are the primary source of water for outlying areas. The Bremerton watershed, located in the Gold Mountain area, is the largest single source for the city of Bremerton. A dam on the Union River provides the water storage reservoir. Freshwater is received at the shipyard from the city of Bremerton public water supply. A saltwater system is used at the piers and dry docks for firefighting, flushing, and cooling of ship systems. Refer to Section 4.1.1.8 for further discussion of water resources.

The Bonneville Power Administration and the Puget Sound Power and Light Company provide electrical service to Kitsap County. Rates for electrical power are relatively low due to the close proximity of hydroelectric facilities. The shipyard steam plant provides emergency electrical service, as well as steam.

A limited industrial natural gas distribution system exists in the east end of the complex. A majority of the military support area in the west end of the shipyard has been converted to natural gas. Natural gas is used industrially, since most of the buildings are heated by steam. The forge shop, foundry, and pipe shops are the largest users of gas. The only natural gas space heating in the industrial area is in the foundry (Navy 1991a).

Shipyard freshwater usage is approximately 676 million gallons annually.

Electricity usage is about 247,000 megawatt hours annually.

4.1.1.14 Materials and Waste Management

All of Bremerton's sewage is treated by the Bremerton Wastewater Utility at the Charleston Water Treatment Plant, located at the intersection of State Routes 3 and 304. This plant was completed in 1985 to provide secondary treatment. Navy ships produce sewage which is transferred to the city of Bremerton's Water Treatment Plant. Berthed ships generally have on-board pumps to discharge their sewage into the piers' sewage lines. In some cases, portable pumps are utilized to lift and pressurize.

Most of the solid waste produced by the shipyard is hauled by a private contractor to the privately owned Olympic View landfill. Miscellaneous acid and alkaline cleaning solution (concentrated liquid) is collected, stored on base, and eventually shipped to hazardous waste treatment storage and disposal facilities. Solid and liquid chemical wastes are collected, characterized, packaged, and labeled at the shipyard, then turned over to a contractor for disposal. A facility at the Manchester Fuel Department provides for the collection and recycling of oily wastes, sludges, and bilge waters (Navy 1991a).

Solid radioactive waste materials are packaged in strong, tight containers, shielded as necessary, and shipped to burial sites licensed by the U.S. Nuclear Regulatory Commission or a State under agreement with the U.S. Nuclear Regulatory Commission. Shipyards and other shore facilities are not permitted to dispose of radioactive solid wastes by burial on their own sites. During 1992, approximately 851 cubic yards of routine low-level radioactive waste containing 59 curies were shipped from the shipyard for burial.

Waste which is both radioactive and chemically hazardous is regulated under both the Atomic Energy Act and the Resource Conservation and Recovery Act (RCRA) as "mixed waste." Within the Naval Nuclear Propulsion Program, concerted efforts are taken to avoid commingling radioactive and chemically hazardous substances so as to minimize the potential for generation of mixed waste. For example, these efforts include avoiding the use of acetone solvents, lead-based paints, lead shielding in disposal containers, and chemical paint removers. Radioactive wastes, including those containing chemically hazardous substances, are handled in accordance with long-standing Program radiological requirements. Such handling includes solidification to immobilize the radioactivity, separation of the radioactive and chemically hazardous substances, removal of liquids from solids, and other simple techniques. A determination is then made as to whether the resulting waste is hazardous. As a result of Program efforts to avoid the use of chemically hazardous substances in radiological work, Program activities typically generate only a few hundred cubic feet of mixed waste each year. This small amount of mixed waste, along with limited amounts of mixed waste from Program work conducted prior to 1987, will be stored pending the licensing of commercial treatment and disposal facilities.

Since the complex contains so much pavement, surface drainage is required. An extensive storm sewer system exists, which is separate from the sanitary sewer system. The storm sewer discharges runoff into Sinclair Inlet through 15 outfalls (Navy 1991a).

4.1.2 NORFOLK NAVAL SHIPYARD: PORTSMOUTH, VIRGINIA

4.1.2.1 Overview

Norfolk Naval Shipyard is located in the Tidewater region of Virginia as shown on Figure 4.1.2-1. The shipyard is contiguous with the city of Portsmouth at 36y 49' 5" north latitude and 76y 17' 38" west longitude. The shipyard consists of over 1,200 acres and includes over 500 administrative, industrial, and support structures and 4 miles of shoreline. Figure 4.1.2-2 provides a vicinity map, and Figure 4.1.2-3 provides the site map for the Norfolk Naval Shipyard. For information, Figures 4.1.2-4 and 4.1.2-5 show the location and vicinity of Newport News Shipbuilding. Six city areas are within 15 miles of the shipyard: Portsmouth, Chesapeake, Norfolk, Virginia Beach, Hampton and Newport News, and Suffolk. The cities of Portsmouth to the immediate west, Chesapeake to the south, and Norfolk to the north and east surround the shipyard. The land area of Norfolk is separated from the shipyard proper by the Southern Branch of the Elizabeth River to the east and by the confluence of the Southern, Eastern, and Western Branches of the Elizabeth River to the north.

4.1.2.2 Land Use

Over 95 percent of the land area within the boundaries of the shipyard is covered by structures or paved with concrete and asphalt. The shipyard is divided internally into a controlled industrial area and a non-industrial area. All of the piers, dry docks, and work facilities accomplishing naval nuclear propulsion plant work are within the controlled industrial area.

The surrounding six city areas are a mix of urban, suburban, light industrial, and rural areas with the land areas dissected by the numerous rivers, creeks, bays, and wetlands.

Portsmouth is predominantly urban and suburban. The two main industries are the shipyard and the Portsmouth Marine Terminals, which are cargo shipping terminals operated by Virginia International Terminals. There are few undeveloped tracts of land in Portsmouth.

Figure 4.1.2-1. Location of Norfolk Naval Shipyard within Virginia. Figure 4.1.2-2. Norfolk Naval Shipyard vicinity map. Figure 4.1.2-3. Norfolk Naval Shipyard site map. Figure 4.1.2-4. Location of Newport News Shipbuilding within Virginia. Figure 4.1.2-5. Newport News Shipbuilding vicinity map.

Norfolk is north and east of the shipyard and separated from the Portsmouth land mass by the Elizabeth River. Downtown Norfolk is about 2.5 miles north-northeast of the shipyard and is the financial, cultural, and educational hub of the Southside area. Norfolk is primarily urban and suburban with light industrial centers scattered throughout the city. The Norfolk waterfront has commercial shipyards, coal terminals, various piers for bulk cargo such as gypsum and phosphate, and the Norfolk Naval Base. Like Portsmouth, Norfolk has few undeveloped tracts of land.

The Chesapeake corporate limit adjoins the Norfolk corporate limit just south of the St. Helena Annex and the Portsmouth corporate limit mid-stream of the Southern Branch of the Elizabeth River due east of the shipyard. The majority of the shipyard industrial area is across the river from Chesapeake. The land area immediately along the riverfront is industrial, bulk cargo terminals, and manufacturing. Chesapeake is a mixture of suburban and rural areas. The Western Branch Area adjoins Portsmouth and is primarily suburban with large tracts of undeveloped land currently used for crops to the south and west. Greenbriar adjoins Norfolk and is the central commercial hub of Chesapeake. Great Bridge adjoins Virginia Beach and is primarily residential with commercial corridors and regional shopping areas. The southern part of Chesapeake partially contains the Great Dismal Swamp and is rural with isolated residential areas scattered throughout the region.

Virginia Beach is not contiguous with any shipyard property but is within 15 miles. Virginia Beach adjoins Norfolk and Chesapeake on their eastern borders and fronts the Atlantic Ocean from Cape Henry to the North Carolina state line. The area between the ocean front resort strip and the Norfolk city line has undergone explosive growth over the past 20 years. The area is primarily residential with several commercial corridors connecting various parts of the city. A so-called "Green Line" divides the southern agricultural rural area from the developed areas in the northern part of Virginia Beach. This line has moved south in steps over the years in response to increasing pressure for further development.

Hampton and Newport News are adjoining cities lying on a peninsula formed by the James and York rivers. Newport News Shipbuilding and port facilities for coal and containerized cargo are the major industries. Although within 15 miles, the peninsula cities have historically been isolated from the southside cities economically and demographically as well as politically. This is slowly changing with the opening of the bridge-tunnel connecting western Tidewater with the peninsula. Inclusion of the peninsula cities into the Regional Standard Metropolitan Statistical Area joined the regions demographically. Land use is primarily suburban with several major commercial corridors dissecting and connecting the two cities. A downtown area of Newport News sits at the tip of the peninsula separated from the James River waterfront by coal terminals and the Newport News Shipbuilding facilities. The limited agricultural land is being rapidly supplanted by expanding residential and commercial development.

Suffolk is the westernmost of the southside cities. Suffolk is predominantly rural and has substantial land area under cultivation with peanuts, soybeans, and produce vegetables being the major crops. Residential areas are scattered but are becoming more numerous as land in Portsmouth and the Western Branch Area of Chesapeake is developed.

4.1.2.3 Socioeconomics

The shipyard is centrally located in relation to the six city population centers that comprise the Tidewater region. At the time of the 1990 census, approximately 1.5 million persons resided within a 50-mile radius of the shipyard. The six-city metropolitan area houses most of this population. Figure 4.1.2-6 provides a population distribution rose showing the population density and population for principal centers within 50 miles of the shipyard. Population data are based on the 1990 census.

As of 1993, Norfolk Naval Shipyard employed approximately 8,500 civilian personnel. The number of military personnel at the shipyard is typically between 2,000 and 3,000 and can vary at times up to approximately 15,000.

The majority of the labor force that would be employed at the shipyard for construction and operation of the naval spent nuclear fuel area would be expected to reside within about 20 miles from the shipyard. The total calculated population, labor force, and employment within this region for the base year (1995) are presented in Table 4.1.2-1. Projections of employment and population for the years beyond 1995 have not been presented because, as discussed in Section 5, the number of additional jobs that might be created at the shipyard under any alternative could be small.

Figure 4.1.2-6. 50-mile population distribution around Norfolk Naval Shipyard.

Table 4.1.2-1. Regional employment factors at Norfolk Naval Shipyard.

Regional Employment	Regional Labor Force	Regional Population
498,000	533,000	1,138,400

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the Norfolk Naval Shipyard, consistent with the population data provided in Figure 4.1.2-6.

Figure 4.1.2-7 shows the locations of populations which have more than 50 percent minority members within the 50-mile radius. Minorities make up approximately 33 percent of the total population in this area. These populations have been identified following an approach developed by the Environmental Protection Agency which, for purposes of environmental justice evaluation, defines minority communities as those which have percentages of minorities greater than the average in the region analyzed (EPA 1994).

Figure 4.1.2-8 shows the locations of populations which have more than 25 percent of their members living in poverty, reflecting a common definition of low-income communities (EPA 1993). The U. S. Census Bureau characterizes persons in poverty as those whose income is less than a "statistical poverty threshold." For the 1990 census, this threshold was based on a 1989 income of $12,500 per household.

4.1.2.4 Cultural Resources

Founded November 1, 1767 under the British flag, the shipyard pre-dates the United States Navy Department by 30 years. The first drydocking in the western hemisphere occurred at the shipyard on June 17, 1833. Dry dock 1 is a National Historic Landmark. Over the years, the shipyard has been greatly expanded. Beginning in 1963, the yard was authorized to perform Naval Nuclear Propulsion Program work.

Figure 4.1.2-7. Minority population distribution within 50 miles of the Norfolk Naval Shipyard.

Figure 4.1.2-8. Low-income population distribution within 50 miles of the Norfolk Naval Shipyard.

The Naval Shipyard Museum located at the foot of High Street in downtown Portsmouth contains many historical photographs and drawings, valuable artifacts, and archives of records tracing the 226-year history of the shipyard and its close ties to the city of Portsmouth. This museum is open to the public and to researchers.

No prehistoric archaeological sites have been identified at the Norfolk Naval Shipyard. In addition, no submerged cultural resources have been recorded in the immediate vicinity of the shipyard. There are no Native American properties or ceremonial sites in the areas where spent nuclear fuel would be stored. In the area where naval spent nuclear fuel would be stored, there are no historic sites that are potentially eligible or listed on the National Register of Historic Places (NPS 1991). Due to the historic nature of the shipyard, there might be areas of archaeological interest. In the past, artifacts from the early shipbuilding era have been uncovered during construction excavation.

4.1.2.5 Aesthetic and Scenic Resources

The lower Chesapeake Bay - Hampton Roads region is a flat coastal plain with minimal topographic relief. The numerous bays, rivers, and creeks that dissect the region provide access to various wetlands consisting of saltwater marshes, bogs, and swamps. The unique ecology of these wetlands provides habitat for numerous indigenous and migratory species of aquatic and avian wildlife. Area beaches fronting the Atlantic Ocean from Cape Henry southward and along the Chesapeake Bay westward from Cape Henry provide both scenic and recreational opportunities to area residents and visitors.

The shipyard is centrally located in a highly developed urban area and has an industrialized character. The area within the shipyard where the naval spent nuclear fuel would be stored has low visual sensitivity since the area is an industrial site. The original character of the area has been extensively modified in the 300 years that western man has occupied the area.

4.1.2.6 Geology

4.1.2.6.1 General Geology (Coch 1971).

The coastal plain is characterized by a series of marine transgressions with extended periods of non-marine erosion and deposition of river sediment. From the surface down to a depth of about 120 feet, the most recent sediments of the Columbia Group occur. Underlying the Columbia Group is the Yorktown Formation (deposits of fine silt, sand, and shells), which, at the location of the shipyard, is about 100 feet thick. The Calvert Formation, with a thickness of about 345 feet, underlays the Yorktown Formation.

The Calvert Formation consists of usually consolidated greenish-brown clays, silty clays, and silicon-based clays over a basic layer of coarse sand. The Calvert clays form an impermeable hard-packed barrier which limits the vertical migration of shallow groundwater. This barrier also isolates the Columbia and Yorktown regional aquifers from deeper lying aquifers contained in permeable formations underlying the Calvert. Extensive studies of the Coastal Plain of Virginia sponsored by the Virginia Division of Mineral Resources have been conducted and published in various bulletins and reports (Teifke and Onuschak 1973; Coch 1971).

4.1.2.6.2 Geologic Resources.

There are no unique or economic geological resources in the shipyard region. (Teifke and Onuschak 1973; Coch 1971)

4.1.2.6.3 Seismic and Volcanic Hazards.

Seismic risk related to structural damage may be represented in the United States by a relative scale of 0 through 4, with Zone 0 not expected to encounter damage and Zone 4 expected to encounter the greatest seismic risk. The Norfolk Naval Shipyard is located in Zone 1. (UBC 1991) No volcanic hazards exist. The Uniform Building Code seismic classification provides a means for a comparable assessment of the seismic hazard between the alternate sites. If the Record of Decision identifies this site for the interim storage of naval spent fuel, then a detailed seismic evaluation would be conducted. More detailed information regarding the design basis considerations for storage of naval spent nuclear fuel at the shipyard is presented in Attachment D.

4.1.2.7 Air Resources

4.1.2.7.1 Climate and Meteorology.

The Tidewater area is nearly surrounded by water with Chesapeake Bay to the north, Hampton Roads to the west, and the Atlantic Ocean to the east. The area contains numerous bays and is traversed by several rivers and creeks. The climate of the region is essentially marine. The land is level and low with an average elevation of 13 feet above sea level.

Based on the 1951 through 1980 period, the average first occurrence of 32 degrees Fahrenheit is November 17 and the average last occurrence is March 23. Temperatures of above 100 degrees are infrequent and below zero temperatures are almost nonexistent. The proximity to the surrounding water modifies the invading air masses. Summer winds are predominantly from the south and southwest, pulling large amounts of moisture up from the Gulf of Mexico. During the summer months, afternoon thunderstorms due to daytime heating of the near surface air are very common. Large areas of high pressure frequently stall just east of the southern coast. These "Bermuda Highs" can lead to extended periods of hot, humid weather with very little precipitation other than scattered thunderstorms. Thunderstorms occasionally spawn isolated tornadic activity throughout the region. Although locally destructive, the tornados move through the area rapidly along with storm centers.

Precipitation is distributed fairly evenly throughout the year and totals about 43 inches on the average. Snowfall is usually light and is frequently gone within 24 hours. Large accumulations do occur but are infrequent. July and August are generally the wettest months due to thunderstorms while November and December are the dryest. Average monthly precipitation is 3.5 inches. Spring weather can begin as early as March but more frequently occurs in April. This is a transitional period between winter and summer weather patterns. During the spring, summer-like days, rain, snow, and cold-humid weather can and frequently do occur during the same week. Mild weather in the fall usually extends through Thanksgiving.

Winter climate is primarily determined by the latitude of the upper level jet stream which steers eastwardly moving arctic air masses. Usually, winters are mild with alternating periods of cold and warm weather. Winter rains are frequent due to the frontal boundaries formed from low-pressure storm cells to the north and moisture-laden Gulf air moved into the area by a high-pressure area to the south. North to northeast winds predominate during the winter months. Northeast winds can affect the Atlantic Coast from the Carolinas northward. Strong northeast winds and heavy rains can cause localized flooding of low-lying areas. Since the Chesapeake Bay is shallow, a strong northeast wind can move large amounts of water from the north end of the bay southward. When this elevated water level is combined with a high tide, flooding occurs. Added to this is the heavy rainfall and poor drainage due to the low elevation. High tide levels 6 to 8 feet above normal are experienced during major northeast winds along with major beach erosion from Cape Henry to Cape Hatteras.

4.1.2.7.2 Air Quality.

An area can be designated by the Environmental Protection Agency as having air quality that is better than defined by the National Ambient Air Quality Standards (attainment) or as exceeding one or more of those standards (nonattainment for one or more pollutants). The Code of Federal Regulations, Title 40, Part 81, states that the Air Quality Control Region, in which the shipyard is located, is in marginal nonattainment for ozone and is better than national standards for total suspended particulate matter and SO2. The area has no specific classification for carbon monoxide and NO2. The nearest Class I Area is the Swanquarter National Wilderness Area, approximately 161 kilometers (100 miles) from the shipyard.

4.1.2.7.3 Existing Radiological Conditions.

Radiological facilities at all naval shipyards are designed to ensure that there are no uncontrolled discharges of radioactivity in airborne exhausts. Radiological controls are exercised to preclude exposure of working personnel to airborne radioactivity exceeding federal limits. Air exhausted from radiological work facilities is passed through high-efficiency particulate air filters and monitored during discharges. The annual airborne radioactivity emissions from the shipyards do not result in any measurable radiation exposure to the general public. Calculations of site radioactive airborne emissions for 1992 have been performed as described in Attachment F. These calculations have shown that emissions of radionuclides from each shipyard result in an effective dose equivalent of less than 0.1 mrem per year to any member of the general public.

4.1.2.8 Water Resources

4.1.2.8.1 Surface Water.

Hampton Roads is a relatively wide body of water formed by the confluence of the James, Elizabeth, and Nansemond Rivers. It connects on the east with the Chesapeake Bay. The natural depth of the main part of Hampton Roads ranges from 20 to 80 feet; however, the harbor shoals to less than 10 feet toward shore. Two channels are maintained at a depth of 40 feet by dredging. The currents in Hampton Roads are influenced considerably by the winds and have a velocity of 0.5 m/sec.

The Elizabeth River is the most downriver tributary of the James River. The Elizabeth River system is comprised of a main stem, running from Sewell's Point and Craney Island to Town and Pinner Points, plus four tributary arms: the Lafayette River and the Eastern, Western, and Southern Branches.

Deep navigation channels are maintained from Hampton Roads up the main stem and Southern Branch of the Elizabeth River. Project depths decrease from 45 feet at the mouth to 35 feet between the Norfolk Naval Shipyard and Newton Creek. The channels in the Eastern and Western Branch and Lafayette River are maintained at 25 feet, 14 feet, and 8 feet, respectively.

The Southern Branch of the Elizabeth River is an estuarine body of water in which tidal action brings about a mixing of salt and fresh water. This portion of the river is a slow-moving, heavily sediment-laden body of water. The movement of the water is affected by the narrowness of the channel and the influence of tidal action.

Located along the river banks and in the surrounding territory are extensive and important naval bases and docking facilities, pleasant exurbs and yacht clubs, dry docks and international shipping terminals, the commercial centers of Norfolk and Portsmouth, relatively quiet rural areas, and the Great Dismal Swamp.

Neither the Southern Branch of the Elizabeth River, nor the Hampton Roads Harbor, is fished commercially. Within these waterbodies, it has been established by the Virginia Department of Health that it shall be unlawful for any person, firm, or corporation to take shellfish from the condemned areas for any reason.

Norfolk Naval Shipyard is located on the Southern Branch of the Elizabeth River in a highly industrialized area of the city of Portsmouth, Virginia, 8 miles upstream from the confluence of the James and Elizabeth Rivers. The Southern Branch is a deep-water river which provides access to heavy industry (i.e., ship repairs, gas and oil distribution, etc.) in the vicinity of the shipyard. In addition, the Southern Branch is a major north-south part of the Army Corp of Engineers Intercoastal Waterway System.

The Southern Branch is brackish and is not a source of drinking water. The Southern Branch of the Elizabeth River-Naval Shipyard waterbody extends from Jones and Paradise Creeks to the Downtown Tunnel (Route 264). Shellfish condemnations impact 429 acres. This condemnation is due to historical sediment toxic contamination, and the potential for pollutants of fecal coliform bacteria (Virginia WCB 1992a). Sixteen industrial facilities discharge to the Southern Branch Elizabeth River main stem and tributaries. Surveys of finfish in the Elizabeth River (primarily in the Southern Branch) show obvious signs of stress and/or disease, especially among those species exposed to the contaminated bottom sediments. Many fish have external lesions, fin erosion, inflamed fins, and cataracts.

The bottom sediments of the Elizabeth River are highly contaminated with a variety of organic and inorganic compounds at several locations (Virginia WCB 1992a). The majority of the contamination problems occur in the highly industrialized Southern Branch. Of particular concern among the synthetic organic compounds found in the Southern Branch of the Elizabeth are polynuclear aromatic hydrocarbons (PAH's). They are long-lived, and many are mutagenic and carcinogenic. PAH's are found in a variety of sources including creosote, coal tar, coal pile runoff, fly and bottom ash from coal-fired boilers, roofing tar, asphalt oil, petroleum oil, bilge discharge, diesel soot, and wood stove soot. One source of this class of compounds in the Elizabeth River has been attributed to the wood-preserving facilities, which have been in operation along the Southern Branch since the early 1900's.

The James River-Hampton Roads waterbody encompasses the James River mainstem and tributaries from Old Point Comfort to Willoughby Spit (northern border) to the west side of Craney Island (eastern border), west to Barrel Point (southern border), and north to Boat Harbor, Hampton River, and Mill Creek. Shellfish condemnations impact 17,281 acres (Virginia WCB 1992a). This condemnation is due to historical toxic contamination, and the potential for fecal coliform bacteria pollution. This portion of the James River mainstem receives additional discharges from 14 facilities, at least half of which are seafood preparation waste discharges.

Surrounding the Nansemond River watershed are seven lakes (Lake Kilby, Lake Cahoon, Lake Meade, Speights Run Lake, Lake Prince, Lake Burnt Mills, and Western Branch Reservoir) which are used as public water supply sources for the surrounding cities. Lake Taylor, located in the city of Norfolk, is the closest lake and is approximately 7 miles from Norfolk Naval Shipyard. The other lakes are approximately 20 miles to the west of the shipyard.

The Flood Insurance Rate Map (FIRM COMMUNITY-PANEL No. 515529 0060 B) shows that most of the Norfolk Naval Shipyard, including the location considered for the interim storage of naval spent nuclear fuel, is in the 100-year floodplain. However, the location considered for naval spent nuclear fuel is not in a high-hazard area (as defined by Title 10, Part 1022 of The Code of Federal Regulations for floodplains) which is an area where frequent flooding occurs.

4.1.2.8.2 Groundwater.

Shallow groundwater underlies the whole region. Designated as the Columbia aquifer, it is composed primarily of sediments that were deposited up to 1.7 to 2.2 million years ago as channel fill and river or ocean terraces. The aquifer is composed of interbedded gravel, sand, silt, and clay and is unconfined throughout the region. The saturated thickness of the Columbia aquifer is about 80 feet in the Tidewater area.

A consolidated layer of silty clay underlies the water table and separates it from the Yorktown Formation. In general, water flow within the Columbia aquifer is from the topographic highs to topographic lows. This flow distribution is modified locally by the pumping of wells, dewatering of borrow pits, and by the upper contours of the Yorktown Formation. As a result, the depth of shallow wells can vary drastically in only a few hundred yards.

Underlying the Columbia aquifer are seven distinct aquifers that originate east of the Fall Line and progressively deepen as they proceed eastward. The names of the aquifers and their approximate depths at the location of the shipyard are shown in Table 4.1.2-2.

The material confining the individual aquifers thickens from west to east so that the vertical leakage between aquifers due to gravity or artesian pressure differentials decreases eastward. The Yorktown-Eastover aquifer is both confined and unconfined, depending on location, and consists of fine to coarse sand interbedded with clay, shell, and sandy clay. The formation thickness is about 100 feet in the vicinity of the shipyard. Where the aquifer is unconfined, it is a major source of recharge to both the water table aquifer and to underlying confined flow systems.

Table 4.1.2-2. Aquifers that underlie the Columbia aquifer.

Aquifer	Depth Below Sea Level (ft)
Yorktown - Eastover	Sea Level
Chickahominy - Piney Point	200
Aquia	400
Brightseat	500
Upper Potomac	750
Middle Potomac	900
Lower Potomac	>1500

Artesian pressure existing in the confined portions of the Yorktown aquifer causes an upward vertical leakage from the Yorktown aquifer into the water table aquifer. In the vicinity of the shipyard, the thickness of the confining layer is about 80 feet. The confining layer consists of blue-gray to green-gray clay interbedded with massive silty clay, fine sand, and chalky shell fragments.

The Yorktown aquifer is a major source of domestic, commercial, and light industrial water. Yields are reported to range from 20 to 250 gallons per minute. This aquifer is the usual source of drinking and domestic consumption water for those localities within the region not served by municipal water systems. The groundwater aquifers have been extensively monitored and results published in numerous papers, bulletins, and reports (Siudyla et al. 1981; USGS 1990). Groundwater quality is monitored by several state agencies and boards with annual reports submitted to the EPA and Congress (Virginia WCB 1992b).

Since the underlying layers slope downward from west to east, the flow of groundwater in the vicinity of the shipyard generally trends from west to east, with localized modifications as previously described.

Rivers and creeks bound the shipyard on the immediate east and south. The confluence of the Southern, Eastern, and Western Branches of the Elizabeth River occurs about 1.5 miles north of the shipyard. These stream beds are below sea level and thus intercept the water table aquifer.

Where an aquifer is interfaced with surface streams or impoundments, the net flow within the aquifer is toward the surface water. In the case of the shipyard, the water table aquifer is intercepted on three sides (N, E, S) by a surface stream. This confines any contaminant infiltrating into the aquifer to the area of and immediately adjacent to the shipyard property. With a net easterly flow due to gravity, any contaminant infiltrating from the shipyard area would percolate through the soil zone into the water table under the shipyard and be intercepted by bounding surface waters.

4.1.2.8.3 Existing Radiological Conditions.

The normal activities associated with current naval nuclear operations at all naval shipyards do not result in the intentional discharge of any radioactive liquid effluent. However, there were occasions, primarily in the early 1960's, when measurable levels of radioactivity were discharged with liquid effluent. In all cases, effluent releases were less than permitted under the then current limits imposed by state and federal agencies.

The United States Environmental Protection Agency Office of Radiation Programs has performed monitoring of the water, plant life, aquatic life, and sediment in the vicinity of Norfolk Naval Shipyard. The purpose of the survey was to determine if operations related to U.S. Navy nuclear warship activities resulted in releases of radionuclides which could contribute to significant population exposure or contamination of the environment. "Radiological Surveys of the Norfolk Naval Station, the Norfolk Naval Shipyard, and Newport News Shipbuilding" (Sensintaffar and Blanchard 1988) discusses the most recent Environmental Protection Agency monitoring data. Pertinent conclusions are as follows:

1. "The trace amounts of cobalt-60 measured in the harbor sediments are significantly less than observed during the 1968 survey and exist about 5 inches beneath the surface of the sediment, indicating that no detectable cobalt-60 has been deposited in the sediments since the 1968 survey.
2. In addition to cobalt-60, only radionuclides of natural origin plus trace amounts of cesium-137 from previous nuclear weapons testing were detected in any of the harbor sediment samples.
3. No tritium or gamma-ray emitters, other than those occurring naturally, were detected in harbor water, or samples of sediment, water, and vegetation collected from public areas.
4. Drinking water samples contained no detectable levels of radioactivity other than those occurring naturally.
5. The shoreline gamma-ray surveys failed to detect any elevated exposure levels except at one location where the levels are attributed to the naturally occurring radionuclides that exist in granite rock.
6. The levels and locations of radioactivity identified and the limited media in which it was found show that operations related to nuclear-powered warship activities resulted in no discernible adverse effects on public health or the environment."

Environmental monitoring is conducted by the shipyard. The results of this monitoring program corroborate the Environmental Protection Agency's conclusions.

4.1.2.9 Ecological Resources

4.1.2.9.1 Terrestrial Ecology.

The shipyard area is highly developed and its surface is about 95% covered with impervious materials. The few green areas are outside the controlled industrial area and have been extensively graded. Landscaping consists primarily of turf grasses and native trees. The oldest growth areas are in the vicinity of the Shipyard Commander's residence and Trophy Park. Appendix B of the "Land Management Plan for Norfolk Naval Shipyard" (NFEC 1991) lists those plants known to or likely to occur on the shipyard or its annexes.

The shipyard bird population consists of urban species commonly found in southeastern Virginia. These species include pigeons, jays, robins, finches, chickadees, starlings, flickers, blackbirds, grackles, cowbirds, chimney swifts, martins, mocking birds, cardinals, herons, egrets, terns, and several species of gulls. There are few mammals that inhabit the shipyard and their populations are limited. Squirrels and other rodents common to developed areas are observed.

The shipyard offers little refuge for reptiles and amphibians. Non-poisonous garter snakes and the occasional black snake are found in vegetated areas and in warehouse structures. Toads, newts, salamanders, and other semi-aquatic reptiles can be found in wet areas where suitable forage and habitat exists. Sightings are infrequent due to the dispersed habitat locations and the limited number of suitable sites.

The Tidewater area is part of the Mid-Atlantic flyway. Migratory species pass through the area or over-winter in the numerous bays, sounds, creeks, and wetlands that occur in the region. During migratory periods and over the winter, more than a hundred species of water fowl have been observed in the region. Since there is no suitable habitat or forage areas on the shipyard, the appearance of migrating species is rare.

4.1.2.9.2 Wetlands.

There are no freshwater wetlands on the main shipyard site where naval spent nuclear fuel would be stored. The majority of the shipyard is developed and covered with an impervious surface. National Wetlands Inventory Maps (DOI 1986) show a number of estuarine wetlands along the banks of Paradise, Blows, and St. Juliens Creeks. There are no remaining tidal wetlands along the western shoreline of the Southern Branch from its mouth to Paradise Creek (Silberhorn and Dewing 1989). The total wetland area along Paradise Creek is, according to this reference, about 422 acres.

Blows Creek wetlands occur along the Southern Branch and encompass about 2.54 acres. St. Juliens Creek tidal marshes are subdivided into eight locations and total about 52 acres (Silberhorn and Dewing 1991).

4.1.2.9.3 Aquatic Ecology.

The majority of the shipyard property is located on land that has been filled to raise its elevation above the level of the river. The shipyard shoreline consists of concrete bulkheads and finger piers built on concrete pilings. Wooden wharfs and quays have been replaced over the years with concrete structures. Marine vegetation along the shipyard waterfront is limited to red and green algae. As reported in Section 4.1.2.8.1, the marine life in the Southern Branch is limited due to the pollution in the river from sewage treatment plants and riverfront industries. There is no commercial fishing and only limited sport fishing in the Southern Branch. In the contiguous shipyard waters, there is no fishing due to a security buffer zone and because of the heavy traffic along the river.

Estuarine wetland ecology is principally vegetative and consists of Saltmarsh Cord grass and Reed grass. The abundance of Reed grass in these areas is indicative of disturbed wetlands that have been filled or are impacted by overloads of upland sediment.

Herring gulls, several species of terns, brown pelicans, egrets, herons, cormorants, and migratory bird species common along the Atlantic flyway take refuge in or feed on riverine or marshland environments and biota.

The waters adjoining the shipyard are frequently dredged to maintain the depth along the piers, at the entrance to dry docks, and in the turning basin. The periodic removal of silt and detritus limits the habitat of benthic organisms common in other parts of the lower bay and tributaries.

4.1.2.9.4 Endangered and Threatened Species.

There are no critical habitats as defined in 50CFR424.02 within the 15-mile tidal influence area. Several federally designated threatened (T) or endangered (E) species have been identified as existing in the vicinity. The exact locations of specific habitats could not be located; however, surveys of the area have not identified any habitat on shipyard property. The U.S. Fish and Wildlife Service lists the following species as endangered or threatened in the South Hampton Roads area from Suffolk eastward (DOI 1990).

1. Loggerhead turtle (T)
2. Bald eagle (E)
3. Peregrine falcon (E)
4. Piping plover (T)
5. Red-cockaded woodpecker (E)
6. Eastern cougar (E)
7. Dismal Swamp southeastern shrew (T)
8. Northeastern beach tiger beetle (T)

No state rare, threatened, or endangered species exist within the 15-mile tidal influence zone (Buhlmann and Ludwig 1992).

There are no marine mammals that are routinely found within the lower Chesapeake Bay or its tributaries. Manatees and Atlantic Bottlenose dolphins occasionally appear in the bay and Hampton Roads; however, their presence is transient. Stranding and grounding of pods of migratory whales and dolphins as well as carcasses of dead animals occasionally appear along Atlantic beaches from Virginia's Eastern Shore to the North Carolina Outer Banks but sightings of whales in the bay or near the ocean shore are rare.

Various oceanic turtles may nest along the sandy beaches surrounding the Chesapeake Bay and Outer Banks. The highly developed regions along the Elizabeth River do not provide suitable nesting sites for these marine reptiles.

4.1.2.10 Noise

Norfolk Naval Shipyard is an existing industrial-type environment characterized by noise from truck and auto traffic; yard cranes and related internal combustion engine powered equipment; and operating transmission lines for steam, air, and water along with associated pumps and compressors. The eastern shoreline of the Southern Branch contains private shipyards, manufacturing plants, and bulk material handling and storage terminals. These activities, along with Norfolk Naval Shipyard, add to the ambient noise levels of the river corridor.

Intervening structures and distance separate adjacent residential areas to the south and immediately west of the shipyard from the waterfront ship repair activities and thus attenuate the noise generated by those activities.

4.1.2.11 Traffic and Transportation

Within the city of Portsmouth, three main corridors, High Street, Portsmouth Boulevard, and George Washington Highway serve as access to suburban commercial and residential areas. The Downtown and Midtown tunnels link Portsmouth and Norfolk and join via connecting arteries the regional interstate highway network consisting of I-64, I-262, I-464, and I-664. I-64 crosses Hampton Roads while I-664 crosses the lower James River linking the southside cities to Newport News and Hampton on the peninsula. The bridge-tunnels allow the unimpeded flow of the largest commercial ships and warships through Hampton Roads.

Tidewater Regional Transit provides bus services throughout Portsmouth and Norfolk. Only limited public transportation is available in Chesapeake and Virginia Beach.

The Norfolk International Airport provides commercial scheduled passenger and cargo air service to major connecting hubs. Most private and general aviation not operating from Norfolk International operate from airports in Chesapeake, Suffolk, and Virginia Beach.

A passenger ferry across the Elizabeth River connects the Portsmouth downtown area with the Waterside Berths on the Norfolk side. This ferry service is primarily designed for tourist and recreational passengers rather than commuter service.

Norfolk Southern and CSX corporations operate extensive networks of rail transportation for freight and bulk cargo. Norfolk and Newport News are the nation's largest terminals for coal exports and, along with Portsmouth, have a large capacity for containerized and bulk cargos. Lines operated by CSX and Norfolk Southern subsidiaries serve the shipyard at the north and south ends, Southgate, and St. Juliens Creek annexes.

Naval spent nuclear fuel has been removed from Navy nuclear-powered ships and transported to the Idaho National Engineering Laboratory Expended Core Facility (ECF) for examination and evaluation as a routine part of their operating cycle. Naval spent nuclear fuel shipments from Norfolk Naval Shipyard to ECF were initiated in 1965. Since that time, 10 shipments of naval spent nuclear fuel originating at Norfolk Naval Shipyard have been made to ECF. The naval spent nuclear fuel was shipped by rail. Attachment A provides a list of these shipments made to date by year. Attachment A also contains detailed descriptions of the shipping containers used for naval spent nuclear fuel shipments from shipyards.

Norfolk Naval Shipyard has 30 miles of paved roads, 19 miles of railroad tracks, and dry docks.

4.1.2.12 Occupational and Public Health and Safety

4.1.2.12.1 Occupational Radiological Health and Safety. The Navy has well established and

effective Occupational Safety, Health, and Occupational Medicine programs at all of its shipyards. In regard to radiological aspects of these programs, the Naval Nuclear Propulsion Program policy is to reduce to as low as reasonably achievable the external exposure to personnel from ionizing radiation associated with naval nuclear propulsion plants. These stringent controls on minimizing occupational radiation exposure have been successful. No civilian or military personnel at Navy sites have ever exceeded the federal accumulated radiation exposure limit which allows 5 rem exposure for each year of age beyond age 18. Since 1967, no person has exceeded the federal limit which allows up to 3 rem per quarter year and since 1980, no one has received more than 2 rem per year from radiation associated with naval nuclear propulsion plants. The average occupational exposure of each person monitored at all shipyards is 0.26 rem per year. The average lifetime accumulated radiation exposure from radiation associated with naval nuclear propulsion plants for all shipyard personnel who were monitored is 1.2 rem. (NNPP 1994a) This corresponds to the likelihood of a cancer fatality of 1 in 2083.

The Navy's policy on occupational exposure from internal radioactivity is to prevent radiation exposure to personnel from internal radioactivity. The limits invoked to achieve this objective are one-tenth of the levels allowed by federal regulations for radiation workers. As a result of this policy, no civilian or military personnel at shipyards have ever received more than one-tenth the federal annual occupational exposure limit from internal radiation exposure caused by radioactivity associated with naval nuclear propulsion plants.

For work operations involving the potential for spreading radioactive contamination, containments are used to prevent personnel contamination or generation of airborne radioactivity. The controls for contamination are so strict that precautions sometimes have had to be taken to prevent tracking contamination from fallout and natural sources into radiological areas because the contamination control limits used in these areas were well below the levels of fallout and natural contamination occurring outside in the general public areas. A basic requirement of contamination control is monitoring all personnel leaving any area where radioactive contamination could possibly occur. Workers are trained to survey themselves (i.e., frisk), and their performance is checked by radiological control personnel. Frisking of the entire body is required, normally using sensitive hand-held survey instruments. Major work facilities are equipped with portable monitors, which are used in lieu of hand-held friskers. These stringent controls to protect the workers and the public from contamination have proven effective in the past.

In 1991, researchers from Johns Hopkins University, Baltimore, Maryland, completed a very comprehensive epidemiological study of the health of workers at the six naval shipyards and two private shipyards that service the Navy's nuclear-powered ships (Matanoski 1991). This independent study evaluated a population of 70,730 civilian workers over a period from 1957, beginning with the first overhaul of the first nuclear-powered submarine, USS NAUTILUS, through 1981, to determine whether there was an excess risk of leukemia or other cancers associated with exposure to low levels of gamma radiation.

The Johns Hopkins study found no evidence to conclude that the health of people involved in work on U.S. naval nuclear-powered ships has been adversely affected by exposure to low levels of radiation incidental to this work. Additional studies are planned to investigate the observations and update the shipyard study with data beyond 1981.

The radiation exposure during normal operations at each shipyard for workers who have their radiation levels monitored is determined based on the annual radiation exposure of 0.26 mrem per worker for all shipyards based on Naval Nuclear Propulsion Program Report NT-94-2 (NNPP 1994a). The total number of shipyard personnel monitored for radiation exposure associated with the Naval Nuclear Propulsion Program has been about 164,000.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population. Under the limiting assumption that the same worker is associated with every shipment for the entire historical period, this person would receive a total exposure of 7.5 rem over the approximately 40-year period, or about 0.19 rem per year, which is within DOE standards for occupationally exposed individuals. The radiation exposures to workers correspond to much less than one incident cancer, which means that it is unlikely that there have been any past health impacts due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.2.12.2 Occupational Non-radiological Health and Safety.

In the non-radiological Occupational Safety, Health, and Occupational Medicine area, the Navy complies with the Occupational Safety and Health Administration Regulations. The Navy policy is to maintain a safe and healthful work environment at all naval facilities. Due to the varied nature of work at these facilities, there is a potential for certain employees to be exposed to physical and chemical hazards. These employees are routinely monitored during work and receive medical surveillance for physical hazards such as exposure to high noise levels or heat stress. In addition, employees are monitored for their exposure to chemical hazards such as organic solvents, lead, asbestos, etc., and where appropriate are placed into medical surveillance programs for these chemical hazards.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact due to the historical shipment of naval spent nuclear fuel over the entire history of such shipments.

The shipyard has an occupational health/preventive medicine unit and a branch clinic (industrial dispensary). Personnel may also be taken to Portsmouth Naval Hospital and Portsmouth General Hospital as needed.

The shipyard maintains two fire stations with approximately 60 personnel. The fire department is fully equipped for structural and industrial firefighting and hazardous material spill response.

The shipyard security force has approximately 100 personnel providing law enforcement services, emergency services, security clearances, and parking and traffic control for the Norfolk Naval Shipyard Complex.

Relative to social services, military personnel receive assistance through various programs at Portsmouth Naval Hospital and the Navy's Morale Welfare and Recreation Department.

4.1.2.12.3 Public Radiological Health and Safety.

In order to quantify the exposures resulting from normal shipyard radiological releases to the general public, detailed analyses were performed based on conservative estimates of radioisotopic releases since releases began. Attachment F provides detailed annual release values used in the analyses.

The GENII computer code (Napier et al. 1988) was used to calculate exposures to human beings due to the estimated radionuclide releases from normal operations at the shipyards.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from stored fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F.

The hypothetical exposures calculated in Attachment F for the period 1995 through 2035 were adjusted from an annual basis (1995) to the historical basis by multiplying by 38 years and by a factor of 1.7 to take into consideration variations in the number of ships and operations.

The calculated accumulated exposures through 1995 to the general population within 50 miles of the site (about 1.5 million people) are 3.9 person-rem. To provide perspective, the exposures received due to natural radiation sources through 1995 are approximately 18 million person-rem, based on 0.3 rem per person per year.

The results of environmental monitoring as described in Naval Nuclear Propulsion Program Report NT-94-1 show that Naval Nuclear Propulsion Program activities had no distinguishable effect on normal background radiation levels at site perimeters (NNPP 1994b).

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities.

All of the radiation exposures to the general population correspond to much less than one incident cancer, which means that it is unlikely that there has been any past health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.2.12.4 Public Non-radiological Health and Safety.

Portsmouth has three hospitals: Portsmouth General Hospital, Maryview Hospital, and Portsmouth Naval Hospital.

Fire protection in Portsmouth is administered by local fire departments and fire districts. The Portsmouth Fire Department has nine stations. Police protection services are provided by the city of Portsmouth.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.2.13 Utilities and Energy

The shipyard purchases all of its water from the city of Portsmouth. Section 4.1.2.8.1 describes the sources of public water supplies for the region. A saltwater system is provided at berths and dry docks for cooling supplies to ship systems and for fire and flushing mains.

Shipyard and ship sewage effluents are discharged to the Hampton Roads sanitation district mains via the Portsmouth sewer system. Sewage treatment plants along the Southern Branch and lower James River receive and treat sewage from surrounding cities.

Electricity is purchased from Virginia Power Company transmission grids and is obtained from the Refuse Derived Fuel Plant located just south of the shipyard and operated by the Southeastern Public Service Authority. During periods of low demand, the Refuse Derived Fuel Plant sells electricity to Virginia Power. The Refuse Derived Fuel Plant also provides yard steam for operations and space heating.

Natural gas serves six buildings within the shipyard. Industrial uses include forging and tempering furnaces, various ovens and torches, laboratory burners, and cooking appliances in the cafeteria. This gas is purchased from Commonwealth Gas Company which serves the Portsmouth area.

Shipyard freshwater usage is approximately 823 million gallons annually.

Electricity usage is about 20,000 megawatt hours annually.

4.1.2.14 Materials and Waste Management

Solid waste generated by the shipyard is collected by a private contractor. Metals are segregated on-site in specially marked dumpsters to be recycled by the Defense Marketing and Reutilization Office. Solid burnable waste is transferred to the Southeastern Public Service Authority where it is either compacted into fuel blocks for use in the Refuse Derived Fuel Plant or disposed of at a regional landfill located in Suffolk. Once turned over, the Southeastern Public Service Authority determines the final disposition depending on the regional waste volume inventory at the fuel plant adjacent to the shipyard.

The Refuse Derived Fuel Plant provides electricity and steam to the shipyard and can provide power to the Virginia Power grid when excess capacity exists.

Liquid chemical wastes are collected, characterized, packaged, and labeled by the shipyard then turned over to a licensed contractor for disposal.

Solid radioactive waste materials are packaged in strong, tight containers, shielded as necessary, and shipped to burial sites licensed by the U.S. Nuclear Regulatory Commission or a State under agreement with the U.S. Nuclear Regulatory Commission. Shipyards and other shore facilities are not permitted to dispose of radioactive solid wastes by burial on their own sites. During 1992, approximately 1333 cubic yards of routine low-level radioactive waste containing 15 curies were shipped from the shipyard for burial.

Waste which is both radioactive and chemically hazardous is regulated under both the Atomic Energy Act and the Resource Conservation and Recovery Act (RCRA) as "mixed waste." Within the Naval Nuclear Propulsion Program, concerted efforts are taken to avoid commingling radioactive and chemically hazardous substances so as to minimize the potential for generation of mixed waste. For example, these efforts include avoiding the use of acetone solvents, lead-based paints, lead shielding in disposal containers, and chemical paint removers. Radioactive wastes, including those containing chemically hazardous substances, are handled in accordance with long-standing Program radiological requirements. Such handling includes solidification to immobilize the radioactivity, separation of the radioactive and chemically hazardous substances, removal of liquids from solids, and other simple techniques. A determination is then made as to whether the resulting waste is hazardous. As a result of Program efforts to avoid the use of chemically hazardous substances in radiological work, Program activities typically generate only a few hundred cubic feet of mixed waste each year. This small amount of mixed waste, along with limited amounts of mixed waste from Program work conducted prior to 1987, will be stored pending the licensing of commercial treatment and disposal facilities.

An extensive storm drain system exists on the shipyard to remove the runoff from precipitation. Outfalls empty into the Southern Branch, Paradise Creek, and St. Juliens Creek. About 100 outfalls serving the shipyard property have been mapped and located.

4.1.3 PORTSMOUTH NAVAL SHIPYARD: KITTERY, MAINE

4.1.3.1 Overview

Portsmouth Naval Shipyard is located in York County, in the southeast corner of Maine as shown on Figure 4.1.3-1. The Portsmouth Naval Shipyard is located in Portsmouth Harbor, the estuary of the Piscataqua River. This river flows between the states of Maine and New Hampshire. The shipyard is located on Seavey Island near the mouth of the river and is separated from Portsmouth, New Hampshire, by the main channel of the Piscataqua River and from Kittery, Maine by a back channel. Access to the shipyard is provided by two bridges from the Kittery shore. Figure

4.1.3-2 provides a shipyard site map.

Seavey Island has an area of 278 acres. The center reference point on the island is at 70y44'22" longitude and 43y04'56" latitude. The Portsmouth Harbor and its tributaries are used extensively for fishing, lobstering, and recreational boating. The port of Portsmouth is involved in importing salt and petroleum products, as well as exporting a variety of products, such as raw lumber.

4.1.3.2 Land Use

At the mouth of the Piscataqua River, several creeks and the river converge and mix with the Atlantic Ocean. The shipyard has been developed over time by filling in between five smaller islands and building a rock causeway to the approximately 5-acre undeveloped Clarks Island.

To the north, across the back channel, is the predominantly low-density residential community of Kittery, Maine. Kittery's land along the river and back channel is virtually all designated for residential use. The exceptions are two commercial areas located on Badgers Island and at the intersection of Routes 103 and 236 and several public use areas consisting of playgrounds and parks. The main commercial land use area is located along Route 1 and the Route 1 bypass. Most of Kittery's land further north is undeveloped due to natural constraints. The developable land is primarily designated for low-density residential use.

Figure 4.1.3-1. Location of Portsmouth Naval Shipyard within New Hampshire and Maine. Figure 4.1.3-2. Portsmouth Naval Shipyard site map.

Across the river, south of the shipyard, are the city of Portsmouth and the town of New Castle in the state of New Hampshire. Portsmouth's waterfront is nearly fully developed and has played an important role in the growth and prosperity of Portsmouth since it was settled as Strawberry Banke in 1623. Today there are areas of commercial, industrial, residential, and public/semi-public land use along the river.

Further inland, Portsmouth has large undeveloped land areas. Development on some of this land is constrained by wetlands and other natural factors; however, there still remains much acreage to accommodate future development.

Directly south of the shipyard is a large body of estuarine water containing several small islands. These islands are either undeveloped or have low-density housing.

The town of New Castle is predominantly developed with housing and is the location of a Coast Guard Station. Other land uses on the island town include commercial, public, and semi-public land.

4.1.3.3 Socioeconomics

Portsmouth Naval Shipyard is located in the small town of Kittery, Maine, a region of New England that consists predominantly of small rural towns.

Portsmouth, New Hampshire is the closest urban municipality to the shipyard. With a population of about 22,300, it is also the largest municipality in the area. Other larger municipalities within the area include Sanford and Biddeford in Maine and Rochester and Dover in New Hampshire. They have populations of approximately 20,500, 20,700, 26,600, and 25,000, respectively. Portland, Maine has a population of about 64,400. This major southern Maine urban center is located about 55 miles north of the shipyard. Also, the city of Boston, Massachusetts, with a population of about 574,300, is located approximately 50 miles south of the shipyard. Figure 4.1.3-3 provides a population distribution rose centered on the shipyard and covering a 50-mile radius.

Figure 4.1.3-3. 50-mile population distribution around Portsmouth Naval Shipyard.

The overall population of the Portsmouth region has grown through the 1980 to 1990 decade. On the Maine side of the Piscataqua River, the increase in population in York County from 1980 to 1990 was 24,848 which was a 17.8% increase. On the New Hampshire side of the river, the municipalities within Rockingham County gained in population through the 1980 to 1990 decade. There was a gain of 55,500 people or about a 29.2% increase.

Portsmouth Naval Shipyard is located within the "seacoast region" which is defined by seven job centers. Each center includes the smaller communities adjacent to them.

The seacoast region is made up of the Portsmouth, Exeter-Epping, Hampton, Dover-Somersworth, and Rochester centers in New Hampshire and the Kittery and Biddeford centers in Maine.

Historically, the economy of the seacoast region has been based on manufacturing. Textiles, shoes, and marine vessels were for many years the most important products of the region. Shipbuilding and ship repair, primarily at Portsmouth Naval Shipyard, have maintained a dominant role in the economy. Textiles and shoe manufacturing have declined over the past 30 years, but have been supplemented in part by plastics, electronics, and metals industries. The wages paid by these employers are low relative to those paid at the shipyard. On balance, the seacoast region has experienced consistent declines in manufacturing employment in recent years.

Non-manufacturing employment, especially in the trade and service sectors, is increasing. The Hampton, Portsmouth, Kittery, and Biddeford job centers have experienced economic growth as vacation resorts. Communities close to Massachusetts such as Hampton and Exeter-Epping, have grown as part of the Boston metropolitan area.

The city of Portsmouth is the seacoast region's trade and cultural center and a major distribution market for points in northern New England.

The generally healthy state of Portsmouth's economy is reflected by its excellent employment situation. As of July 1993, the unemployment rate was just 3.4% compared to the national average of 6.9%. The civilian labor force in the Portsmouth labor market area numbered 14,600 in July 1993.

The majority of the labor force that would be employed at the shipyard for construction and operation of the naval spent nuclear fuel area would be expected to reside within about 20 miles from the shipyard. The calculated total population, labor force, and employment within this region for the base year (1995) are presented in Table 4.1.3-1. Projections of employment and population for the years beyond 1995 have not been presented because, as discussed in Section 5, the number of additional jobs that might be created at the shipyard under any alternative could be small.

Table 4.1.3-1. Regional employment factors at Portsmouth Naval Shipyard.

Regional Employment	Regional Labor Force	Regional Population
115,230	121,550	258,900

Portsmouth has the distinction of being the only natural deep-water harbor between Boston and Portland, making it a major factor in New England seaborne commerce. Modern year-round port facilities, an established Foreign Trade Zone, and reliable container ship service are all available.

The chief commodities transported through the port are petroleum products which comprise over 90 percent of the marine commerce shipped. Large quantities of limestone (gypsum) and salt are also received. The chief products shipped out of Portsmouth are petroleum products and steel scrap. Commercial fishing in the area represents a multi-million dollar industry.

As of 1994, the region's largest employer, with approximately 4900 employees, was Portsmouth Naval Shipyard. The shipyard is the largest employer in the states of Maine and New Hampshire. The 1993 payroll amounted to $228 million.

Other contributing factors to the region's economic development include Pease Development Authority in Newington, the University of New Hampshire in Durham, and the New Hampshire Vocational/Technical College in Stratham.

The Kittery-York labor market area in York County had 86,165 people in the civilian labor force as of July 1993 and an unemployment rate of 2.3% for July 1993. The majority of the civilian labor force was employed in non-farm related jobs including manufacturing, transportation and utilities, wholesale and retail trade, finances, services, and government.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the Portsmouth Naval Shipyard, consistent with the population data provided in Figure 4.1.3-3.

Figure 4.1.3-4 shows the locations of populations in which minority membership exceeds the average within the 50-mile radius by more than 20 percentage points and populations which have more than 50 percent minority members. These populations have been identified following an approach developed by the Environmental Protection Agency which, for purposes of environmental justice evaluation, defines minority communities as those which have percentages of minorities greater than the average in the region analyzed (EPA 1994).

Figure 4.1.3-5 shows the locations of populations which have more than 25 percent of their members living in poverty, reflecting a common definition of low-income communities (EPA 1993). The U. S. Census Bureau characterizes persons in poverty as those whose income is less than a "statistical poverty threshold." For the 1990 census, this threshold was based on a 1989 income of $12,500 per household.

4.1.3.4 Cultural Resources

The Portsmouth-Kittery area has been part of the country's history since its very beginning. Many structures and sites from the late seventeenth, eighteenth, and nineteenth centuries have survived within the framework of new development over the years, especially in the city of Portsmouth. Considered as a group, these preserved structures and sites constitute an aesthetic, cultural, and educational resource, and a heritage with increasing value to future generations in the Portsmouth-Kittery vicinity.

Figure 4.1.3-4. Minority population distribution within 50 miles of the Portsmouth Naval Shipyard. Figure 4.1.3-5. Low-income population distribution within 50 miles of the Portsmouth Naval Shipyard.

On November 17, 1977, the National Park Service, Department of the Interior, entered the Portsmouth Naval Shipyard Historic District on the National Register of Historic Places. The district includes 54 acres of land, and 59 buildings and structures. The shipyard qualified for the Historic Status because of its shipbuilding and repair function throughout the history of the United States, its unique industrial site, and its historical and architecturally interesting buildings. From the early colonial period to the present day, this shipbuilding and repair site served first, the British government, later, the revolutionary colonies, and finally, the United States through the eras of sail, steam, and atomic power. Portsmouth Naval Shipyard represents one of the country's earliest complete industrial operations. (Navy 1993a)

There are no known cultural resources in the area of the site where naval spent nuclear fuel would be stored. Due to the historic nature of the shipyard, there might be areas of archaeological interest. In the past, artifacts from the early shipbuilding era have been uncovered during construction excavation.

4.1.3.5 Aesthetic and Scenic Resources

The majority of the 303 acres (278 acres on the shipyard, 25 in Admiralty Village) that make up the Portsmouth Naval Shipyard is considered industrial use land. Although there are no exact figures on the breakdown of land classifications, it is estimated that over 75% of the area is covered by either buildings or pavement. The area within the shipyard where naval spent nuclear fuel would be stored has low visual sensitivity since the area is an industrial site. Improved grounds on the shipyard include the parade grounds, athletic fields and various lawns dispersed throughout. Semi-improved grounds include several small picnic areas on the shipyard, the Jamaica Island Family Recreation area, and the isolated grassy areas on the fringe of the streets and sidewalks. The major areas of unimproved grounds (includes all other unpaved acreage not classified as improved or semi-improved) include the two freshwater ponds and the small beach front on what was once Jamaica Island. Because Admiralty Village is a housing facility, what little open space remained after development was utilized for recreational purposes (e.g., tennis courts) or landscaped to enhance aesthetic value.

4.1.3.6 Geology

4.1.3.6.1 General Geology.

Portsmouth Naval Shipyard is located on Seavey Island in the Seaboard Lowland Section of the New England Province. This section has a low, undulating topography with low hills that are either bedrock with a light veneer of rocks or sediment left by glaciers, or marine clay.

The general area near Portsmouth Naval Shipyard is relatively flat, rising gradually to the foothills of the White Mountains and dissected by numerous streams and rivers that have, for example, carved gorges 20 to 100 feet deep in the granite hills of the Mount Agamenticus-Ogunquit area. What remains of the mountain range in the southern and western portions of the area are scattered and isolated, high, smooth, weathered rock hills.

The thickness of the overburden of loose materials varies from 0 to 200 feet over the region, with 80% of the area having less than 50 feet depth to bedrock. A predominant characteristic of the soil in the area is the presence of the groundwater table near or at the surface. (Navy 1984)

4.1.3.6.2 Geologic Resources.

The physical geography of the general area near the Portsmouth Naval Shipyard is characterized by bedrock prominences surrounded by and dissected by inlets and stream courses of the Piscataqua River. Seavey Island, itself a rock knob, is one of these prominent bedrock outcrops. The bedrock of Seavey Island is almost entirely the Kittery formation, a fine-grained, lime-silicate material consisting of chalky sandstone formed under heat and pressure, siltstone, and gray sandstone shale from approximately 400 million years ago. (Navy 1984)

There are no economic geologic resources at the shipyard.

4.1.3.6.3 Seismic and Volcanic Hazards.

Seismic risk related to structural damage may be represented in the United States by a relative scale of 0 through 4, with Zone 0 not expected to encounter damage and Zone 4 expected to encounter the greatest seismic risk. The shipyard is located in Zone 2A according to the "Uniform Building Code" (UBC 1991). No volcanic hazards exist. The Uniform Building Code seismic classification provides a means for a comparable assessment of the seismic hazard between the alternate sites. If the Record of Decision identifies this site for the interim storage of naval spent fuel, then a detailed seismic evaluation would be conducted.
More detailed information regarding the design basis considerations for storage of naval spent nuclear fuel at the shipyard is provided in Attachment D.

Numerous small faults are to be seen in all rock units of the region. Quantitatively, their abundance appears to be related to the brittleness of the rock containing them. Most involve displacement of a few inches or feet. Only one was deemed to be sufficiently important to show on the geologic map. This is the Portsmouth fault which forms the Rye-Kittery contact for approximately 9 miles. There are so few outcrops of the fault zone, and these are poor, that no attempt was made to calculate the fault displacement. It is not known if the fault continues across the Piscataqua River and into Southeastern Maine. (Navy 1993b)

4.1.3.7 Air Resources

4.1.3.7.1 Climate and Meteorology.

The overall climate in the Portsmouth region is characterized as variable. Weather conditions can change dramatically over short intervals. There are alternating frontal systems on a day-to-day basis, widely ranging daily and annual temperatures, and overall differences between the same seasons in different years.

Although this region is situated in the path of the prevailing westerly winds, the coastal area experiences a variety of air changes over the course of a year. These include: cold dry arctic air from the north, warm land air from the Gulf states, and cool, damp air from the Atlantic Ocean. It is the combinations of, or switches between, these conditions that generally cause the area's characteristic weather.

Weather conditions, especially temperature, in the Portsmouth general area are moderated by its maritime setting. The average daily temperature ranges from 80yF in July to 13yF in January and February. Temperatures can fluctuate outside this range, but they are not usually persistent.

Precipitation is fairly evenly distributed over the year, with 2.7 to 4.6 inches falling per month for a 42.6-inch annual total. On the average, there are about 130 days each year having more than a trace of precipitation. Most summer precipitation results from showers and, infrequently, thunderstorms. Winter precipitation is generally associated with stormy conditions caused by air masses moving up along the coast.

The cool Atlantic waters can produce extensive advection fog when warmer moist air is carried over the cool water. With any persistent eastern component in the wind direction, the fog that often lies just offshore during the summer can reach the coastline. This situation is increased during the summer by local sea breezes. All months of the year have a fairly consistent occurrence of fog. Localized and continuous fog was observed at the former Pease Air Force Base an average of 15% of the time and was dense enough to restrict visibility to 1.2 miles (2 kilometers) or less, about 35% of the time.

The predominant direction the wind blows from for the Portsmouth Harbor area is a combination of the western, southwestern, and southern sectors for a combined total of 36% of the time. Differences in wind characteristics occur on a seasonal basis with west-northwest winds dominating in the winter, and southwest-southeast winds increasing in frequency during spring and summer.

The wind speed averages 8.8 miles per hour in the Portsmouth Harbor area. Speeds greater than 40 miles per hour, however, can occur any time of the year. During the winter, increased wind speeds are normally caused by the northeast winds moving down the coast, while during the summer, high winds are more often associated with thunderstorms of squall lines moving through the area. (Navy 1991b)

4.1.3.7.2 Air Quality.

A Reasonably Available Control Technology analysis was conducted in response to Maine Department of Environmental Protection (DEP) regulations requiring Reasonably Available Control Technology for Volatile Organic Compound (VOC) emission sources, such as the Portsmouth Naval Shipyard, which are located in ozone nonattainment areas. The Reasonably Available Control Technology analysis was conducted for point and fugitive sources of VOC emissions at the shipyard.

The shipyard is a large industrial complex that emits VOC emissions from a variety of sources located throughout the site. Many of the sources of VOC are small and represent fugitive losses of emissions. VOC emissions from these operations are best controlled through the implementation of good housekeeping practices.

It has been determined that current VOC operations at the shipyard meet Reasonably Available Control Technology. Continuation of current practices will ensure that VOC emissions from the shipyard are maintained at or below Reasonably Available Control Technology levels. (Navy 1991b)

An area can be designated by the Environmental Protection Agency as having air quality that is better than defined by the National Ambient Air Quality Standards (attainment) or as exceeding one or more of those standards (nonattainment for one or more pollutants). The Code of Federal Regulations, Title 40, Part 81, states that the Air Quality Control Region for the shipyard is in moderate nonattainment for ozone and is better than national standards for total suspended particulate matter and SO2. The area has no specific classification for carbon monoxide and NO2. The nearest Class I Area to the shipyard is at the Presidential Range - Dry River Wilderness Area, approximately 120 kilometers (75 miles) from the shipyard.

4.1.3.7.3 Existing Radiological Conditions Radiological facilities at all naval shipyards are

designed to ensure that there are no uncontrolled discharges of radioactivity in airborne exhausts. Radiological controls are exercised to preclude exposure of working personnel to airborne radioactivity exceeding federal limits. Air exhausted from radiological work facilities is passed through high-efficiency particulate air filters and monitored during discharges. The annual airborne radioactivity emissions from the shipyards do not result in any measurable radiation exposure to the general public. Calculations of site radioactive airborne emissions for 1992 have been performed as described in Attachment F. These calculations have shown that emissions of radionuclides from each shipyard result in an effective dose equivalent of less than 0.1 mrem per year to any member of the general public.

4.1.3.8 Water Resources

4.1.3.8.1 Surface Water.

A large portion of York County's surface runoff from precipitation is drained by coastal basins reaching a short distance inland from the coast. The system of water drainage channels used by runoff waters, varying from very small brooks to larger rivers, generally are in a southeasterly direction towards the Atlantic Ocean, but tributaries naturally flow from all directions into the larger channels. The remainder of the area is drained by larger river drainage basins that reach further inland. The Saco River basin and the Piscataqua-Salmon Falls River basins are the largest drainage systems, the Mousam and Kennebunk Rivers being considerably smaller. In each of these drainage basins, surface water is held in swamps, ponds and lakes, both natural and man-made, and by dams for storage, water supply, and development of power.

The largest quantities of surface runoff occur during March, April, and May with the lowest occurring in August and September. On the average, runoff is approximately 22 inches of the 44 inches annual precipitation. The combination of spring rains and snow melt not only serve to greatly increase stream flow, but also tend to replenish groundwater supplies.

The Piscataqua River, formed by the confluence of the Cocheco River and the Salmon Falls River, flows southeasterly for 13 miles until it enters the ocean at Portsmouth Harbor. The entire 13 miles of the river is tidal. The river is one of the fastest flowing tidal waterways of any commercial port in the northeastern United States. Due to abrupt channel changes and the strengths of flood and ebb currents, hazardous cross-currents and eddies are found in the main channel passing north and east of Pierce and New Castle Island. The average current velocity at full strength in the main harbor varies from about 2.6 to 4.0 knots, whereas in the back channels, the velocity varies from less than 1 to 2 knots.

The tide at Portsmouth occurs twice daily. The average tidal range from Portsmouth Harbor is 8.4 feet. The average mean spring range is 9.7 feet and the average mean tide level is 4.2 feet.

New Hampshire and Maine have an agreement to maintain acceptable water quality in the Piscataqua River and both states regulate their effluent discharges into the river. The river is designated by the state of New Hampshire as a Class B segment and by the state of Maine as Class SB-1. New Hampshire Class B waters are acceptable for bathing, other recreational purposes, fish habitat, and public water supply after adequate treatment. Maine Class SB-1 waters are suitable for all clean water usages including water contact recreation, fishing, shellfish harvesting and propagation, and fish and wildlife habitat. (Navy 1984)

The Flood Insurance Rate Map (FIRM COMMUNITY-PANEL No. 230171 0008D) shows that the Portsmouth Naval Shipyard is not in a 100 or 500 year floodplain.

4.1.3.8.2 Groundwater.

Groundwater reserves constitute an important natural resource and are especially important to the more populated communities in the area. The majority of the public water supply in the area is taken from lakes and rivers, with groundwater providing the remainder of the requirements.

As much as 35% of the total area of York County is underlain by soils which are generally adapted to storage and yield of groundwater, but this figure is based only on surface data. In some localities, marine clays overlie deeper gravels and may represent excellent future sources. When favorable groundwater soils are measured to adequate depths, it is quite probable that the good groundwater yield areas will shrink to a few percent of the total land areas. (Navy 1984)

4.1.3.8.3 Existing Radiological Conditions.

The normal activities associated with current naval nuclear operations at all naval shipyards do not result in the intentional discharge of any radioactive liquid effluent. However, there were occasions, primarily in the early 1960's, when measurable levels of radioactivity were discharged with liquid effluent. In all cases, effluent releases were less than permitted under the then current limits imposed by state and federal agencies.

The United States Environmental Protection Agency Office of Radiation Programs has performed monitoring of the water, plant life, aquatic life, and sediment in the vicinity of Portsmouth Naval Shipyard. The purpose of the survey was to determine if operations related to U.S. Navy nuclear warship activities resulted in releases of radionuclides which could contribute to significant population exposure or contamination of the environment. "Radiological Survey of Portsmouth Naval Shipyard, Kittery, Maine and Environs" (Semler 1991) discusses the most recent Environmental Protection Agency monitoring data. Pertinent conclusions are as follows:

1. "No trace of Co-60 was detected in any samples at Portsmouth Naval Shipyard. All radioactivity detected in the 40 sediment samples is attributed to naturally occurring radionuclides or fallout from past nuclear weapons testing.
2. Results of core sampling did not indicate any previous deposit of Co-60 in the sediment.
3. The water samples contained no detectable levels of radioactivity.
4. All radioactivity detected in the biota samples is attributed to naturally occurring radionuclides or fallout.
5. External gamma ray measurements did not detect any increased radiation exposure to the public above natural background levels.
6. Based on the survey, it was concluded that current practices regarding nuclear-powered warship operations have resulted in no increases in radioactivity that would result in major exposure or contamination of the environment."

Environmental monitoring is conducted by the shipyard. The results of this monitoring program corroborate the Environmental Protection Agency's conclusions.

4.1.3.9 Ecological Resources

4.1.3.9.1 Terrestrial Ecology.

Portsmouth Naval Shipyard is an isolated land mass that has been highly developed. There is almost no remaining natural habitat in the shipyard area, with the major exception being Clarks Island and the surrounding estuary. Even these areas are not unaffected by activities on the shipyard and nearby industry.

The estuary around the shipyard could be classified as an intertidal river system which supports a subtidal estuary community. The shoreline is characterized by steep, rocky banks and low-lying marshlands. The shipyard mass would probably be classified as a rock outcrop ecosystem, characterized by sparse vegetation of low-lying shrubs and herbs with scattered trees. The community would be classified as an acidic shoreline outcrop.

The vegetation of the shipyard is made up primarily of trees, shrubs, and grasses that have been planted for landscaping purposes. No naturally occurring species remain at this time. Because Clarks Island has remained undeveloped, there is much greater diversity. It supports a variety of herbaceous and shrub species including rushes, skunk cabbage, jewelweed, spike grass, swamp azalea, bittersweet, witch hazel, and dogwood. Several lowland tree species are also growing on the island, including red maple, sycamore, willow, and poplar.

The fringe marshes along the shore of Admiralty Village and along portions of Clarks Island are dominated by two species, cord grass (Spartina alterniflora) and salt hay (Spartina patens). These perennial grasses are year-round producers of vital organic matter that is distributed to the detrital food chain or deposited in the marsh as part of the underlying peat marsh.

Another important plant species present within the Piscataqua River and abundant around the shipyard is Zostera marina, commonly called eel grass. This submerged marine flowering plant is vital to the health and productivity of the estuary. It provides habitat essential to the life cycle of species such as crabs, fin fish, geese, and ducks. Eel grass beds are also preferred nursery habitat for lobsters. Other valuable functions of eel grass beds include: sediment trapping, bottom stabilization, and water filtration. This filtration ability also causes eel grass beds to be susceptible to algal blooms resulting from excessive wastewater and fertilizer nutrients. Thus, eel grass is essential to the health of the estuary and can also serve as an indicator of unhealthy conditions.

The limited amount of vegetation and the highly industrialized nature of the shipyard area severely limit the availability of suitable habitat for most terrestrial species. There are some mammals on the shipyard, primarily those species that tend to live in close association with man, including: mice, squirrels, raccoons, and rabbits. There are white-tailed deer and moose in close vicinity of the shipyard. However, there are no known resident species of deer or moose on the shipyard. The Navy's 1993 "Natural Resources Management Plan for Portsmouth Naval Shipyard" contains a complete listing of all mammals and reptiles found in the southeastern Maine-New Hampshire region (Navy 1993b).

One notable ecological feature of the shipyard is its avian population. Bird species are most abundant in the region during the months of April and September, coinciding with the migratory seasons. The most common species in the area are the herring gull, American black duck, doublecrested commorant, great blue heron, and American crow. The most abundant winter migrant species are Canada geese, greater scaup, bufflehead, and common goldeye. Sea birds in general are the most abundant, and the year-round species include herring gulls and great black-backed gulls. The commom tern can also be found in large numbers during the late spring and summer. Osprey have also been known to frequent the area and there is one known nesting pair in the Great Bay Estuary vicinity. Appendix V. . of the Navy's Natural Resources Management Plan contains a complete list of bird species common to the coastal region (Navy 1993b).

Clarks Island serves as a safe haven for a multitude of birds. It is an optimum habitat for migratory species in that it has rocky shore, a small beach area, and an inland area of fairly dense wood and low-lying vegetation. It would not be unreasonable to expect that during the early spring and fall, Clarks Island would be utilized by a variety of songbird species along with the typical coastal species mentioned above. (Navy 1993b)

4.1.3.9.2 Wetlands.

There are a few isolated marine wetlands in the vicinity of the shipyard and a small freshwater wetland on the shipyard. There are two freshwater ponds on the southern portion of the base, which have been characterized as palustrine, unconsolidated bottom, and permanently flooded. There is a small area on the banks of the larger pond which is characterized as palustrine, scrub shrub, broadleaf deciduous wetland. There are also two very minute areas southwest of the freshwater ponds which have been characterized as palustrine emergent, persistent, seasonally flooded wetlands. Two areas of estuarine wetlands are noted. Along the northeast shoreline, they are classified as intertidal, unconsolidated shore, mud bottom, and regularly flooded. This same classification has been given to the northern shoreline of Clarks Island. Finally, on the western side of Clarks Island and on the southwestern corner of the shipyard, there are areas of estuarine intertidal aquatic bed, algal, regularly flooded wetlands. It should be noted that these determinations were based on stereoscopic analysis of aerial photographs and cannot be considered completely accurate without ground truthing. (Navy 1993b)

Because natural drainage systems are limited, the shipyard has developed an extensive storm water collection system and a drainage system to control flooding of the freshwater ponds. This collection system eventually drains into the Piscataqua River, as does surface runoff. (Navy 1993b)

4.1.3.9.3 Aquatic Ecology.

The waters surrounding the Portsmouth Naval Shipyard support a vast amount of marine life, from mammals to benthic organisms. Although the larger mammalian species, like whales and dolphin, are not common to the estuarine waters of the Piscataqua River, harbor seals can be seen throughout the Great Bay region in winter and spring. The estuary also supports a number of commercially and recreationally important fin fish including smelt, winter flounder, Atlantic silversides, alewives, and striped bass. A more complete list can be found in Appendix V. . of the Navy's Natural Resources Management Plan (Navy 1993b).

These fish species rely heavily on a healthy benthic invertebrate population for survival. Substrate type has a major impact on the number and variety of species that will be found in any particular area. The areas around the shipyard that have a rocky bottom will be populated by epibenthic organisms. Sandy or muddy bottoms can support both epibenthic and infaunal organisms. Some of the more common shellfish species include lobster, softshell clams, and blue muscles. A more detailed list of benthic infauna can be found in Appendix V. . of the Navy's Natural Resources Management Plan (Navy 1993b).

The freshwater ponds on the shipyard also serve as a source of aquatic species. There is a healthy benthic community within this ecosystem as well, including a variety of polychaete worms. There is an abundance of vegetation in and around the ponds, which provides habitat for freshwater fish. The most abundant fish species at this time is the smallmouth bass (Micropterus dolomieui), which were stocked at one time. (Navy 1993b)

4.1.3.9.4 Endangered and Threatened Species.

In the coastal area from Portland, Maine to Portsmouth, New Hampshire, the threatened or endangered species include the Piping Plover, Roseate Tern, Bald Eagle, Peregrine Falcon, Shortnose Sturgeon, and several species of whales and sea turtles.

Appendix V. . of the Navy's Natural Resources Management Plan (Navy 1993b) includes a list of the threatened and endangered species of southeastern Maine and New Hampshire. Both Maine and New Hampshire officials were consulted and have determined that there is no evidence to suggest that any threatened or endangered species reside on the Portsmouth Naval Shipyard. Marine mammals are afforded full federal protection under the Marine Mammal Protection Act of 1972 (Navy 1993b).

4.1.3.10 Noise

Portsmouth Naval Shipyard is an existing industrial-type environment characterized by noise from truck and auto traffic; ship loading cranes and related diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related compressors for those and other liquids. In addition, new construction of buildings, reconstruction and rehabilitation activities for streets, buildings, parking lots, and ships all contribute to a pervasively industrial environment.

4.1.3.11 Traffic and Transportation

The Kittery-Portsmouth area is very accessible to vehicular traffic due to the proximity of Interstate 95. The major cities of Boston, Massachusetts and Portland, Maine are approximately one hour away. U.S. Route 1, a primary road, runs parallel to I-95 in a north-south direction and provides good access to the local communities along the seacoast. Because of the shipyard's location on an island in the Piscataqua River, access is restricted to two federally owned bridges. The bridges provide access directly to the shipyard's northern boundary from residential streets in the town of Kittery. The majority of installation oriented traffic traverses five local secondary roadways:

Walker Avenue, Wenworth Street, and Shapleigh, Whipple, and Rogers Roads. Walker Avenue is the primary access route to Bridge 1 and Whipple Road provides direct access to Bridge 2. Most shipyard generated traffic is funneled from the two major highways, I-95 and U.S. Route 1, through the local roadways and over the bridges.

Daily rail service, freight only, is provided to Portsmouth Naval Shipyard by the Boston and Maine Railroad. The railroad connects Portsmouth with Manchester, New Hampshire; Portland, Maine; and Boston, Massachusetts. Rail passenger service is available via AMTRAK connecting to Boston.

Limited air service is provided at small airports at Eliot and Sanford, Maine, and Hampton and Rochester, New Hampshire. Pease Airport provides the opportunity for commuter flights to Logan Airport in Boston, Massachusetts and to other cities. In addition, Portsmouth is within one hour travel time by car from major airports at Boston, Massachusetts and Portland, Maine.

The Portsmouth Harbor, about 3 nautical miles from deep water of the Atlantic Ocean, is accessible year round via the Piscataqua River channel. The river channel is 35 feet deep below mean low water and 400 feet wide. There are about 500 vessel trips each way through the channel each year. About 150 of these trips involve ships with drafts greater than 18 feet, and more than 200 trips are made by tankers. A Coast Guard Station is located at New Castle near the harbor entrance. (Navy 1984)

Naval spent nuclear fuel has been removed from Navy nuclear-powered ships and transported to the Idaho National Engineering Laboratory Expended Core Facility (ECF) for examination and evaluation as a routine part of their operating cycle. Naval spent nuclear fuel shipments from Portsmouth Naval Shipyard to ECF were initiated in 1959. Since that time, 43 shipments of naval spent nuclear fuel originating at Portsmouth Naval Shipyard have been made to ECF. The naval spent nuclear fuel was shipped by rail. Attachment A provides a list of these shipments made to date by year. Attachment A also contains detailed descriptions of the shipping containers used for naval spent nuclear fuel shipments from shipyards.

4.1.3.12 Occupational and Public Health and Safety

4.1.3.12.1 Occupational Radiological Health and Safety. Portsmouth Naval Shipyard and the

Admiralty Village housing area are physically located in York County, Kittery, Maine on government-owned land. The U.S. Government provides its own police and fire protection on the shipyard, while Kittery provides police and fire protection for the Admiralty Village Housing Area. (Navy 1984)

The Navy has well established and effective Occupational Safety, Health, and Occupational Medicine programs at all of its shipyards. In regard to radiological aspects of these programs, the Naval Nuclear Propulsion Program policy is to reduce to as low as reasonably achievable the external exposure to personnel from ionizing radiation associated with naval nuclear propulsion plants. These stringent controls on minimizing occupational radiation exposure have been successful. No civilian or military personnel at Navy sites have ever exceeded the federal accumulated radiation exposure limit which allows 5 rem exposure for each year of age beyond age 18. Since 1967, no person has exceeded the federal limit which allows up to 3 rem per quarter year and since 1980, no one has received more than 2 rem per year from radiation associated with naval nuclear propulsion plants. The average occupational exposure of each person monitored at all shipyards is 0.26 rem per year. The average lifetime accumulated radiation exposure from radiation associated with naval nuclear propulsion plants for all shipyard personnel who were monitored is 1.2 rem. (NNPP 1994a) This corresponds to the likelihood of a cancer fatality of 1 in 2083.

The Navy's policy on occupational exposure from internal radioactivity is to prevent radiation exposure to personnel from internal radioactivity. The limits invoked to achieve this objective are one-tenth of the levels allowed by federal regulations for radiation workers. As a result of this policy, no civilian or military personnel at shipyards have ever received more than one-tenth the federal annual occupational exposure limit from internal radiation exposure caused by radioactivity associated with naval nuclear propulsion plants.

For work operations involving the potential for spreading radioactive contamination, containments are used to prevent personnel contamination or generation of airborne radioactivity. The controls for contamination are so strict that precautions sometimes have had to be taken to prevent tracking contamination from fallout and natural sources into radiological areas because the contamination control limits used in these areas were well below the levels of fallout and natural contamination occurring outside in the general public areas. A basic requirement of contamination control is monitoring all personnel leaving any area where radioactive contamination could possibly occur. Workers are trained to survey themselves (i.e., frisk), and their performance is checked by radiological control personnel. Frisking of the entire body is required, normally using sensitive hand-held survey instruments. Major work facilities are equipped with portable monitors, which are used in lieu of hand-held friskers. These stringent controls to protect the workers and the public from contamination have proven effective in the past.

In 1991, researchers from Johns Hopkins University, Baltimore, Maryland, completed a very comprehensive epidemiological study of the health of workers at the six naval shipyards and two private shipyards that service the Navy's nuclear-powered ships (Matanoski 1991). This independent study evaluated a population of 70,730 civilian workers over a period from 1957, beginning with the first overhaul of the first nuclear-powered submarine, USS NAUTILUS, through 1981, to determine whether there was an excess risk of leukemia or other cancers associated with exposure to low levels of gamma radiation.

The Johns Hopkins study found no evidence to conclude that the health of people involved in work on U.S. naval nuclear-powered ships has been adversely affected by exposure to low levels of radiation incidental to this work. Additional studies are planned to investigate the observations and update the shipyard study with data beyond 1981.

The radiation exposure during normal operations at each shipyard for workers who have their radiation levels monitored is determined based on the annual radiation exposure of 0.26 mrem per worker for all shipyards based on Naval Nuclear Propulsion Program Report NT-94-2 (NNPP 1994a). The total number of shipyard personnel monitored for radiation exposure associated with the Naval Nuclear Propulsion Program has been about 164,000.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population.
Under the limiting assumption that the same worker is associated with every shipment for the entire historical period, this person would receive a total exposure of 7.5 rem over the approximately 40-year period, or about 0.19 rem per year, which is within DOE standards for occupationally exposed individuals. The radiation exposures to workers correspond to much less than one incident cancer, which means that it is unlikely that there have been any past health impacts due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.3.12.2 Occupational Non-radiological Health and Safety.

In the non-radiological Occupational Safety, Health, and Occupational Medicine area, the Navy complies with the Occupational Safety and Health Administration Regulations. The Navy policy is to maintain a safe and healthful work environment at all Navy facilities. Due to the varied nature of work at these facilities, there is a potential for certain employees to be exposed to physical and chemical hazards.
These employees are routinely monitored during work and receive medical surveillance for physical hazards such as exposure to high noise levels or heat stress. In addition, employees are monitored for their exposure to chemical hazards such as organic solvents, lead, asbestos, etc., and where appropriate are placed into medical surveillance programs for these chemical hazards.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact due to the historical shipment of naval spent nuclear fuel over the entire history of such shipments.

4.1.3.12.3 Public Radiological Health and Safety.

In order to quantify the exposures resulting from normal shipyard radiological releases to the general public, detailed analyses were performed based on very conservative estimates of radioisotopic releases since releases began. Attachment F provides detailed annual release values used in the analyses.

The GENII computer code (Napier et al. 1988) was used to calculate exposures to human beings due to the estimated radionuclide releases from normal operations at the shipyards.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from stored fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F.

The hypothetical exposures calculated in Attachment F for the period 1995 through 2035 were adjusted from an annual basis (1995) to the historical basis by multiplying by 38 years and by a factor of 1.7 to take into consideration variations in the number of ships and operations.

The calculated accumulated exposures through 1995 to the general population within 50 miles of the site (about 2.4 million people) are 0.65 person-rem. To provide perspective, the exposures received due to natural radiation sources through 1995 are approximately 28 million person-rem, based on 0.3 rem per person per year.

The results of environmental monitoring as described in Naval Nuclear Propulsion Program Report NT-94-1 show that Naval Nuclear Propulsion Program activities had no distinguishable effect on normal background radiation levels at site perimeters (NNPP 1994b).

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities.

All of the radiation exposures to the general population correspond to much less than one incident cancer, which means that it is unlikely that there has been any past health impacts to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.3.12.4 Public Non-radiological Health and Safety.

The Naval Medical Clinic located on the shipyard is used by Navy personnel and dependents for their general medical care requirements. Medical problems that require treatment not available at the clinic are taken care of at hospitals located in York, Maine and Portsmouth, New Hampshire. (Navy 1984)

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.3.13 Utilities and Energy

Portsmouth Naval Shipyard has its own Security, Fire, Public Works, and Supply departments.

Portsmouth Naval Shipyard obtains its electricity from Central Maine Power, but has a central power plant capable of producing all of the required steam and electricity. Potable water is furnished by the town of Kittery, Maine. (Navy 1984)

The 1993 electrical power usage at Portsmouth Naval Shipyard was 76,262 megawatt hours. The water usage at the shipyard was approximately 668 million gallons for 1993.

4.1.3.14 Materials and Waste Management

The shipyard's sewage is pumped to the town of Kittery's sewage treatment system.

Disposition of solid waste is as follows: 58% is recycled, 38% is burned for energy recovery at the Maine Energy Recovery Incinerator, and 4% is landfilled at licensed off-site facilities. Bulk aqueous waste is collected and shipped for off-site licensed treatment/disposal. Containerized hazardous waste is collected, consolidated, characterized, and labeled at the shipyard's state-licensed Hazardous Waste Storage Facility prior to manifesting to off-site licensed treatment/disposal/energy recovery facilities. Oily waste is presently contracted for off-site disposal; however, an oily waste treatment system has been installed and should be on line in the near future. The effluent from treatment operations will be discharged to the sewer, and the separated waste oil will be sold through the Defense Logistics Agency.

Solid radioactive waste materials are packaged in strong, tight containers, shielded as necessary, and shipped to burial sites licensed by the U.S. Nuclear Regulatory Commission or a State under agreement with the U.S. Nuclear Regulatory Commission. Shipyards and other shore facilities are not permitted to dispose of radioactive solid wastes by burial on their own sites. During 1992, approximately 74 cubic yards of routine low-level radioactive waste containing 2 curies were shipped from Portsmouth Naval Shipyard for burial.

Waste which is both radioactive and chemically hazardous is regulated under both the Atomic Energy Act and the Resource Conservation and Recovery Act (RCRA) as "mixed waste." Within the Naval Nuclear Propulsion Program, concerted efforts are taken to avoid combining radioactive and chemically hazardous substances so as to minimize the potential for generation of mixed waste. For example, these efforts include avoiding the use of acetone solvents, lead-based paints, lead shielding in disposal containers, and chemical paint removers. Radioactive wastes, including those containing chemically hazardous substances, are handled in accordance with long-standing Program radiological requirements. Such handling includes solidification to immobilize the radioactivity, separation of the radioactive and chemically hazardous substances, removal of liquids from solids, and other simple techniques. A determination is then made as to whether the resulting waste is hazardous. As a result of Program efforts to avoid the use of chemically hazardous substances in radiological work, Program activities typically generate only a few hundred cubic feet of mixed waste each year. This small amount of mixed waste, along with limited amounts of mixed waste from Program work conducted prior to 1987, will be stored pending the licensing of commercial treatment and disposal facilities.

4.1.4 PEARL HARBOR NAVAL SHIPYARD: PEARL HARBOR, HAWAII

4.1.4.1 Overview

The Pearl Harbor Naval Shipyard is located in the Southeast Loch of Pearl Harbor, Oahu, Hawaii (Figures 4.1.4-1 and 4.1.4-2). This shipyard consists of approximately 350 acres. The island of Oahu is the third largest (593 square miles) in the State of Hawaii and is the population center of the Hawaiian Islands. The 1990 Oahu population of approximately 820,000 residents comprised over 75% of the state's total, and the City and County of Honolulu are the fastest growing areas in the state, with the highest population densities. Honolulu is the state capital, largest city, and center of business and government.

Pearl Harbor is a principal harbor for U.S. Navy activities and is the base of Navy operations for the mid-Pacific. Figure 4.1.4-3 provides a Pearl Harbor site map. Its water surface area of about 8 square miles and its docks accommodate all classes of Navy vessels up to the largest aircraft carriers. Ship maintenance and repairs are performed for all types of vessels in Pearl Harbor Naval Shipyard's dry docks and docking areas. All of the docks are located in the Southeast Loch area with the exception of Dry Dock 4 which is adjacent to the Pearl Harbor main channel. (Navy 1991c)

4.1.4.2 Land Use

There are six major land use activities at Pearl Harbor. Commander Naval Base Pearl Harbor (NAVBASE) hosts various operational commands that include the Headquarters for the Pacific Fleet and the Headquarters of the Third Fleet.

Pearl Harbor Naval Shipyard provides the maintenance and repair services noted above. The Naval Supply Center provides fuel, ammunition, other supplies, and storage. The other primary land use activities are for: the Submarine Base; the Public Works Center; and the U.S. Naval Inactive Ship Maintenance Detachment.

Land use is designated as urban by the State of Hawaii, and military by the City and County of Honolulu. As can be seen in Figure 4.1.4-2, the Pearl Harbor Naval Shipyard is surrounded by military land with Hickam Air Force Base in the southern quadrant and naval installations occupying the remaining three quadrants. Other activities commonly occurring in the Pearl Harbor area are commercial fishing, tourism, and recreational facilities, along with a few retail complexes. (Navy 1990b)

Figure 4.1.4-1. Location of Pearl Harbor Naval Shipyard in Hawaii. Figure 4.1.4-2. Pearl Harbor vicinity with average annual rainfall gradient. Figure 4.1.4-3. Pearl Harbor Naval Shipyard site map.

4.1.4.3 Socioeconomics

Oahu has experienced a high rate of economic growth over the past decade due to its location in the Pacific, which benefits both military defense and visitor industries. These two industries have surpassed the two historical bases of the Hawaiian economy, which are pineapple and sugar cultivation and production.

Oahu's visitor industry continues to prosper. Visitor arrivals to the state are projected by the Department of Business and Economic Development to reach 7.8 million visitors by 2000, with Oahu capturing approximately half of the visitors. This would represent a visitor growth rate on Oahu of about 3.4 percent compounded annually.

Defense expenditures cushion Oahu's economy from the seasonal and cyclical fluctuations of tourism. The military is also a primary source of highly skilled employment opportunities for civilians. Pearl Harbor has the largest concentration of Department of Defense employment in the state, with about 7,700 shore-based Navy personnel and 10,900 civilians, for a total of 18,600 at the naval base. In 1993, shipyard employment accounted for about 5,000 of the total. The population distribution within 50 miles of Pearl Harbor Naval Shipyard is shown in Figure 4.1.4-4.

Unemployment figures in the state and for the island of Oahu are among the lowest in the nation. Oahu is at a 2.3 percent unemployment level as of October 1989, reflecting the strong local economy that prevailed in the latter half of the 1980s. With the outlook favorable for continued expansion, job growth is currently expected to equal or better the 2 to 3 percent historical annual increase in Oahu's work force. (Navy 1990b)

Figure 4.1.4-4. Population distribution within 50 miles of Pearl Harbor Naval Shipyard.

The majority of the labor force that would be employed at the shipyard for construction and operation of the naval spent nuclear fuel area would be expected to reside on the island of Oahu. The calculated total population, labor force, and employment within this region for the base year (1995) are presented in Table 4.1.4-1. Projections of employment and population for the years beyond 1995 have not been presented because, as discussed in Section 5, the number of additional jobs that might be created at the shipyard under any alternative could be small.

Table 4.1.4-1. Regional employment factors at Pearl Harbor Naval Shipyard.

Regional Employment	Regional Labor Force	Regional Population
393,260	407,530	812,190

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the Pearl Harbor Naval Shipyard, consistent with the population data provided in Figure 4.1.4-4.

Figure 4.1.4-5 shows the locations of populations which have more than 50 percent minority members within the 50-mile radius. Minorities make up approximately 55 percent of the total population in this area. These populations have been identified following an approach developed by the Environmental Protection Agency which, for purposes of environmental justice evaluation, defines minority communities as those which have percentages of minorities greater than the average in the region analyzed (EPA 1994).

Figure 4.1.4-6 shows the locations of populations which have more than 25 percent of their members living in poverty, reflecting a common definition of low-income communities (EPA 1993). The U. S. Census Bureau characterizes persons in poverty as those whose income is less than a "statistical poverty threshold." For the 1990 census, this threshold was based on a 1989 income of $12,500 per household.

Figure 4.1.4-5. Minority population distribution within 50 miles of the Pearl Harbor Naval Shipyard.

Figure 4.1.4-6. Low-income population distribution within 50 miles of the Pearl Harbor Naval Shipyard.

4.1.4.4 Cultural Resources

Pearl Harbor has been the site of several important historical events and changes, and is most noted for its role in the Pacific Theatre Defense during World War II. Physical sites near and in Pearl Harbor have been designated as historically significant, including several battleships sunk during the December 7, 1941 Japanese bombing of Pearl Harbor, as well as sites where planes were downed. Naval Base Pearl Harbor was designated as a National Historic Landmark in 1964, and in 1974, it was listed on the National Register of Historic Places.

The Pearl Harbor area has been heavily modified over the past 70 years. This includes extensive changes that were intended to stabilize the marshy shorelines. Most surface evidence of any pre-military occupation has long since been obliterated. Due to the historic nature of the shipyard, there might be areas of archaeological interest. However, there are no archaeological sites located within the boundary of the shipyard. Many native Hawaiian cultural resources exist on the Hawaiian Islands. There are three Hawaiian fish ponds located outside the boundary, in West Loch and in East Loch, that have been recommended for preservation. (Navy 1990b)

4.1.4.5 Aesthetic and Scenic Resources

The Pearl Harbor viewshed is dominated by the sweeping mountain to sea vistas characteristic of nearshore areas on Oahu. The City and County of Honolulu's Coastal View Study (1987) states that the "flat terrain and the built up military facilities surrounding Pearl Harbor provide very little public viewing opportunities into this bay." (Navy 1990b) The shipyard area, itself, is an industrial setting. The area within the shipyard where naval spent nuclear fuel would be stored has low visual sensitivity since the area is an industrial site.

4.1.4.6 Geology

4.1.4.6.1 General Geology.

Oahu's topography consists of two parallel mountain ranges running in a northwest to southeast direction, separated by a plateau. A large, relatively level coastal plain borders the plateau at the south. The Pearl Harbor Naval Complex, for the most part, lies within this coastal plain.

Land near the waterfront areas is very flat, rising slightly inland from Kamehameha Highway. There are moderate slopes which exist around the rim of the Makalapa Crater.

4.1.4.6.2 Geologic Resources.

There are several different soil associations within the Pearl Harbor basin. The majority of the U.S. Navy lands surrounding Pearl Harbor are comprised of the Lualualei - Fill Land - Ewa Soil Association. This association consists of well-drained, fine textured, and moderate fine textured soils on fans and in drainage ways on the southern and western coastal plains of Oahu. The soils are formed from sediment deposited by streams, and are nearly level to moderately sloping. This soil association makes up about 14 percent of the island of Oahu.

Pearl Harbor estuary occurs on the coastal sedimentary plain of southern Oahu. The harbor consists of three lochs which join to form a single channel entrance. Streams, springs, and ground-water flow into the harbor; the estuary was formed by freshwater flows that have eroded the coastal plain and retarded coral growth. Since their initial formation, the lochs have been altered by sea-level change, erosion, and silt. The west side of the harbor is composed mostly of limestone reef material known as the Ewa Plain. The east side of the harbor consists mainly of compacted volcanic ash. Hard, dense volcanic rock forms the bulk of the rock material to the north. Marine and terrestrial sediments occur around the perimeter of the harbor. (Navy 1990b)

Much of the land area in Pearl Harbor is fill land created by dredge spoils since 1930. A major dredging effort took place between 1940 and 1943, when dredged material was placed in the Waipio Peninsula and adjacent to Kuahua Island (now Kuahua Peninsula). This landfill resulted in the present shoreline configuration. (Navy 1990b) There are no economic geologic resources at the shipyard.

4.1.4.6.3 Seismic and Volcanic Hazards.

Seismic risk related to structural damage may be represented in the United States by a relative scale of 0 through 4, with Zone 0 not expected to encounter damage and Zone 4 expected to encounter the greatest seismic risk. The Pearl Harbor Naval Shipyard is located in Zone 1. (UBC 1991) Except for the island of Hawaii itself, the Hawaiian Islands are not a highly seismic area. Even on Hawaii, most of the earthquakes are of volcanic origin and do little or no damage, although a few have been quite severe. The Uniform Building Code seismic classification provides a means for a comparable assessment of the seismic hazard between the alternate sites. If the Record of Decision identifies this site for the interim storage of naval spent fuel, then a detailed seismic evaluation would be conducted. More detailed information regarding the design basis considerations for storage of naval spent nuclear fuel at the shipyard is provided in Attachment D.

From review of Tsunami Wave Runup Heights in Hawaii by Harold G. Loomis, Hawaii Institute of Geophysics, University of Hawaii, May 1976, past inundation levels from waves produced by seismic events have been about 3 feet above Mean Sea Level (msl). In addition, a memorandum from the U.S. Army Engineering Division, Pacific Ocean, dated 10 January 1986 indicated projected seismically induced wave elevations for the 10-year, 100-year, and 500-year event to be 0.8 feet, 2.0 feet, and 3.8 feet, respectively, for adjacent coastal areas. (Navy 1990b)

Pearl Harbor is fully protected from ocean waves and swells. Waves propagating through the 15,000-foot entrance channel are completely reduced. The normal tides in Hawaii occur twice daily, with pronounced daily inequalities. Maximum high, or spring tides, reach 2.5 feet above msl. Storm water level rise is caused by four components: astronomical tides, rise from atmospheric pressure reduction (pressure setup), wind setup, and wave setup. Based on information obtained from the Naval Western Oceanography Center, maximum hurricane storm water level rise from setup under the worst conditions foreseeable would be approximately 12 feet above the existing tide level. Thus, maximum total storm water level rise would be approximately 14.5 feet above msl. Under the maximum foreseeable conditions, any material stored in the dry dock area of Pearl Harbor Naval Shipyard, which is about 8 feet above msl, could be flooded to a level of about 6.5 feet.

In September 1992, the worst storm in Pacific history, Hurricane Iniki, hit Kauai with sustained 145-mile-per-hour winds and gusts to 175 miles per hour. Oahu, 80 miles to the east, received comparatively minor damage to that experienced on Kauai. The last hurricane to strike the state prior to Iniki was Iwa in 1982 but it did not cause nearly as much damage.

The Hawaiian Islands were formed by volcanic eruptions; however, the only active volcanic area is on the island of Hawaii. There are no volcanic hazards on the island of Oahu. (Doell and Dalrymple 1973).

4.1.4.7 Air Resources

4.1.4.7.1 Climate and Meteorology.

With the exception of minor differences in temperature and rainfall at Red Hill and Camp Stover, all of the activities at Pearl Harbor lie within the same climatic zone and are subject to the same weather conditions.

The predominant winds are the northeast tradewinds, which prevail most of the year, particularly from February to November. Thus, the predominant winds would carry any airborne contaminant from the shipyard to the unpopulated ocean region adjacent to Pearl Harbor on the south. At certain times of the year, south to southwest winds and mild offshore breezes can be expected. Winds with speeds up to 49 miles per hour may occasionally strike from the north or northeast but rarely reach gale velocities. The south winds are usually accompanied by wet tropical air and frequent heavy showers. During the summer months, periods of no wind occur occasionally but do not persist for more than a day or two. During the winter months, winds tend to be less predictable, with longer periods of light and variable winds, and occurrences of strong southerly or "Kona" winds associated with weather fronts and storms.

The rainfall at Pearl Harbor is light and generally inadequate to sustain lawns and other vegetation for at least nine months of the year. Very heavy precipitation may occasionally fall during times of southerly winds, and this may cause local flooding because of the nature of the soils and the relatively low elevation. The mean annual rainfall for the naval base is between 20 and 30 inches, dependent upon the incidence of the occasional heavy southerly rains mentioned previously. The topography and meteorology of Oahu are responsible for the unusual annual rainfall gradient shown in Figure 4.1.4-2.

Temperatures vary by season as well as daily in the Pearl Harbor region. Highs of 87yF to 89yF are not uncommon during mid-afternoon in summer. Night temperatures during the same season fall between 72yF and 76yF. During the winter and early spring, daytime highs will reach between 76yF and 78yF, and nighttime lows may fall to the low 60's or high 50's. The lows are generally caused by a shallow blanket of cold air that pours down from the mountains and spreads out over the lowlands during periods of low-velocity tradewinds. The low temperatures are almost invariably accompanied by a heavy dewfall which is not normal to the region.

4.1.4.7.2 Air Quality.

An area can be designated by the Environmental Protection Agency as having air quality that is better than defined by the National Ambient Air Quality Standards (attainment) or as exceeding one or more of those standards (nonattainment for one or more pollutants). The Code of Federal Regulations, Title 40, Part 81, states that the Air Quality Control Region for the shipyard is better than national standards for total suspended particulate matter and SO_2. The area has no specific classification for ozone, carbon monoxide, and NO_2.

Air quality on Oahu is primarily affected by the prevalence of the northeast tradewinds which prevail approximately 80 percent of the year, particularly from February to November. Air monitoring of the naval base area conducted in 1989 showed that there was no NAAQS violation. Thus, air quality was in attainment with federal standards. The state standards, which are more restrictive in many cases than federal requirements, were exceeded only at intersections having high traffic during peak rush hours. (Navy 1990b) The nearest Class I Area is Haleakala National Park 188 kilometers (117 miles) from the shipyard.

4.1.4.7.3 Existing Radiological Conditions.

Radiological facilities at all naval shipyards are designed to ensure that there are no uncontrolled discharges of radioactivity in airborne exhausts. Radiological controls are exercised to preclude exposure of working personnel to airborne radioactivity exceeding federal limits. Air exhausted from radiological work facilities is passed through high-efficiency particulate air filters and monitored during discharges. The annual airborne radioactivity emissions from the shipyards do not result in any measurable radiation exposure to the general public. Calculations of site radioactive airborne emissions for 1992 have been performed as described in Attachment F. These calculations have shown that emissions of radionuclides from each shipyard result in an effective dose equivalent of less than 0.1 mrem per year to any member of the general public.

4.1.4.8 Water Resources

4.1.4.8.1 Surface Water.

Pearl Harbor receives surface runoff from seven watersheds. The Waikele Watershed (54 square miles) is the largest of the seven, comprising nearly 40 percent of the Pearl Harbor Basin. It is drained primarily by Waikele Stream, which discharges the heaviest sediment load of any of the Pearl Harbor Basin streams.

The Waiawa Watershed (24.6 square miles) consists of forest, agricultural, and urban land. It is drained by Waiawa Stream and its tributaries into Middle Loch. The Waimalu Watershed (17.7 square miles) is drained by the Waimano, Waimalu, and Kalauao Streams, which discharge into the East Loch of Pearl Harbor. The watershed is primarily undeveloped forest land with established urban areas on the coastal plain and lower slopes. The Aiea and Halawa Watersheds are drained by the Aiea and Halawa Streams, respectively, which discharge into East Loch. They are similar in nature to the Waimalu Watershed. Honouliuli Stream drains the Honouliuli Watershed and discharges intermittently into West Loch. The watershed consists primarily of agricultural and forested land. Only 20 percent of the Ewa Beach Watershed drains into Pearl Harbor. Sediment discharges into Pearl Harbor from the flat lowland area adjacent to West Loch are negligible.

Of the eight streams discharging into Pearl Harbor, two are intermittent: Honouliuli Stream and Aiea Stream. The remaining are perennial streams (Waikele, Waiawa, Waimano, Waimalu, Kalauao, and Halawa), which have their headwaters in the high rainfall area of the Koolau Range. All streams drain the forested and agricultural lands and pass through urban areas before entering Pearl Harbor. Some flooding occurs along the major streams throughout much of the basin but is not a major problem on the Naval Complex, affecting only a narrow strip of land along Aiea stream. (Navy 1990b)

An assessment in 1988 by the State of Hawaii, Department of Health indicated that Pearl Harbor's large drainage basin in central Oahu and the abundant rainfall in headwaters of the eight streams that flow into the harbor are major contributors to the harbor's role as a catchment for nonpoint runoff from agricultural, urban, and military sources. Violations of water quality criteria were noted for nitrogen, phosphorus, turbidity, and fecal coliforms in the harbor water. (Navy 1990b)

The Flood Insurance Rate Map (FIRM) COMMUNITY-PANEL No. 150001 0110 C shows that the floodplain is "undetermined" for the Pearl Harbor Naval Shipyard. Based on FIRM maps and topographical maps of areas approximately 3 miles away, the conceptual interim storage location is in the 100-year floodplain. However, based on experience, the location considered for naval spent nuclear fuel is not in a high-hazard area (as defined by Title 10, Part 1022 of The Code of Federal Regulations for floodplains) which is an area where frequent flooding occurs.

4.1.4.8.2 Groundwater.

The major source of potable water on Oahu is dependent on a hydrologic cycle that starts with evaporation of water from the ocean, condensation of that vapor into rain, and the capture of that rain by the Koolau Mountains. A portion of the rainwater percolates down into the porous ground to become groundwater. The groundwater is a limited resource found in three types of groundwater bodies, or aquifers: major basal aquifers, which consist of freshwater floating on heavier seawater sealed from the ocean by layers of dense, hard volcanic rock; perched aquifers in which rainfall is caught behind impermeable dikes at high elevations; and groundwater standing on impermeable beds of volcanic ash, thus creating springs. Naval Base Pearl Harbor receives most of its water from the Koolau Aquifer and a small portion from the Waianae Aquifer, which are basal aquifers located in south central Oahu, partially within the Pearl Harbor Water Management Area (PHWMA). As of 1990, the military had an allocation of 28.125 million gallons per day (mgd) from the PHWMA, of which 22.670 mgd was authorized for the Navy. Over 4 mgd of this allocation was not used in 1988. Approximately 3 mgd of this unused allocation is attributed to the Navy. The quality of groundwater from the above aquifers is good. (Navy 1990b)

4.1.4.8.3 Existing Radiological Conditions.

The normal activities associated with current naval nuclear operations at all naval shipyards do not result in the intentional discharge of any radioactive liquid effluent. However, there were occasions, primarily in the early 1960's, when measurable levels of radioactivity were discharged with liquid effluent. In all cases, effluent releases were less than permitted under the then current limits imposed by state and federal agencies.

The United States Environmental Protection Agency Office of Radiation Programs has performed monitoring of the water, plant life, aquatic life, and sediment in the vicinity of Pearl Harbor Naval Shipyard. The purpose of the survey was to determine if operations related to U.S. Navy nuclear warship activities resulted in releases of radionuclides which could contribute to significant population exposure or contamination of the environment. "Radiological Surveys of the Pearl Harbor Naval Shipyard and Environs" (Callis 1987) is the most recent Environmental Protection Agency report which discusses data taken in 1985. Pertinent conclusions from this report are as follows:

1. "Neither harbor water nor drinking water from surrounding areas contain detectable cobalt-60 or tritium radioactivity.
2. Very small quantities of cobalt-60 were found in sediment and in two aquatic vegetation samples from the harbor. No cobalt-60 was found in any of the aquatic life samples.
3. The levels of cobalt-60 in the harbor sediment have decreased significantly since the surveys of 1966 and 1968 and are consistent with those expected from the radioactive decay of the amounts found in the 1966 and 1968 surveys.
4. The current practice of restricting the release of radioactive material into the harbor to the minimum practical has been effective and should allow the cobalt-60 radioactivity remaining in harbor sediment to continue to decrease.
5. The levels and locations of radioactivity identified and the limited media in which it was found show that operations related to nuclear-powered warship activities resulted in no release of radionuclides having adverse effects on public health or the environment."

Environmental monitoring is conducted by the shipyard. The results of this monitoring program corroborate the Environmental Protection Agency's conclusion.

4.1.4.9 Ecological Resources

4.1.4.9.1 Terrestrial Ecology.

Because the Pearl Harbor area has been disturbed extensively and for such a long period of time, the vegetation is dominated by introduced or alien species. Vegetation consists of maintained landscaped specimens or, on unmaintained areas, mangrove thickets and weedy scrub. The few native taxa which occur on these unmaintained areas such as 'uhaloa (Waltheria indica) and 'ilima (Sida fallax) occur throughout the Hawaiian Islands and the Pacific in similar environmental habitats. No plants considered threatened or endangered occur on this location.

Fauna in the Pearl Harbor area is also typically urban. In general, various feral and domestic cats and dogs, rodents, and exotic bird species are found in the area. No endemic land birds were recorded during the course of the field surveys completed in 1989. (Navy 1990b)

4.1.4.9.2 Wetlands.

There are several wetland areas at Pearl Harbor identified in the East Loch, Middle Loch, and West Loch, as well as an area on the Waipio Peninsula. There is also a Pearl Harbor National Wildlife Refuge. These are habitats for endangered species of birds, principally the Hawaiian Coot and Hawaiian Stilt. A cooperative agreement established between the U.S. Navy, and the U.S. Fish and Wildlife Service, the National Marine Fisheries Service, and the State of Hawaii, Department of Land and Natural Resources, protects these wetlands. (Navy 1990b)

4.1.4.9.3 Aquatic Ecology.

Most of the Pearl Harbor marine community structure is characterized by four zones: sand-rubble zone, algal-mud zone, channel wall zone, and channel floor mud-silt zone. Sedimentation is the major factor determining the constituents of the Pearl Harbor marine community. Hence, stony corals, which are especially sensitive to high sediment loads, have not been observed. Predominant biota include the sea cucumber (Ophiodesoma spectabilis), a species commonly found in areas of high organic particulate input; benthic (bottom dwelling) algae; sponges; Sabellid (feather duster) worms; Serpulid worm tubes; and various benthic shrimps and crabs. (Navy 1990b)

4.1.4.9.4 Endangered and Threatened Species.

Most of the land at Pearl Harbor Naval Shipyard has been urbanized, and the present vegetation consists almost exclusively of introduced plant species. Consequently, no federally or state listed threatened or endangered species or critical habitats are known to exist within the confines of Pearl Harbor Naval Shipyard. Because the area has been greatly disturbed and the native vegetation completely eliminated, there is little remaining terrestrial habitat of any consequence. Small tracts of weedy fields and isolated pockets of disturbed secondary vegetation within the station's boundaries provide limited habitat for introduced species of birds and rodents. Some migratory birds as well as endemic and indigenous waterfowl species may occasionally frequent the shoreline areas of Pearl Harbor Naval Shipyard, but none are considered residents of the activity. The mangrove stands and associated shoreline habitats act as nurseries to a variety of fish and wildlife and aid in shoreline stabilization and erosion control. (Navy 1989)

Marine mammals are afforded full Federal protection under the Marine Mammal Protection Act of 1972. As noted above, there are wetland areas in the Pearl Harbor Complex that include a National Wildlife Refuge and provide habitats for endangered species of birds, principally the Hawaiian Coot (Fulica americana alai) and Hawaiian Stilt [Himantopus mexicanus (=himantopus) knudseni].

4.1.4.10 Noise

Noise sensitive locations in the Pearl Harbor area have been identified as the U.S.S. Arizona Memorial, U.S.S. Arizona Memorial Visitor Center, U.S.S. Bowfin Park, Marina Restaurant, Richardson Recreation Center, and existing or planned residential areas of Ford Island. Field noise measurements were taken at these locations on December 5, 1989; previous measurements also were taken at some of these locations. All appear to meet state and federal noise standards at present.

Pearl Harbor Naval Shipyard is an existing industrial environment characterized by noise from truck and auto traffic, ship loading cranes and related diesel-powered equipment, and continuously operating transmission lines for steam, fuel, water, and related compressors for these and other liquids. In addition, new construction of buildings, reconstruction and rehabilitation activities for streets, buildings, parking lots, and ships all contribute to the noise associated with an industrial environment. (Navy 1990b)

4.1.4.11 Traffic and Transportation

The main portion of traffic into and out of the base is an aggregate of commuting traffic to work, residential related traffic, and service traffic related to the business of the base. Kamehameha Highway is the primary access route to the base from the Ewa/Pearl City/central Oahu direction. Both Kamehameha Highway and Interstate Highway H-1 provide access to the Naval Base from the Honolulu direction. (Navy 1990b)

The Honolulu International Airport provides scheduled passenger and cargo air service to major connecting hubs. In addition, Hickam Air Force Base services the military.

Naval spent nuclear fuel has been removed from Navy nuclear-powered ships and transported to the Idaho National Engineering Laboratory Expended Core Facility (ECF) for examination and evaluation as a routine part of their operating cycle. Naval spent nuclear fuel shipments from Pearl Harbor Naval Shipyard to ECF were initiated in 1962. Since that time, 20 shipments of naval spent nuclear fuel originating at Pearl Harbor Naval Shipyard have been made to ECF. The naval spent nuclear fuel containers were transported by ship to the Puget Sound Naval Shipyard where the containers were then transported to ECF by rail. Attachment A provides a list of these shipments made to date by year. Attachment A also contains detailed descriptions of the shipping containers used for naval spent nuclear fuel shipments from shipyards.

Traffic circulation related to Naval Base Pearl Harbor is determined by the working and residential populations of the base, by the geometry of the existing roadways and intersections, and by the access gates into the base.

4.1.4.12 Occupational and Public Health and Safety

4.1.4.12.1 Occupational Radiological Health and Safety. The Navy has well established and

effective Occupational Safety, Health, and Occupational Medicine programs at all of its shipyards. In regard to radiological aspects of these programs, the Naval Nuclear Propulsion Program policy is to reduce to as low as reasonably achievable the external exposure to personnel from ionizing radiation associated with naval nuclear propulsion plants. These stringent controls on minimizing occupational radiation exposure have been successful. No civilian or military personnel at Navy sites have ever exceeded the federal accumulated radiation exposure limit which allows 5 rem exposure for each year of age beyond age 18. Since 1967, no person has exceeded the federal limit which allows up to 3 rem per quarter year and since 1980, no one has received more than 2 rem per year from radiation associated with naval nuclear propulsion plants. The average occupational exposure of each person monitored at all shipyards is 0.26 rem per year. The average lifetime accumulated radiation exposure from radiation associated with naval nuclear propulsion plants for all shipyard personnel who were monitored is 1.2 rem. (NNPP 1994a) This corresponds to the likelihood of a cancer fatality of 1 in 2083.

The Navy's policy on occupational exposure from internal radioactivity is to prevent radiation exposure to personnel from internal radioactivity. The limits invoked to achieve this objective are one-tenth of the levels allowed by federal regulations for radiation workers. As a result of this policy, no civilian or military personnel at shipyards have ever received more than one-tenth the federal annual occupational exposure limit from internal radiation exposure caused by radioactivity associated with naval nuclear propulsion plants.

For work operations involving the potential for spreading radioactive contamination, containments are used to prevent personnel contamination or generation of airborne radioactivity. The controls for contamination are so strict that precautions sometimes have had to be taken to prevent tracking contamination from fallout and natural sources into radiological areas because the contamination control limits used in these areas were well below the levels of fallout and natural contamination occurring outside in the general public areas. A basic requirement of contamination control is monitoring all personnel leaving any area where radioactive contamination could possibly occur. Workers are trained to survey themselves (i.e., frisk), and their performance is checked by radiological control personnel. Frisking of the entire body is required, normally using sensitive hand-held survey instruments. Major work facilities are equipped with portable monitors, which are used in lieu of hand-held friskers. These stringent controls to protect the workers and the public from contamination have proven effective in the past.

In 1991, researchers from Johns Hopkins University, Baltimore, Maryland, completed a very comprehensive epidemiological study of the health of workers at the six naval shipyards and two private shipyards that service the Navy's nuclear-powered ships (Matanoski 1991). This independent study evaluated a population of 70,730 civilian workers over a period from 1957, beginning with the first overhaul of the first nuclear-powered submarine, USS NAUTILUS, through 1981, to determine whether there was an excess risk of leukemia or other cancers associated with exposure to low levels of gamma radiation.

The Johns Hopkins study found no evidence to conclude that the health of people involved in work on U.S. naval nuclear-powered ships has been adversely affected by exposure to low levels of radiation incidental to this work. Additional studies are planned to investigate the observations and update the shipyard study with data beyond 1981.

The radiation exposure during normal operations at each shipyard for workers who have their radiation levels monitored is determined based on the annual radiation exposure of 0.26 mrem per worker for all shipyards based on Naval Nuclear Propulsion Program Report NT-94-2 (NNPP 1994a). The total number of shipyard personnel monitored for radiation exposure associated with the Naval Nuclear Propulsion Program has been about 164,000.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population.
Under the limiting assumption that the same worker is associated with every shipment for the entire historical period, this person would receive a total exposure of 7.5 rem over the approximately 40-year period, or about 0.19 rem per year, which is within DOE standards for occupationally exposed individuals. The radiation exposures to workers correspond to much less than one incident cancer, which means that it is unlikely that there have been any past health impacts due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.4.12.2 Occupational Non-radiological Health and Safety.

In the non-radiological Occupational Safety, Health, and Occupational Medicine area, the Navy complies with the Occupational Safety and Health Administration Regulations. The Navy's policy is to maintain a safe and healthful work environment at all naval facilities. Due to the varied nature of work at these facilities, there is a potential for certain employees to be exposed to physical and chemical hazards. These employees are routinely monitored during work and receive medical surveillance for physical hazards such as exposure to high noise levels or heat stress. In addition, employees are monitored for their exposure to chemical hazards such as organic solvents, lead, asbestos, etc., and where appropriate are placed into medical surveillance programs for these chemical hazards.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact due to the historical shipment of naval spent nuclear fuel over the entire history of such shipments.

4.1.4.12.3 Public Radiological Health and Safety.

In order to quantify the exposures resulting from normal shipyard radiological releases to the general public, detailed analyses were performed based on very conservative estimates of radioisotopic releases from 1961 through 1992. Attachment F provides detailed annual release values used in the analyses.

The GENII computer code (Napier et al. 1988) was used to calculate exposures to human beings due to the estimated radionuclide releases from normal operations at the shipyards.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from stored fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F.

The hypothetical exposures calculated in Attachment F for the period 1995 through 2035 were adjusted from an annual basis (1995) to the historical basis by multiplying by 38 years and by a factor of 1.7 to take into consideration variations in the number of ships and operations.

The calculated accumulated exposures through 1995 to the general population within 50 miles of the site (about 0.8 million people) are 1.9 person-rem. To provide perspective, the exposures received due to natural radiation sources through 1995 are approximately 9.3 million person-rem, based on 0.3 rem per person per year.

The results of environmental monitoring as described in Naval Nuclear Propulsion Program Report NT-94-1 show that Naval Nuclear Propulsion Program activities had no distinguishable effect on normal background radiation levels at site perimeters (NNPP 1994b).

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities.

All of the radiation exposures to the general population correspond to much less than one incident cancer, which means that it is unlikely that there has been any past health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.4.12.4 Public Non-radiological Health and Safety.

The military is responsible for providing health care services for its personnel and dependents. Navy families receive both in-patient and out-patient care at Tripler Army Medical Center. Services are also provided at on-base clinics and dispensaries. Active-duty personnel are required to use military health care facilities. In addition, military dependents have the option of going to private providers and being partially reimbursed for the cost.

The Oahu Civil Defense Agency is responsible for developing, preparing, and assisting in the implementation of civil defense plans and programs to protect the safety, health, and welfare of island residents during disasters and emergency situations. However, responsibility for military personnel and dependents on the base rests with the Navy.

Fire protection within Naval Base Pearl Harbor is provided by the Federal Fire Department. A Mutual Aid Pact between the federal (military) fire departments and the Honolulu Fire Department affords dual coverage in times of emergencies.

Naval Base Pearl Harbor is under federal jurisdiction; therefore, federal authorities are normally responsible for providing all needed police service. The City and County of Honolulu Police Department, however, is responsible for traffic control in areas around the base. The closest police station is located in Pearl City. (Navy 1990b)

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.4.13 Utilities and Energy

4.1.4.13.1 Water Consumption. Naval Base Pearl Harbor receives most of its water from the

Koolau Aquifer and a small portion from the Waianae Aquifer, which are basal aquifers located in south central Oahu, partially within the Pearl Harbor Water Management Area (PHWMA). In early 1989, a Water Management Plan for the PHWMA was proposed by the Commission on Water and Resource Management (CWRM) to preserve and manage the Koolau and Waianae basal aquifers and the Schofield high-level aquifer. One important portion of the Water Management Plan recommended that the sustainable yield for the PHWMA be revised downward from the then current 225 million gallons of water per day (mgd) to 195 mgd. The purpose of the revision was to eliminate possible shrinkage of the aquifer in the PHWMA from over-withdrawal. Actual use in 1989 totaled 198.298 mgd, of which the military portion was about 13 percent. The major water users in the PHWMA are the Board of Water Supply (87.5 mgd) and the Oahu Sugar Company (78.6 mgd). In the revised plan, water allocation to the military is not decreased. The stated management policy of the CWRM is that "total allocation of authorized use will not at any time exceed sustainable yield." As of 1990, the military had an allocation of 28.125 mgd from the PHWMA, of which 22.670 mgd was authorized for the Navy. Of the total allocation to the U.S. Navy, Koolau Aquifer provides 20.333 mgd, and Waianae Basal Aquifer provides 2.337 mgd. (Navy 1990b)

4.1.4.13.2 Electricity Consumption.

The electrical power service for the Pearl Harbor Naval Complex is provided by the Hawaiian Electric Company. The Hawaiian Electric Company power grid on the island of Oahu consists of three power plants with a total capacity of 1,271 MW, plus two plants in planning or under construction totaling 390 MW. The peak island demand in 1989 was approximately 1,090 MW.

The power plants are located at Kahe, Waiau, and downtown Honolulu and are inter-connected via 138-kV transmission and 46-kV sub-transmission circuits. The Pearl Harbor Naval Complex is served via three 46-kV feeders, each from a separate 80-MVA transformer at the Makalapa substation, which is part of the island's 138-kV grid. The feeders serve two Hawaiian Electric Company substations located on the base (Puuloa and Kuahua), which step the voltage down to 11.5 kV, and serve two normally separated 11.5-kV networks.

One of the 46-kV feeders serves only the Puuloa substation. The second serves only the Kuahua substation. The third serves both substations. Any one feeder has the capacity to carry the entire Pearl Harbor load or approximately 57 MVA. In addition to the three feeders from the Makalapa substation, there are two alternate 46-kV circuits, one a dedicated spare, from the Waiau power plant.

The Puuloa substation consists of two 20/33-MVA transformers located in the Pearl Harbor Naval Shipyard area and serves the Pearl Harbor Naval Shipyard, Naval Station Pearl Harbor, and Ford Island. The Kuahua substation consists of two 15/20-MVA transformers located in the Submarine Base Pearl Harbor area and serves the Submarine Base Pearl Harbor and Naval Supply Center Pearl Harbor areas.

4.1.4.13.3 Fuel Consumption.

One major type of energy use is vehicular fuel consumption. No estimates are available to differentiate vehicle fuel use at Pearl Harbor from other areas. The ferry system consumed 152,088 gallons of diesel fuel in 1988. An occupancy rate of 1.5 persons per vehicle was used, so the ratio of fuel consumed per person per trip was 0.144 gallon of diesel fuel per person crossing. The second major source of energy consumption originates in buildings. The analysis of building energy use is based on standards for energy consumption per unit of designated building floor area by type of building and the geographical location.

4.1.4.13.4 Wastewater Systems and Discharges.

Sewage at the Pearl Harbor Naval Complex is collected and treated in several separate systems. Most of the sewage generated by U.S. Navy shore activities and family housing areas receives secondary treatment at Navy-operated sewage treatment plants. The largest volume is treated at the Fort Kamehameha Sewage Treatment Plant which serves the Naval Station Pearl Harbor, Pearl Harbor Naval Shipyard, Naval Supply Center Pearl Harbor Complexes, Camp Smith, Navy and Air Force housing areas, Hickam Air Force Base, and other adjacent military areas.

4.1.4.13.5 Energy Conservation.

To minimize the use of fossils fuels and conserve energy, the military has adopted conservation criteria for new construction and major renovation projects. The policies used under the conservation criteria focus on meeting design energy targets, based on Btu/per square foot/per year (Btu/sf/yr). Guidelines are provided for ventilation, insulation, and energy life cycle cost of structures. (Navy 1990b)

4.1.4.14 Materials and Waste Management

The City and County of Honolulu's HPOWER (Honolulu Program of Waste Energy Recovery) "garbage-to-energy" facility at Campbell Industrial Park is currently in full operation and burning roughly 1,500 to 1,800 tons per day, which is most of the combustible rubbish generated on the island of Oahu. Approximately 20 percent (by weight) of the refuse handled by the HPOWER facility is reduced to ash and other residue which requires landfill disposal.

There are two city and county landfills: the Kapaa Landfill in Kailua (Windward Oahu) and the Waimanalo Gulch Landfill in Nanakuli (Leeward Oahu). The Kapaa Landfill has reached full capacity, and plans are underway to locate a new site in Windward Oahu. The Nanakuli facility, which opened in September 1989, is programmed for 1,000 tons per day for seven to eight years. According to the city, the facility should be able to accommodate projected needs for at least 15 years and maybe longer. (Navy 1990b)

Solid radioactive waste materials are packaged in strong, tight containers, shielded as necessary, and shipped to burial sites licensed by the U.S. Nuclear Regulatory Commission or a State under agreement with the U.S. Nuclear Regulatory Commission. Shipyards and other shore facilities are not permitted to dispose of radioactive solid wastes by burial on their own sites. During 1992, approximately 110 cubic yards of routine low-level radioactive waste containing a total of 1 curie were shipped from the shipyard for burial.

Waste which is both radioactive and chemically hazardous is regulated under both the Atomic

Energy Act and the Resource Conservation and Recovery Act as "mixed waste." Within the Naval Nuclear Propulsion Program, concerted efforts are taken to avoid commingling radioactive and chemically hazardous substances so as to minimize the potential for generation of mixed waste. For example, these efforts include avoiding the use of acetone solvents, lead-based paints, lead shielding in disposal containers, and chemical paint removers. Radioactive wastes, including those containing chemically hazardous substances, are handled in accordance with long-standing Program radiological requirements. Such handling includes solidification to immobilize the radioactivity, separation of the radioactive and chemically hazardous substances, removal of liquids from solids, and other simple techniques. A determination is then made as to whether the resulting waste is hazardous. As a result of Program efforts to avoid the use of chemically hazardous substances in radiological work, Program activities typically generate only a few hundred cubic feet of mixed waste each year. This small amount of mixed waste, along with limited amounts of mixed waste from Program work conducted prior to 1987, will be stored pending the licensing of commercial treatment and disposal facilities.

4.1.5 KENNETH A. KESSELRING SITE: WEST MILTON, NEW YORK

4.1.5.1 Overview

The Kenneth A. Kesselring Site of the Knolls Atomic Power Laboratory (KAPL) is located in the mid-eastern sector of New York State as shown on Figure 4.1.5-1. The Site is located near West Milton in Saratoga County, New York at 43y2'28" north latitude and 73y57'13" west longitude. This United States Government owned reservation consists of over 3900 acres centered about 15 miles north of the city of Schenectady and about 8 miles west of Saratoga Springs. The Site includes three operating naval nuclear propulsion prototype plants and support facilities. The Site also includes one prototype plant that is in the process of being permanently shut down; one of the three operating plants is currently scheduled to be shut down in 1996. All the operating facilities are located in a secure area near the center of the reservation (see Figure 4.1.5-2). A more detailed illustration of the site is provided in Figure 4.1.5-3.

4.1.5.2 Land Use

All the land within the Site perimeter is owned by the Department of Energy (DOE). There are no permanent residents within this area. The surrounding region, within 50 miles of the Site, contains a population of about 1,150,000 as obtained from the 1990 census.

Most of the land surrounding the Site is either wooded or is used for farming, with some residential areas. Both dairy farms and agricultural farms are located in the immediate vicinity of the reservation.

The West Milton area is located within the undulating transition zone between the Adirondack Highlands and the Hudson-Mohawk Lowlands physiographic provinces. The area is characterized by a series of irregular northwest-southwest trending topographic steps that descend from the highlands southeasterly towards the lowlands.

Figure 4.1.5-1. Kesselring Site vicinity map. Figure 4.1.5-2. Kesselring Site location map. Figure 4.1.5-3. Kesselring Site map.

Ground elevations in the vicinity of the reservation range from 400 to 900 feet above mean sea level. The Glowegee Creek, its various tributaries, and the Crook Brook drain the reservation. The developed portion of the reservation, which contains the prototype plants, consists of approximately 50 acres (see Figure 4.1.5-2). The terrain surrounding the Site forms a partial bowl having a bottom diameter of about 2000 feet and a maximum height of 150 feet. The Site is essentially flat-lying with ground elevations ranging from 480 to 490 feet. The western half of the Site is surrounded by elliptical hills approximately 600 feet in elevation. Drainage from the Site is eastward, to the Glowegee Creek.

4.1.5.3 Socioeconomics

As of 1993, the Kesselring Site employed about 1,450 civilian workers, and about 1,250 naval personnel worked at the Site.

The only industry within 4 miles of the Site is the Cottrell Paper Company, located in Rock City Falls, about 3 miles from the Site.

The region surrounding the Site, within 50 miles, contains a population of about 1,150,000 as obtained from the 1990 census. Figure 4.1.5-4 provides a population distribution rose centered on the Site and lists the total population within concentric rings covering a 50-mile radius from the Site.

The majority of the labor force that would be employed at the Site for construction and operation of the naval spent nuclear fuel area would be expected to reside within about 20 miles from the Site. The calculated total population, labor force, and employment within this region for the base year (1995) are presented in Table 4.1.5-1. Projections of employment and population for the years beyond 1995 have not been presented because, as discussed in Section 5, the number of additional jobs that might be created at the Site under any alternative could be small.

Table 4.1.5-1. Regional employment factors at the Kesselring Site.

Regional Employment	Regional Labor Force	Regional Population
165,830	176,600	373,970

Figure 4.1.5-4. 50-mile population distribution around the Kesselring Site.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the Kesselring Site, consistent with the population data provided in Figure 4.1.5-4.

Figure 4.1.5-5 shows the locations of populations in which minority membership exceeds the average within the 50-mile radius by more than 20 percentage points and populations which have more than 50 percent minority members. These populations have been identified following an approach developed by the Environmental Protection Agency which, for purposes of environmental justice evaluation, defines minority communities as those which have percentages of minorities greater than the average in the region analyzed (EPA 1994).

Figure 4.1.5-6 shows the locations of populations which have more than 25 percent of their members living in poverty, reflecting a common definition of low-income communities (EPA 1993). The U. S. Census Bureau characterizes persons in poverty as those whose income is less than a "statistical poverty threshold." For the 1990 census, this threshold was based on a 1989 income of $12,500 per household.

4.1.5.4 Cultural Resources

Historically, the Kesselring Site reservation was used for agricultural purposes. Although old farmhouse foundations, grove sites, stone walls, and land fences exist on the Kesselring Reservation, there are no known archaeological, cultural, or Native American sites in the secure area of the Kesselring Site (USAEC 1972). There are no historic structures on the Site that are potentially eligible for or are listed on the National Register of Historic Places (NPS 1991).

Figure 4.1.5-5. Minority population distribution within 50 miles of the Kesselring Site.

Figure 4.1.5-6. Low-income population distribution within 50 miles of the Kesselring Site.

4.1.5.5 Aesthetic and Scenic Resources

The Kesselring Site is located in an area of moderately undulating topography at the northern edge of the Hudson-Mohawk Lowlands. Most of the Site facilities including the prototype reactor plants are located within a fenced security area. This security area and adjacent parking lots are located near the center of the Government reservation. (UE&C 1973) Since the balance of the reservation consists of wooded lands, there is very little public viewing opportunity of the Site facilities from the boundaries of the Government reservation. The area within the Site fenced security region where naval spent nuclear fuel would be stored has low visual sensitivity since the area is an industrial site.

4.1.5.6 Geology

4.1.5.6.1 General Geology.

In 1973, a Site evaluation and foundation engineering investigation were conducted for the Kesselring Site (UE&C 1973) to establish suitable parameters for the analysis and design of the S8G prototype structures. A prior evaluation of the Site was conducted for the Modifications and Addition to Reactor Facilities. In both investigations, the local and regional geology and seismicity of the West Milton area were examined through a literature search, a detailed subsurface investigation, and a geophysical survey involving refraction and cross-hole velocity measurements. Major soil boring, sampling, and laboratory testing for the S8G Site evaluation were reported in various documents (UE&C 1973; EDCE 1974a; EDCE 1974b). Additional boring information and a geophysical field investigation performed for the Modifications and Addition to Reactor Facilities project were also utilized in the S8G Site evaluation. A 1974 Site geology evaluation was also conducted and a report issued (DGC 1974).

4.1.5.6.2 Geologic Resources.

At Kesselring, unconsolidated materials, primarily of glacial origin, overlie bedrock. The thickness of these materials or overburden sequence is variable, ranging from 0 to several hundred feet. The overburden sequence, in ascending order, consists of three basic kinds of depositional units: glacier debris, lake, and ice-contact/outwash deposits. Deposits from glaciers overlie much of the bedrock and form the elliptical hills (drumlins) throughout most of the reservation. The glacier deposits are a dense and poorly sorted mixture of clay, silt, sand, gravel, and boulders. Thinly stratified lake clay and silt deposits are mapped over the reservation's southeastern quadrant. The ice-contact/outwash deposits mostly consist of stratified sands and gravels. The ice contact/outwash deposits, characterized by low clay and silt content, have better aquifer potential than the silt-and-clay-rich glacier and lake deposits.

Bedrock geology is also variable at the reservation and consists of crystalline rocks, Potsdam Sandstone, Galway Formation (dolomites and sandstones), Gailor Dolomite, Trenton/Amsterdam/ Lowville Limestones, and Canajoharie Shale. The Canajoharie Shale underlies the majority of the reservation. This black shale generally is considered a poor aquifer and its productivity is dependent on the presence or absence of fractures. Also, its water may contain naturally occurring hydrogen sulfide.

At the Site, approximately 20 to 30 feet of overburden deposits overlie the Canajoharie Shale. These deposits consist of layers of deposits from glaciers and lakes. Locally, these deposits have been altered as the result of facility construction. Generally, groundwater exists from 5 to 10 feet below the ground surface. Groundwater flows easterly, toward the nearby Glowegee Creek.

There are no economic geologic resources at the Site.

4.1.5.6.3 Seismic and Volcanic Hazards.

In 1973, a seismicity evaluation of the Kesselring Site was conducted (UE&C 1973). An additional investigation was conducted in 1981 (EDCE 1981). The following is a summary of their findings.

Three branch faults exist in the vicinity of the Site: The West Galway, the East Galway, and the Rock City Falls faults. These branch faults are the lines of demarcation between the various bedrock formations in the immediate area. The East Galway branch lies approximately 3500 feet northwest of the Site and is believed to be the predominant influence on the earthquake loading for Site facilities. The two Galway faults are end branches of the Hoffman's Ferry fault.

Seismic risk related to structural damage may be represented in the United States by a relative scale of 0 through 4, with Zone 0 not expected to encounter damage and Zone 4 expected to encounter the greatest seismic risk. The Site is located in Zone 2A according to the "Uniform Building Code" (UBC 1991). The Uniform Building Code seismic classification provides a means for a comparable assessment of the seismic hazard between the alternate sites. If the Record of Decision identifies this site for the interim storage of naval spent fuel, then a detailed seismic evaluation would be conducted. More detailed information regarding the design basis considerations for storage of naval spent nuclear fuel at the Site is provided in Attachment D.

Data accumulated indicate that the maximum intensity earthquake for the region within a 100-mile radius of the Site had a value of VII. The most recent earthquake of that intensity occurred at Lake George, New York, on April 30, 1931. It is postulated that this event had an epicenter at the point where the Rock City Falls fault meets the Hoffman's Ferry fault. Since the West Galway and East Galway branch faults are extensions of the Hoffman's Ferry fault, an earthquake of similar intensity might occur anywhere along the East Galway fault within the lifetime of the Site structures.

Several earthquakes having an intensity VIII or greater have occurred at distances greater than 100 miles from the Site. However, due to attenuation effects, the ground motion at the Site associated with these earthquakes has not been greater than that equivalent to an intensity VI. The most recent event occurred in 1983 at Newcomb, New York (about 75 miles northwest of the Site) and was of intensity VI.

Details regarding the seismic characteristics of the area and the design bases seismic evaluations performed for the Kesselring Site are provided in the "Site Geology Evaluation Report - S8G for Kesselring Site" (UE&C 1973) and in "Geotechnical Site Investigation, Kesselring Site, West Milton, New York" (EDCE 1981).

There are no volcanic hazards in the vicinity of the Site.

4.1.5.7 Air Resources

4.1.5.7.1 Climate and Meteorology.

The east-central part of New York State, in which the West Milton area is located, is situated at the northern end of the Hudson River Valley and is approximately 150 miles inland from the Atlantic coastline and about 200 miles south of the Canadian border. The climate of the region is primarily continental in character, but is subjected to some modification by the Atlantic Ocean. The moderating effect on temperatures is more pronounced during the warmer months than in winter when outbursts of cold air sweep down from Canada. In the warmer seasons, temperatures rise rapidly in the daytime, but also fall rapidly after sunset so that the nights are relatively cool. Occasionally, there are extended periods of oppressive heat up to a week or more in duration.

During the winter months, winds are generally from the west or northwest. During the warmer months, the winds are from the south. Wind velocities are moderate, and generally average less than 10 mph. Destructive winds (i.e., winds in excess of 80 mph) occur infrequently and tornadoes are rare. Tornadoes are rare in the region served by the Albany, New York weather station.

The mean monthly temperature of the region is about 50yF. Daily extremes can range from -30yF in the winter months to 100yF in the summer. On an annual basis, the mean daytime relative humidity values range from 50 to 80 percent. During the summer months, relative humidity values frequently approach 100 percent during the night.

Total yearly precipitation averages about 36 inches. The average yearly snowfall is about 58 inches and the maximum snowfall in 24 hours is about 22 inches. On the average, a frost depth of about 3 feet can be expected.

For weather reporting purposes, the West Milton area of northeastern New York is included in the National Weather Service Zone Forecast for Saratoga County. The principal weather recording location is at the Albany, New York airport. Its elevation is 275 feet above mean sea level. Because of the proximity of West Milton to Albany, temperature data for the Site should differ little from the Albany data. The two locations are generally within one or two degrees of each other, with West Milton tending to have lower temperatures.

4.1.5.7.2 Air Quality.

The principal sources of industrial gaseous effluents from the Kesselring Site are two 21-million, one 30-million, and one 110-million Btu/hr steam generating boilers. The number 2 fuel oil that is used to fire all of the boilers contains less than 0.5 weight percent sulfur. Combustion gases from the boilers are released through three elevated exhaust stacks. Operations such as ozalid reproduction, carpenter shops, welding hoods, paint shop, and industrial cleaning processes constitute other permitted point sources of airborne effluents. All point source emissions conform to the applicable state and federal clean air standards. Sulfur emitted from all boiler units is monitored via analysis of fuel sulfur content and reported to the Environmental Protection Agency (EPA) on a quarterly basis in compliance with the EPA's New Source Performance Standards in The Code of Federal Regulations, Title 40, Part 60. Sulfur emissions from the boilers are well within the EPA's New Source Performance Standards emission standard for stationary combustion installations. All other industrial emission sources at the Kesselring Site do not require monitoring under terms of the current New York State permits due to the very low levels of the emissions.

An area can be designated by the Environmental Protection Agency as having air quality that is better than defined by the National Ambient Air Quality Standards (attainment) or as exceeding one or more of those standards (nonattainment for one or more pollutants). The Code of Federal Regulations, Title 40, Part 81, states that the Air Quality Control Region for this site is in marginal nonattainment for ozone and is better than national standards for total suspended particulate matter and SO_2. The area has no specific classification for carbon monoxide and NO_2.

The nearest Class I area is at Lye Brook Wilderness, Suarderland, Vermont, which is 46 miles from the Site.

4.1.5.7.3 Existing Radiological Conditions.

Radiological facilities at the Kesselring Site are designed to ensure that there are no discharges of radioactivity in airborne exhausts in excess of prescribed operational limits. Radiological controls are exercised to preclude exposure of working personnel to airborne radioactivity exceeding federal limits. Air exhausted from radiological work facilities is passed through high-efficiency particulate air filters and monitored during discharges. The annual airborne radioactive emissions from Kesselring Site do not result in any measurable radiation exposure to the general public. As described in the "Knolls Atomic Power Laboratory Environmental Monitoring Report for Calendar Year 1992" (KAPL 1992), the estimated 1992 radiation exposure to off-site individuals attributed to radioactive air emissions from Kesselring Site operations was less than 1 percent of the Environmental Protection Agency standards given in Subpart H of 40CFR61 (CFR 1989). In order to quantify the risk of normal (non-accident) Kesselring Site radiological airborne releases to the general public, detailed analyses were performed based on conservative estimates of radioisotopic releases in the exhaust air. In 1992, the airborne radioactivity emissions from the Kesselring Site totaled about 2 curies (KAPL 1992).

4.1.5.7.4 Existing Non-radiological Conditions.

New York State emission standards for all permitted emission sources at the Kesselring Site, with the exception of the site boilers, are stipulated in the individual permits for these sources. State regulations provide specific guidance on what types of emissions require a permit. Compliance with the operating permit is the responsibility of the permit holder under the condition that all planned changes in operating permit conditions require prior review and approval by the New York State Department of Environmental Conservation (NYSDEC). In addition, all operating permits are reviewed and renewed at least every 5 years.

Stationary combustion sources such as the Site's boilers are not specifically regulated by NYSDEC, but fall under the federal New Source Performance Standards in The Code of Federal Regulations, Title 40, Part 60. Compliance with these standards is accomplished by utilization of number 2 fuel oil certified by the vendor that it contains less than 0.5 percent sulfur. Reports documenting fuel use and sulfur content are provided to the EPA Region II office on a quarterly basis.

4.1.5.8 Water Resources

The hydrology information contained herein was extracted from two independent evaluations. One was performed by the U. S. Geological Survey in November 1951. The second survey was performed in 1955. Additional hydrological surveys were performed in 1975 (Moody 1975; DGC 1975), and 1985 and 1986 (DGC 1986).

4.1.5.8.1 Surface Water.

Most of the Site is drained by the Glowegee Creek, which meanders through rolling farmlands and woodlands to a junction with Kayaderosseras Creek at a point approximately 1 mile east of West Milton. The quality of the water in Kayaderosseras Creek and Glowegee Creek is satisfactory for public water supply and most industrial purposes, although Glowegee Creek is not used for these purposes. The average stream flow measured at the U. S. Coast and Geodetic Survey gaging station 0.5 mile downstream of the Site is 41 cfs. The range of elevation for Glowegee Creek is approximately 580 feet above mean sea level at the western entry to the Site to about 380 feet above mean sea level at its junction with the Kayaderosseras Creek. Swamp area and natural surface storage in the basin are small, but the soils and the unconsolidated materials below the soils can hold a considerable volume of groundwater. A number of perennial springs exist in the area. There are no records indicating flooding of the Site.

The Kayaderosseras Creek empties into Saratoga Lake and ultimately, by way of Fish Creek, into the Hudson River. Kayaderosseras Creek rises in the Kayaderosseras Range on the southern edge of the Adirondack Mountains. The basin above West Milton ranges approximately 1600 feet in elevation and contains a sizeable aggregate area of swamps.

The Flood Insurance Rate Map (FIRM COMMUNITY-PANEL No. 360 722 B) shows that the Kesselring Site is not in a 100 or 500 year floodplain.

4.1.5.8.2 Groundwater.

At the Site, the overburden sequence, consisting of glacier and lake deposits, and the underlying Canajoharie Shale generally form poor aquifer systems. In the West Milton area, neither of these systems are designated as sole source aquifers by the EPA or as primary/principal aquifers by New York State.

The dense glacial deposits and fine-grained lake deposits have characteristically low permeabilities in comparison to ice-contact/outwash deposits. Historically, both the glacier and lake deposits produce very low volumes of groundwater. At the Site, shallow water table mapping shows that the groundwater gradient is low. This low gradient combined with the low permeability of the glacial deposits indicates that the groundwater flow rate is very low, on the order of 5 to 10 feet/year. Also, water table mapping indicates that the Glowegee Creek, approximately 200 to 1000 feet east of the operating facilities boundary, forms an aquifer boundary.

The source of potable water is a well field, located on the far eastern side of the Site, and is composed of six wells which draw water from both deep and shallow aquifers. Monitoring of groundwater from the Site service water well field has shown that all chemical constituents measured are within the New York State drinking water standards (KAPL 1992). This well field, which is adjacent to the Kayaderosseras Creek, is underlain by two sand and gravel aquifers. The uppermost aquifer exists under water-table conditions and extends to a depth of approximately 30 feet below ground surface. The lowermost aquifer exists under artesian head pressure with the potentiometric surface rising several feet above the static water-table surface. The depth of the artesian aquifer is approximately 55 to 100 feet below the ground surface. Recharge to the water-table aquifer during simultaneous water withdrawal comes primarily from the Kayaderosseras Creek, and to a lesser degree from Crook Brook. (DGC 1986)

There are 19 monitoring wells within the operating area. These recently installed wells are used to provide depth-to-groundwater information, related water table mapping, and water quality assessment. Test borings on the reservation have generally showed the water table to be within 5 to 10 feet of the ground surface. The test boring data also indicate that the configuration of the water table is, for the most part, a replica of the configuration of the surface topography, but at a lower elevation and somewhat softened in relief.

4.1.5.8.3 Existing Radiological Conditions.

The liquid effluent environmental monitoring program at the Kesselring Site consists of radiological monitoring of the Glowegee Creek water, aquatic life, and sediment in the vicinity of the Site to confirm that the general public is not affected by operations at the Site. There is no detectable radioactivity present in the Glowegee Creek sediment due to Site operations (KAPL 1992). The concentrations of chemical constituents in liquid effluent from the Kesselring Site resulted in no adverse effect on the quality of Glowegee Creek aquatic life. This is substantiated by results of fish and aquatic life surveys that confirmed the existence of a diverse and healthy aquatic community in the creek water. Only naturally occurring radionuclides were detected in the Glowegee Creek water samples. The results of analysis for fish collected from Glowegee Creek show no radioactivity attributable to Site operations.

Currently, Kesselring Site does not discharge radioactive liquid effluent to the environment. Since the beginning of prototype operations, the release of radioactivity into Glowegee Creek has been small (about 15 curies) and has had no measurable effect on the natural background radioactivity in the sediment. Over 98 percent of the radioactivity discharged to the creek was tritium but included traces of other radionuclides such as cobalt-60, iron-55, nickel-63, and antimony-125 (KAPL 1992). The amount of tritium released was greatly decreased when water reuse was started by the prototype plants. In addition, the average concentration of tritium discharged to Glowegee Creek was over 1000 times lower than allowed by federal regulations. In over three decades of operation, there has been no measurable impact from Kesselring Site operations on the environment or adverse effect on the community or the public.

4.1.5.9 Ecological Resources

4.1.5.9.1 Terrestrial Ecology.

The conceptual location where naval spent nuclear fuel would be stored is illustrated in Attachment D. This location is within an existing industrial complex and is surrounded by buildings and paved areas. The industrial nature of the Site and the fact that the land has already been disturbed from its natural state by earlier activities mean that plant or animal species sensitive to disturbance by human activities would not be expected to be present.

4.1.5.9.2 Wetlands.

There are 13 areas located on the Kesselring Site classified as either Class II or III wetlands in accordance with the New York State Department of Environmental Conservation (NYCRR 1987). Current operations which include the secured area of the Site, parking lots, well field, and pumphouse area do not impact the listed wetlands. Access and perimeter roadways abut listed wetlands at four locations (within 100 feet); however, construction of these roadways predates all current regulatory requirements.

4.1.5.9.3 Aquatic Ecology.

In accordance with the Environmental Statement for the S8G Prototype, Kesselring Site, West Milton, New York (USAEC 1972), an expanded chemical and biological monitoring program was initiated in Glowegee Creek early in 1975. An important part of this monitoring program is an annual fish survey in Glowegee Creek upstream and downstream of Site discharges because Glowegee Creek is classified as a Class "C" trout stream by New York State. These surveys conducted by the New York State Department of Environmental Conservation and by environmental consultants from the Knolls Atomic Power Laboratory indicate that stocking downstream merely supplements the fish population that is removed by fishermen. The section of Glowegee Creek above the Site, although not stocked, contains a population of native trout which is maintained by natural spawning of the fish.

4.1.5.9.4 Endangered and Threatened Species.

There are several endangered and threatened species listed by the New York State Department of Environmental Conservation located in the Saratoga County area. The endangered species are the karner blue butterfly, bald eagle, and peregrine falcon, and the threatened species is the red-shouldered hawk. To date, there have been no direct observations of these species documented on the Kesselring Site.

4.1.5.10 Noise

Plant operations and maintenance at the Kesselring Site generate noise equivalent to light industrial activity.

4.1.5.11 Traffic and Transportation

Two corridors, the Hudson-Champlain, 10 to 17 miles to the east, and the Mohawk-Hudson, 10 to 17 miles to the south and southwest, contain the major transportation systems and the relevant industrial complexes in the vicinity of the Site. The Cottrell Paper Company, located in Rock City Falls, 3 miles from the Site, is the only industry within a 5-mile radius.

Except for their use by Kesselring Site employees, the secondary routes bounding the Site are auxiliary commuting and delivery routes for small products and produce. State Route 29 runs 2 miles to the north, State Route 147 runs 4 miles to the west, and State Route 67 runs 4 miles to the south. State Route 50, 6 miles east, running from Saratoga Springs to Scotia, carries the only appreciable amount of truck and bus traffic. The majority of through traffic uses either Interstate I-87 or parallel route U.S. Highway 9, in the Hudson-Champlain corridor, 10 miles to the east.

Two lines of the Delaware and Hudson Railroad cross the region within 10 miles of the Site. The main north-south line runs through Ballston Spa, just over 5 miles to the east, and a trunkline runs just over 5 miles to the northeast into the central Adirondack area.

Commercial barge traffic occurs on the New York State Barge Canal, 12 miles southwest of the Site at its closest point, and on the less used Champlain Division, 17 miles east of the Site.

Saratoga County has the nearest airport, 4-1/2 miles east of the Site, followed by

Schenectady and Albany airports, approximately 15 and 20 miles to the south-southeast. Data furnished by air traffic representatives for the three area airports indicate that regular flight patterns for military, commercial, and private aircraft, large and small, do not pass within a 5-mile radius of the Site. Only the instrument approach to the Saratoga County Airport, designated by the Federal Aviation Administration (FAA), has the potential for overflying the Site.

Albany County Airport, 22 miles south-southeast of the Site, is the nearest airport with scheduled flights by commercial jet aircraft. Schenectady County Airport, 15 miles south of the Site, is an auxiliary field with a low volume of traffic relative to size. No air carriers provide scheduled service out of Schenectady. The bulk of the airport's traffic is corporate and private aircraft, with the majority of the balance being military aircraft of the 109th New York Air National Guard.

Naval spent nuclear fuel has been removed from the prototypes and transported to the Idaho National Engineering Laboratory Expended Core Facility (ECF) for examination and evaluation as a matter of routine. Naval spent nuclear fuel shipments from the Kesselring Site to ECF were initiated in 1961. Since that time, 21 shipments of naval spent nuclear fuel originating at the Kesselring Site have been made to ECF. The shipping containers were transported by heavy-lift transporter to a nearby commercial rail line where the containers were then transported by rail. Attachment A provides a list of these shipments made to date by year. Attachment A also contains detailed descriptions of the shipping containers used for naval spent nuclear fuel shipments from shipyards.

The Site exclusion area boundary, which is the boundary of the Site, defines the restricted area. No activities unrelated to plant operation are permitted within the exclusion area. Access to the fenced-in security area containing the operating facilities (centered within the exclusion area boundary) is permitted only through one permanent gate facility which is manned by security guards on a 24-hour-per-day basis.

No public roads, highways, railways, or navigable waterways traverse the exclusion area.

4.1.5.12 Occupational and Public Health and Safety

4.1.5.12.1 Occupational Radiological Health and Safety. The Navy has well established and

effective Occupational Safety, Health, and Occupational Medicine programs at all of its facilities. In regard to radiological aspects of these programs, the Naval Nuclear Propulsion Program policy is to reduce to as low as reasonably achievable the external exposure to personnel from ionizing radiation associated with naval nuclear propulsion plants. These stringent controls on minimizing occupational radiation exposure have been successful. No personnel at the Naval Reactors Department of Energy facilities have ever exceeded the applicable federal annual radiation exposure limit. The annual limit was 15 rem per year in 1958 and is currently 5 rem per year. No one has exceeded the Program's limit of 5 rem per year since this limit was established in 1967 and since 1980, no one has received more than 2 rem per year from radiation associated with naval nuclear propulsion plants. The average occupational exposure of each person monitored at Naval Reactors DOE facilities is 0.12 rem per year. The average lifetime accumulated radiation exposure from radiation associated with the Naval Nuclear Propulsion Program for the 141,000 personnel who have been monitored at the DOE Naval Reactors facilities is about 0.35 rem (NNPP 1994c). This corresponds to the likelihood of a cancer fatality of 1 in 7142.

Naval Reactors policy on occupational exposure from ingested or inhaled radioactivity is to prevent significant radiation exposure to personnel from internal radioactivity. The limits invoked to achieve this objective are one-tenth of the levels allowed by federal regulations for radiation workers. Since 1972 as a result of this policy, no one has received more than one-tenth the federal annual occupational exposure limit from internal radiation exposure caused by radioactivity associated with work at the DOE Naval Reactors facilities.

For work operations involving the potential for spreading radioactive contamination, containments are used to prevent personnel contamination or generation of airborne radioactivity. The controls for contamination are so strict that precautions sometimes have had to be taken to prevent tracking contamination from fallout and natural sources into radiological areas because the contamination control limits used in these areas were well below the levels of fallout and natural contamination occurring outside in the general public areas. A basic requirement of contamination control is monitoring all personnel leaving any area where radioactive contamination could possibly occur. Workers are trained to survey themselves (i.e., frisk), and their performance is checked by radiological control personnel. Frisking of the entire body is required, normally using sensitive hand-held survey instruments. Major work facilities are equipped with portable monitors, which are used in lieu of hand-held friskers. These stringent controls to protect the workers and the public from contamination have proven effective in the past.

In 1991, researchers from Johns Hopkins University, Baltimore, Maryland, completed a very comprehensive epidemiological study of the health of workers at the six naval shipyards and two private shipyards that service the Navy's nuclear-powered ships (Matanoski 1991). This independent study evaluated a population of 70,730 civilian workers over a period from 1957, beginning with the first overhaul of the first nuclear-powered submarine, USS NAUTILUS, through 1981, to determine whether there was an excess risk of leukemia or other cancers associated with exposure to low levels of gamma radiation. This study is also of particular relevance to workers at the Naval Reactors prototypes because the type of radioactivity, level of exposure, and method of radiological controls at these shipyards are similar to the Naval Reactors prototypes.

The Johns Hopkins study found no evidence to conclude that the health of people involved in work on U.S. naval nuclear-powered ships has been adversely affected by exposure to low levels of radiation incidental to this work. The average annual radiation exposure for these shipyard workers is about two times higher than the exposure received by personnel assigned to Naval Reactors nuclear propulsion prototype sites. Additional studies are planned to investigate the observations and update the shipyard study with data beyond 1981.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population.
Under the limiting assumption that the same worker is associated with every shipment for the entire historical period, this person would receive a total exposure of 7.5 rem over the approximately 40-year period, or about 0.19 rem per year, which is within DOE standards for occupationally exposed individuals. The radiation exposures to workers correspond to much less than one incident cancer, which means that it is unlikely that there have been any past health impacts due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.5.12.2 Occupational Non-radiological Health and Safety.

In the non-radiological Occupational Safety, Health and Occupational Medicine area, the Navy complies with the Occupational Safety and Health Administration Regulations. The Navy's policy is to maintain a safe and healthful work environment at all naval facilities. Engineered systems and administrative controls are the primary means employed for minimizing potential employee exposure to occupational hazards. If exposures cannot be controlled with engineering or administrative controls, personal protective equipment is used to provide additional protection. Due to the varied nature of work at these facilities, there is a potential for certain employees to be exposed to physical and chemical hazards.
These employees are routinely monitored during work and receive medical surveillance for physical hazards such as exposure to high noise levels or heat stress. In addition, employees are monitored for their exposure to chemical hazards such as organic solvents, lead, asbestos, etc., and where appropriate are placed into medical surveillance programs for these chemical hazards.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact due to the historical shipment of naval spent nuclear fuel over the entire history of such shipments.

4.1.5.12.3 Public Radiological Health and Safety.

The effluent and environmental monitoring results show that the radioactivity in liquid and gaseous effluents from 1992 operations at the Kesselring Site had no measurable effect on background radioactivity levels. Therefore, any radiation exposures from Site operations to off-site individuals were too small to be measured and must be calculated using conservative methods. In accordance with the "Knolls Atomic Power Laboratory Environmental Monitoring Report for Calendar Year 1992" (KAPL 1992), the following estimates were determined: (1) the radiation exposure to the maximally exposed individual in the vicinity of the Site was less than 0.1 mrem, (2) the average exposure to members of the public residing in the 80-kilometer (50-mile) radius assessment area surrounding the Site was less than 0.001 mrem, and (3) the collective exposure to the population residing within 50 miles of the Site was less than 0.1 person-rem.

The hypothetical exposures calculated in Attachment F for the period 1995 through 2035 were adjusted from an annual basis (1995) to the historical basis by multiplying by 40 years (to account for the period of site operations) and by a factor of 1.7 to take into consideration variations in the number of prototypes and operations.

The calculated accumulated exposures through 1995 to the general population within 50 miles of the site (about 1.15 million people) are 3.9 person-rem. To provide perspective, the exposures received due to natural radiation sources through 1995 are approximately 14 million person-rem, based on 0.3 rem per person per year.

The results show that the estimated exposures were less than 0.1 percent of that permitted by the radiation protection standards listed in DOE Order 5400.5 (DOE 1993), and that the estimated exposure to the population residing within 80 kilometers (50 miles) of the Site was less than 0.001 percent of the natural background radiation exposure to the population. In addition, the estimated exposures were less than 1 percent of that permitted by the numerical guide listed in 10CFR50, Appendix I (CFR 1986) for whole-body exposure, demonstrating that exposures are as low as is reasonably achievable. The exposure attributed to radioactive air emissions was less than 1 percent of the EPA standard given in 40CFR61 (CFR 1989).

The collective radiation exposure to the public along travel routes from Kesselring Site shipments of radioactive materials during 1992 was calculated using data given by the NRC in the "Final Environmental Statement of the Transportation of Material by Air and Other Modes" (NUREG 1977). Based on the type and number of shipments made, the collective annual radiation exposure to the public along the transportation routes, including transportation workers, was approximately 1 person-rem. This is less than 0.001 percent of the exposure received by the same population from natural background radiation.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities.

All of the radiation exposures to the general population correspond to much less than one incident cancer, which means that it is unlikely that there has been any past health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.5.12.4 Public Non-radiological Health and Safety.

Liquid effluents from the Kesselring Site are derived from several sources: Site boiler blowdown, sewage treatment plant, cooling tower blowdown and overflow, retention basin discharges, storm water, and site service cooling water. Liquid effluents from the Kesselring Site enter Glowegee Creek through two surface channels (discharges 001 and 002), a submerged drain line from the sewage treatment plant (discharge 003), and a storm water runoff (discharge 004).

With the exception of the sewage treatment plant, intermittent cooling tower blowdowns, and once-through cooling systems that operate continuously, all effluents are released in batches. Control of effluent concentrations is achieved by the analysis of liquid collected from the continuous flow systems and from the collection tanks prior to each release from the batch systems.

A series of gates are located in discharge channels 001, 002, and the lagoon to provide a means to contain effluent if concentrations should ever exceed applicable discharge limits. In addition, continuous pH and temperature monitoring systems are installed in discharge channels 001, 002, and the lagoon. These systems automatically control the discharge gates and provide an alarm if there is ever an out-of-specification pH or temperature level. Periodic samples collected from the effluent channels are analyzed for chemical constituents, and demonstrate compliance with the Site's New York State Department of Environmental Conservation State Pollutant Discharge Elimination System permit.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.1.5.13 Utilities and Energy

4.1.5.13.1 Water Consumption. The Site Service Water System provides the Kesselring Site

with water for operations, fire protection, sanitary, and potable use. The Site uses approximately 512 million gallons of well water per year. The Site is supplied by two pressurized mains from pumps located at the well field. Main and backup chlorination facilities are located at two of the pump locations. Five loops, on site, comprise the central distribution system which is capable of delivering up to 3,800 gallons per minute. Surge capacity for fire fighting and peak usage is provided by two elevated head tanks with a combined capacity of 500,000 gallons.

4.1.5.13.2 Electricity Consumption.

The Kesselring Site is provided with two separate off-site commercial electrical power sources from the Niagara Mohawk Power Company. One source is the 115-kv Transmission Line No. 1 that runs between Spier Falls, New York and Rotterdam, New York. This line is approximately 40 miles long and is tapped at approximately the midpoint to provide service to the Site. The overhead line from the 115-kv tap on Line No. 1 to the Site is 2.4 miles long. The second physically independent commercial source feeding the Site is a 34.5-kv overhead transmission line supplied from a radial system fed from Ballston Spa, New York. The 34.5-kv line is approximately 9.6 miles long. The Site uses 47 thousand megawatt-hours of electricity annually for security, building lighting, and prototype plant support.

4.1.5.13.3 Fuel Consumption.

There is no natural gas used on the Kesselring Site. Number 2 fuel oil is used to fire four Site steam generating boilers for Site heating for which the annual fuel oil consumption averages 640,000 gallons.

4.1.5.13.4 Wastewater Systems and Discharges.

The sewage treatment facility for the Kesselring Site is a third-level treatment facility utilizing the extended aeration/contact stabilization of activated sludge and chemical precipitation of phosphorus followed by sand filtration. This facility meets all federal and New York State standards for sewage treatment. Discharges are controlled in conformance with the terms of a New York State Pollutant Discharge Elimination permit. Waste sludge is stored in a holding tank and is periodically removed by a licensed subcontractor for disposal at a state-approved, off-site disposal area. The treatment plant is automatic and operates unattended. Routine analysis and adjustments are made daily. Approximately 9.125 million gallons of sewage are processed by the Site Sewage Treatment Facility each year.

4.1.5.13.5 Energy Consumption.

The following energy conservation initiatives for the Kesselring Site are scheduled for completion between now and the year 2000:

(1) The shutdown of one prototype plant.
(2) The conversion from fuel oil to natural gas for operating the Site steam heating boilers.
(3) Replacing the existing building lights and windows with modern, more energy efficient systems.
(4) Major building renovations including energy conservation upgrades to various administration and testing facilities.

4.1.5.14 Materials and Waste Management

Operation of the Kesselring Site results in the generation of various types of radioactive materials that require detailed procedures for handling, packaging, transportation, and, if necessary, disposal at a government-operated burial site. Radioactive materials that do not require disposal are handled and transferred in accordance with detailed material control and accountability procedures. Internal reviews are made prior to the shipment of any radioactive materials from the Site to ensure that the material is properly identified, surveyed, and packaged in accordance with federal, state, and local requirements.

Low-level radioactive solid waste material that requires disposal includes filters, metal scrap, resin, rags, paper, and plastic. The volume of waste contaminated with radioactivity that is generated and shipped is minimized through the use of special work procedures that limit the amount of material that becomes contaminated during work on radioactive systems and reactor components. In addition, compressible wastes are compacted in order to further reduce the volume of waste to be buried. Radioactive liquids are solidified prior to shipment. All radioactive wastes are packaged to meet applicable regulations of the Department of Transportation given in 49CFR, Parts 171-175 and 177-178 (CFR 1985). The waste packages also comply with all applicable requirements of the NRC, the DOE, and the burial sites. All shipments of low-level radioactive solid wastes were made by authorized common carriers to government-owned burial sites located outside of New York State. During 1992, approximately 215 cubic meters (281 cubic yards) of routine low-level radioactive waste containing 987 curies were shipped from the Site for burial.

Site operations produce a variety of industrial waste products including sewage treatment plant sludge and effluent, once-through cooling water, chemical wastes, boiler exhaust gases, and other such products typical of a large laboratory facility. All such waste products are controlled in accordance with various permits as required by federal and state laws. Chemically hazardous solids are controlled and disposed of in accordance with the requirements of the Resource Conservation and Recovery Act (RCRA) in accordance with a permit held by the Site and administered by New York State.

All hazardous wastes are transported off-site for disposal at permitted, commercially available, facilities. No treatment (with the exception of exempt simple treatment and elementary neutralization) or disposal occurs at the Kesselring Site. In 1992, the Kesselring Site shipped approximately 15 tons of various hazardous wastes for off-site disposal. In accordance with RCRA, the Site has prepared a hazardous waste minimization plan. The plan requires specific actions to identify and minimize waste-producing operations, compare minimization efforts year to year to demonstrate progress, and establish waste minimization goals. This is accomplished by establishment of strict procurement procedures, substitution of non-hazardous materials where practical, and other similar measures.

Waste which is both radioactive and chemically hazardous is regulated under both the Atomic Energy Act and the RCRA as "mixed waste." Within the Naval Nuclear Propulsion Program, concerted efforts are taken to avoid commingling radioactive and chemically hazardous substances so as to minimize the potential for generation of mixed waste. For example, these efforts include avoiding the use of acetone solvents, lead-based paints, lead shielding in disposal containers, and chemical paint removers. Radioactive wastes, including those containing chemically hazardous substances, are handled in accordance with long-standing Program radiological requirements. Such handling includes solidification to immobilize the radioactivity, separation of the radioactive and chemically hazardous substances, removal of liquids from solids, and other simple techniques. A determination is then made as to whether the resulting waste is hazardous. As a result of Program efforts to avoid the use of chemically hazardous substances in radiological work, Program activities typically generate only a few hundred cubic feet of mixed waste each year. This small amount of mixed waste, along with limited amounts of mixed waste from Program work conducted prior to 1987, will be stored pending the licensing of commercial treatment and disposal facilities.

Sanitary wastewater is processed at a conventional extended aeration treatment plant at the southeast corner of the fenced security area. The treatment train consists of equipment to break down large solids, aeration tanks in which air is bubbled through the waste to provide mixing with activated sludge to reduce biochemical oxygen demand, and a clarifier for the separation of liquids and solids. The treatment plant is effective in reducing biochemical oxygen demand and suspended solids by over 90 percent in the effluent. Discharges are controlled in conformance with the terms of a New York State Pollutant Discharge Elimination System permit held by the Kesselring Site. As the need arises, accumulated sludge is removed from the plant by a New York State licensed subcontractor and disposed of at an approved off-site disposal facility also licensed by New York State.

Non-hazardous wastes are reused and recycled or disposed of off-site. Sanitary wastes such as cafeteria waste, scrap paper, and the like are also disposed of at a licensed off-site facility. No hazardous wastes are being buried in the landfill. Most metal solid waste is accumulated and sold to a scrap salvage vendor.

4.2 IDAHO NATIONAL ENGINEERING LABORATORY

4.2.1 Overview

There are three naval reactor prototype plants at the Idaho National Engineering Laboratory (INEL) at the Naval Reactors Facility (NRF). These plants contain nuclear reactor plants, but they have reached the end of their usefulness and are being placed in layup and safe storage. Dismantlement of each of the prototype plants will be accomplished in the future; however, no specific time has yet been set for this work. Appropriate documentation under the National Environmental Policy Act (NEPA) will be prepared for prototype dismantlement when a specific proposal for these actions has been developed.

Also located at the Naval Reactors Facility is the Expended Core Facility (ECF) to which naval spent nuclear fuel has been shipped for examination since 1957. After examination at the ECF, the spent nuclear fuel is transferred to the Idaho Chemical Processing Plant, also at INEL, for storage. This section provides a brief summary of the INEL affected environment. A detailed description of the affected environment at the INEL is provided in Volume 1, Appendix B and Volume 2, Section 4. The reader should refer to the applicable sections therein for additional information.

4.2.2 Land Use

The INEL site (which has been designated a National Environmental Research Park) occupies approximately 2300 square kilometers (about 890 square miles) of dry, cool desert in southeastern Idaho. Land at the INEL site is currently used for industrial and support operations associated with energy research and waste management activities, grazing, infrastructure, recreational uses, and environmental research. Only about 2 percent of the land is used for facilities and operations. Public access to most facility areas is restricted. Land surrounding the INEL site is primarily used for grazing, mineral and energy production, wildlife management, range land, and recreational uses.

4.2.3 Socioeconomics

INEL plays a substantial role in the regional economy. For fiscal year 1990, INEL directly employed approximately 11,100 personnel, or nearly 12 percent of the total regional employment. The population directly supported by INEL employment was approximately 38,000 persons, or 17 percent of the total regional population. Over 97 percent of INEL employees reside in the region of influence affected by the INEL. The INEL region of influence includes the seven counties surrounding and including the INEL: Bingham, Bonneville, Butte, Clark, Jefferson, Bannock, and Madison counties. Employment in this region experienced an annual average growth rate of approximately 1.3 percent from 1980 to 1991 while the population growth in the same region between 1980 and 1990 was about 0.6 percent per year. Volume 1, Appendix B provides a complete description of the affected environment at the INEL in this category.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the INEL, and are provided in Appendix B to this volume of the Environmental Impact Statement. These data were developed in a manner which ensures that they are consistent with the data on the total population provided in Appendix B.

4.2.4 Cultural Resources

Approximately 4 percent of the INEL has been surveyed for archaeological resources. Over 1500 sites have been identified; however, none are currently on the National Register of Historic Places, but may be placed there after formal evaluation. One structure on the INEL related to nuclear research and development, the Experimental Breeder Reactor I, is on the National Register of Historic Places and is a National Historic Landmark while a number of other reactors and associated buildings are eligible for inclusion. The entire INEL site is culturally important to Native Americans, since they believe the land is sacred. Further information on cultural resources at INEL is provided in Volume 1, Appendix B, Section 4.4 and in Volume 2, Section 4.4.2.

4.2.5 Aesthetic and Scenic Resources

The INEL site is bordered on the north and west by the Bitterroot, Lemhi, and Lost River mountain ranges. Volcanic buttes near the southern boundary of the INEL can be seen from most locations on the site. Most of the area within the INEL site consists of open, undeveloped land. Although many of the site facilities are visible to the public, most facilities are located over 0.5 mile from public roads. The reader should refer to the detailed description of the affected environment in this category at the INEL in Volume 1, Appendix B.

4.2.6 Geology

The INEL site is located on the Eastern Snake River Plain which extends in a broad arc from the Idaho-Oregon border in the west to the Yellowstone Plateau in the east. The resources found within the site are sand, gravel, and pumice.

The Eastern Snake River Plain has low seismicity but is surrounded by an area of high seismicity. A summary of the seismicity at the ECF site is provided in Attachment B.

Volcanic hazards at the INEL site have a low probability of occurrence. Volcanism hazards in the INEL area consist of possible recurrence of silicic volcanism, silicic dome emplacement, and basaltic eruptions. Of these three volcanic hazards, basaltic eruptions have been determined to have the highest expectation of occurrence. The potential for basaltic volcanism that could affect ECF is less than 10-5 per year. The reason that the risk from volcanic hazards at ECF is so low is that the facility is more than 9 miles north of the highest potential source of basaltic eruptions. Because of the viscous nature of basaltic lava flows, they are very slow moving and can be diverted in terrain such as that on the INEL. The potential for silicic volcanism impacting ECF is negligible because the center of silicic volcanism is now located under Yellowstone National Park which is about 125 miles east of ECF. Several small silicic domes were emplaced in the vicinity of INEL in the past 1.5 million years. These silicic domes are about 17 miles south of the Expended Core Facility and would have minimal impact on the site. (Rizzo 1994)

4.2.7 Air Resources

The Eastern Snake River Plain climate exhibits low relative humidity, wide daily temperature swings, and large variations in annual precipitation. The average seasonal temperatures at the INEL site range from -7.3 degrees C (18.8 degrees F) in winter to 18.2 degrees C (64.8 degrees F) in summer. Annual precipitation is light, averaging 22.1 centimeters (8.7 inches). The average annual snowfall is 70.1 centimeters (27.6 inches). Other than thunderstorms, severe weather is uncommon.

The air quality on the INEL site and off-site is generally good and within applicable guidelines. Details of the non-radiological air quality and the radiological air quality are provided in Appendix B of Volume 1.

4.2.8 Water Resources

Surface water features near the INEL site are the Big Lost River, Little Lost River, Birch Creek, and on-site man-made ponds. Water in the rivers does not exceed the applicable drinking water quality standards. The potential for flooding has been assessed. Details on the INEL flood plains can be found in Appendix B and Volume 2.

Groundwater in the area is contained in the Snake River Plain Aquifer. Subsurface water quality is affected by natural water chemistry and contaminants originating at the site. Previous waste discharges to unlined ponds and deep wells have introduced radionuclides, non-radioactive metals, inorganic salts, and organic compounds into the subsurface water. For a complete description of the affected environment in this category, the reader should refer to Volume 1, Appendix B.

4.2.9 Ecological Resources

Vegetation on the INEL site is primarily shrub-steppe vegetation, with sagebrush being the dominant plant. The INEL supports animal communities typical of shrub-steppe vegetation and habitats. Over 270 vertebrate species have been observed on the site. A more thorough treatment of the topic of ecological resources at the INEL is provided in Volume 1, Appendix B. Also presented therein is a description of the threatened and endangered species which include the bald eagle and the peregrine falcon.

4.2.10 Noise

The major sources of noise at the INEL occur primarily in developed operational areas and include various facilities, equipment, and machines. Existing INEL-related noises which might affect the public are those from transporting people and materials to and from the INEL and in-town facilities via buses, trucks, private vehicles, helicopters, and freight trains. In addition, air cargo and business travel of INEL personnel via commercial air transport represent an appreciable fraction of all such travel in and out of regional airports.

4.2.11 Traffic and Transportation

The INEL is surrounded by a system of interstate highways, U.S. highways, state highways, railroads, and airports. The regional railroads include main and branch Union Pacific lines in Southeastern Idaho. The two major airports in Idaho Falls and Pocatello provide passenger and cargo service.

The INEL transportation infrastructure consists of an on-site road system and rail service. There are about 140 kilometers (87 miles) of paved roads, of which 29 kilometers (18 miles) are considered service roads and are closed to the public. The Union Pacific Railroad crosses the southern portion of the INEL and provides rail service to the site. Rail shipments are limited to bulk commodities, spent nuclear fuel, and radioactive materials.

4.2.12 Occupational and Public Health and Safety

4.2.12.1 Occupational Radiological Health and Safety. Radiation exposures to workers at

ECF in recent years have averaged approximately 100 millirem per year, compared to the limit of 5000 millirem per year specified by The Code of Federal Regulations, Title 10, Part 20. The total radiation exposure to workers at ECF makes up about 30% of the occupational exposure to radiation experienced by workers at NRF. Approximately 280 workers at ECF work in radiological areas and are monitored for occupational radiation exposure. The average lifetime accumulated radiation exposure from radiation associated with naval nuclear propulsion plants for the 141,000 personnel who have been monitored at the DOE Naval Reactors facilities including ECF, is about 0.35 rem (NNPP 1994c). This corresponds to the likelihood of a cancer fatality of 1 in 7142.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population.
Under the limiting assumption that the same worker is associated with every shipment for the entire historical period, this person would receive a total exposure of 7.5 rem over the approximately 40-year period, or about 0.19 rem per year, which is within Department of Energy (DOE) standards for occupationally exposed individuals. The radiation exposures to workers correspond to much less than one incident cancer, which means that it is unlikely that there have been any past health impacts due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.2.12.2 Occupational Non-radiological Health and Safety. In the non-radiological Occupational Safety, Health, and Occupational Medicine area, the Navy complies with the Occupational Safety and Health Administration Regulations. The Navy's policy is to maintain a safe and healthful work environment at all naval facilities. Due to the varied nature of work at these facilities, there is a potential for certain employees to be exposed to physical and chemical hazards. These employees are routinely monitored during work and receive medical surveillance for physical hazards such as exposure to high noise levels or heat stress. In addition, employees are monitored for their exposure to chemical hazards such as organic solvents, lead, asbestos, etc., and where appropriate are placed into medical surveillance programs for these chemical hazards.

Operations at ECF have resulted in fewer than 210 days of work lost to injuries in the seven years between 1987 and 1993 out of 736 total lost days of work at NRF during that period. Recordable injuries at ECF represented about 12 percent of the total number of such injuries at NRF during the same period.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. Approximately 0.028 fatalities are estimated as a result of non-radiological sources (vehicle emissions) associated with all historical shipments of spent nuclear fuel. This number includes both the workers and the general public. Since this number is much less than one, it is unlikely that there has been any non-radiological health impact due to the historical shipment of naval spent nuclear fuel over the entire history of such shipments.

Limited quantities of some materials classified as hazardous chemicals are handled at ECF, but the precautions used during the work prevent exposure of the workers to these materials.

4.2.12.3 Public Radiological Health and Safety. The Naval Reactors Facility has from its beginning monitored potential sources of releases of radioactivity to the environment from the NRF site in liquid and airborne effluents. Releases of water containing low levels of radioactivity to various disposal basins, leaching pits, and retention basins were made principally in the 1950s and 1960s. This practice was discontinued in 1979 and the residual activity in the soil from this practice is estimated to be approximately 150 curies, consisting primarily of cesium-137, strontium-90, and cobalt-60. The Naval Reactors Facility maintains a program to monitor these areas to provide assurance that they continue to not present a hazard to the public. Operations at NRF, including ECF, have had no effect on the groundwater of the Snake River Plain Aquifer. Monitoring of the aquifer on the NRF site indicates radioactivity is at or near natural background levels. The comprehensive INEL site radiation monitoring program (Hoff et al. 1992) shows that radiation exposure to persons off-site as a result of all NRF operations is too small to be measured.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. The radiation exposure to the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities. The maximum exposed individual (MEI) is a transportation worker, since these workers are closer to the shipment for a longer time than any member of the general population. The maximum exposure to an individual of the general population is 0.062 rem over the entire historical period, which statistically corresponds to 0.000031 cancer fatalities.

4.2.12.4 Public Non-radiological Health and Safety. Since operations began, NRF has monitored site water and air released from operations at the site to ensure that they meet the requirements of applicable federal and state environmental standards. Results of all effluent monitoring confirm that the operation of NRF has no discernible impact on the environment (WECNRF 1993). Operations at NRF have not caused degradation of the quality of the groundwater of the Snake River Plain Aquifer. Monitoring results indicate no detectable toxic chemicals, solvents, or laboratory chemicals in the groundwater in the vicinity of NRF. Low levels of sodium and chloride (like table salt) used to soften site water and nitrates (which leaked through cracks in the sewage lagoon liners) and discharges to the industrial waste ditch are detectable in the immediate vicinity of NRF at levels below the applicable drinking water standards. No constituent measured in groundwater exceeds applicable drinking water standards.

Attachment A provides a discussion of the calculation of past health impacts associated with all transportation of naval spent nuclear fuel and test specimens. As stated in Section 4.2.12.2, it is unlikely that there has been any non-radiological health impact to the public due to all historical shipments of naval spent nuclear fuel over the entire history of such shipments.

4.2.13 Utilities and Energy

The following discussion briefly describes the current utility and energy usage at INEL. For more detailed information, refer to Volume 1, Appendix B.

Commercial electrical power is supplied to the INEL site by the Idaho Power Company. The water supply for INEL is provided by a system of wells, pumps, and storage tanks which are administered by the DOE. Because of the distance between site facility areas, the water supply systems for each facility are independent of each other. Wastewater systems at most on-site facility areas consist primarily of septic tanks and drain fields, although two areas also have wastewater treatment facilities. The fuels consumed at the site (fuel oil, gasoline, diesel, kerosene, coal, and liquid petroleum gas) are transported to the site by various distributors for storage and use.

4.2.14 Materials and Waste Management

The following discussion briefly describes the current waste disposal practices at the INEL. For more detailed information, refer to Volume 1, Appendix B.

High-level waste is currently in storage at the INEL Idaho Chemical Processing Plant. Liquid waste is blended and then treated by calcination to produce a granular calcine solid.

Transuranic waste is kept in retrievable storage at the Radioactive Waste Management Complex. Although there is no currently available disposal facility, all transuranic wastes are intended to ultimately be retrieved, repackaged, certified, and shipped to the Waste Isolation Pilot Plant for final disposal.

Low-level waste has been stored and disposed of at the Radioactive Waste Management Complex. Most low-level waste is reduced in volume before disposal through incineration, compaction, and sizing at the Waste Experimental Reduction Facility; however, this treatment has been curtailed since 1991 awaiting an operating permit from the State of Idaho. Low-level waste awaiting treatment is stored on asphalt/concrete pads at the Waste Experimental Reduction Facility and in radioactive waste storage containers at the generating facilities.

Most of the mixed low-level waste currently stored at the INEL is alpha-contaminated low-level mixed waste shipped to the INEL for storage and treatment from off-site generators. Currently, only low-level mixed waste from INEL contractors is accepted at INEL for treatment and disposal. All low-level mixed waste generated at INEL is stored at interim storage facilities until treatment systems become available or operational.

Hazardous waste generated at the INEL is not treated or permanently stored at the INEL. It is collected and temporarily stored at the Hazardous Waste Storage Facility, or at temporary accumulation areas, and shipped off-site to permitted treatment, storage, or disposal facilities.

The industrial/commercial solid waste generated at the INEL is disposed of in the INEL Landfill Complex located at the Central Facilities Area. Waste segregation takes place at each INEL facility so recyclable materials do not enter the solid waste stream.

4.3 SAVANNAH RIVER SITE

4.3.1 Overview

As mentioned previously, naval spent nuclear fuel has been shipped to the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) for examination since 1957. One of the alternatives under consideration is to create a facility similar to ECF at or adjacent to the DOE-owned Savannah River Site (SRS) in South Carolina. A detailed description of the environment at the SRS is provided in Volume 1, Appendix C. This section provides a summary of some of the highlights from Volume 1, Appendix C. Therefore, specific source references for information contained in this section are omitted here but can be found in Volume 1, Appendix C.

Two sites have been identified as possible locations for the construction of a full-capability Expended Core Facility. One location for the Savannah River ECF is just to the east of the geographic center of the complex (see Site A on Figure 4.3-1). The other location (Site B) is the unused Barnwell Nuclear Fuel Plant located just outside of the eastern boundary of the present SRS complex. In either case, a separate security area would be established specifically to enclose the Savannah River ECF, with all access controlled by the Naval Reactors Program as has always been the case at the INEL-ECF.

4.3.2 Land Use

The SRS (which has been designated a National Environmental Research Park) occupies an area of approximately 800 square kilometers (310 square miles) in western South Carolina in a generally rural area about 40 kilometers (25 miles) southeast of Augusta, Georgia. Land use on the Savannah River Site can be grouped into three major categories: forest/undeveloped, water/wetlands, and developed facilities. Land use bordering SRS is primarily forest and agricultural. There is also a large amount of open water and non-forested wetlands along the Savannah River Valley. The SRS does not contain any public recreation facilities and only about 5 percent of the land is occupied by constructed facilities.

Figure 4.3-1. Candidate sites for an Expended Core Facility.

4.3.3 Socioeconomics

Approximately 90 percent of the SRS work force lives within the region of influence affected by the SRS. The SRS region of influence includes Aiken, Allendale, Bamberg, and Barnwell Counties in South Carolina, and Columbia and Richmond Counties in Georgia. Employment in this region experienced an annual average growth rate of approximately 5 percent between 1980 and 1990. Over this same time period, the labor force in the six-county region of influence grew approximately 39 percent. Personal income in the region of influence is about $7 billion. Population in the region of influence increased 13 percent from 376,058 in 1980 to 425,607 in 1990. Appendix C of Volume 1 provides a complete description of the affected environment at the SRS in this category.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the SRS, and are provided in Appendix C to this volume of the Environmental Impact Statement. These data were developed in a manner which ensures that they are consistent with the data on the total population provided in Appendix C.

4.3.4 Cultural Resources

Cultural resources on the SRS can be summarized by stating that approximately 60 percent of the SRS area has been examined by the South Carolina Institute of Archaeology, University of South Carolina, in consultation with the South Carolina State Historic Preservation Officer, and more than 850 archaeological sites have been identified. These range in age from Clovis Paleoindian to 1950s farms. Most structures were demolished during initial establishment of the SRS. Appendix C of Volume 1 provides a complete description of the affected environment at the SRS in this category.

4.3.5 Aesthetic and Scenic Resources

The dominant aesthetic setting in the vicinity of the SRS consists mainly of agricultural land and forest, with some limited residential and industrial areas. Because of the distance to the site boundary, the rolling terrain, normally hazy atmospheric conditions, and heavy vegetation, SRS facilities are not generally visible from off the Site. The land on the SRS is heavily wooded, and developed areas occupy only approximately 5 percent of the total land area.

4.3.6 Geology

The SRS is on the Upper Atlantic Coastal Plain of South Carolina, which consists of approximately 200 to 400 meters of sands, clays, and limestones formed millions of years ago. These sediments are underlain by sandstones of Triassic age and older metamorphic and igneous rocks.

There are no known capable faults as defined by the Nuclear Regulatory Commission regulatory guidelines in the SRS region. Therefore, earthquakes capable of producing structural damage are not likely in the vicinity of SRS. Two notable earthquakes have occurred within 320 kilometers (200 miles) of the SRS. The first was a major earthquake in 1886 centered in the Charleston area with an estimated Richter magnitude of 6.8. The second earthquake was the Union County, South Carolina, earthquake of 1913, which had an estimated Richter magnitude of 6.0 and occurred about 160 kilometers (100 miles) from the SRS. Two earthquakes have occurred on the SRS during recent years. One on June 8, 1985, with a local magnitude of 2.6, and the other on August 5, 1988, with a local magnitude of 2.0. Appendix C of Volume 1 provides a complete description of the affected environment at the SRS in this category.

4.3.7 Air Resources

The annual average temperature at the SRS is 17.8 degrees C (64 degrees F); monthly averages range from 7.2 degrees C (45 degrees F) in January to 27.2 degrees C (81 degrees F) in July. Relative humidity readings taken four times per day range from 36 percent in April to 98 percent in August. The average annual precipitation at the SRS is approximately 122 centimeters (48 inches). Precipitation distribution is fairly even throughout the year, with the highest precipitation in the summer and the lowest in autumn. Winter storms in the SRS area occasionally bring strong and gusty surface winds with speeds as high as 32 meters per second (72 miles per hour).

The SRS is in a Class II area in attainment with National Ambient Air Quality Standards (NAAQS) for pollutants, which include sulfur dioxide, nitrogen oxides, particulate matter, lead, ozone (as volatile compounds), and carbon monoxide. The SRS has demonstrated its compliance with the South Carolina Department of Health and Environmental Control regulation R.61-62.5, Standard 8, "Toxic Air Pollutants," which regulates the emission of 257 toxic substances. Appendix C of Volume 1 provides a more detailed description of the affected environment in this category.

4.3.8 Water Resources

The Savannah River bounds the SRS on its southern border for about 32 kilometers (20 miles), approximately 260 kilometers (160 miles) from the Atlantic Ocean. At the SRS, Savannah River flow averages about 283 cubic meters (10,000 cubic feet) per second. Five principal tributaries to the Savannah River are on the SRS: Upper Three Runs Creek, Four Mile Branch Creek, Pen Branch Creek, Steel Creek, and Lower Three Runs Creek. Neither of the sites identified for the Savannah River ECF is located on the 100-year floodplain. Further discussion on the creeks in the SRS as well as the 100-year floodplain is available in Volume 1, Appendix C. Approximately 200 Carolina Bays are scattered across the SRS. Carolina Bays are naturally occurring closed depressions that often hold water. The quality of the water in the Savannah River and the SRS streams is such that on April 24, 1992, the South Carolina Department of Health and Environmental Control changed the classification of these waterways from "Class B waters" to "Freshwaters." This action imposes a more stringent set of water quality standards.

Excellent quality groundwater is abundant in this region of South Carolina from many local aquifers. The main source of recharge to the groundwater is rainfall and the direction of flow in the vadose zone is predominantly downward. In general, the vadose zone thickness ranges from approximately 40 meters (130 feet) in the northernmost part of the SRS to 0 meter where the water table intersects wetlands, streams, or creeks. The groundwater beneath 5 to 10 percent of the SRS has been contaminated by industrial solvents, metals, tritium, or other constituents used or generated on the Site. Appendix C of Volume 1 provides a complete description of the affected environment at the SRS in this category.

4.3.9 Ecological Resources

At the time of acquisition by the U.S. Government, the SRS was approximately two-thirds forested and one-third cropland and pasture. At present, more than 90 percent is forested and an extensive forest management program is conducted by the Savannah River Forest Station. The SRS is an important contributor to the biodiversity of Georgia and South Carolina. Carolina Bays, the Savannah River Swamp, and several relatively intact longleaf pine-wiregrass communities provide important contributions to the diversity of biota of the SRS and of the entire region.

The removal of all human inhabitants in 1951 and the restoration of forest cover since then have provided the wildlife associated with the wetlands of the Savannah River and the pine-dominated sand hills of coastal South Carolina found on the SRS with excellent wildlife habitat. A more thorough treatment of the topic of ecological resources at the SRS is provided in Volume 1, Appendix C. Also presented therein is a description of threatened, endangered, and candidate plant and animal species known to occur or that might occur on the SRS.

4.3.10 Noise

The major noise sources at SRS occur primarily in developed operational areas and include various facilities, equipment, and machines (e.g., cooling towers, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles). Major noise sources outside the operational areas consist primarily of vehicles and railroad operations. Existing SRS-related noise sources of importance to the public are those resulting from the transportation of people and materials to and from the Site. These sources include trucks, private vehicles, helicopters, and freight trains. In addition, a portion of the air cargo and business travel using commercial air transport through the airports at Augusta, Georgia, and Columbia, South Carolina, are attributable to SRS operations. Appendix C of Volume 1 provides a complete description of the affected environment at the SRS in this category.

4.3.11 Traffic and Transportation

The SRS is surrounded by a system of interstate highways, U.S. highways, state highways, and railroads. The regional transportation networks service the four South Carolina counties and two Georgia counties that generate about 90 percent of SRS commuter traffic.

The SRS transportation infrastructure consists of more than 230 kilometers (143 miles) of primary roads, 1,931 kilometers (1,200 miles) of unpaved secondary roads, and 103 kilometers (64 miles) of railroad track. These roads and railroads provide connections among the various SRS facilities and to off-site transportation linkages.

4.3.12 Occupational and Public Health and Safety

The sources of radiation exposure to individuals consist of natural background radiation

from
cosmic, terrestrial, and internal body sources; radiation from medical diagnostic and therapeutic practices; and radiation from man-made sources, including consumer products, industrial products, and nuclear facilities. Programs are in place at the Savannah River Site to protect workers from radiological and non-radiological hazards. These programs help to maintain the doses to workers well
below the regulatory dose limit of 5 rem/year and the DOE Administrative Control Level of
2 rem/year. Appendix C of Volume 1 provides a complete description of the affected environment at
the SRS in this category.

4.3.13 Utilities and Energy

The principal source of water for SRS facilities is the Savannah River, with the remainder supplemented by groundwater wells. The Savannah River Site has its own electric-generating facility,
although it purchases much of the power it uses from the South Carolina Electric and Gas Company.

4.3.14 Materials and Waste Management

The SRS generates high-level radioactive waste, transuranic waste, low-level radioactive waste, hazardous waste, mixed waste, and sanitary waste. DOE treats and stores waste generated from on-site operations at the SRS in waste management facilities. This includes approximately 20,000 cubic meters (700,000 cubic feet) of low-level waste generated annually. SRS packages low-level waste for disposal on the site in accordance with the waste category and its estimated surface dose rate.

Mixed low-level waste contains low-level radioactive materials and hazardous wastes. The SRS mixed waste program consists primarily of providing safe storage until treatment and disposal facilities are available. Appendix C of Volume 1 provides a complete description of the affected environment for this category.

4.4 HANFORD SITE

4.4.1 Overview

As mentioned previously, naval spent nuclear fuel has been shipped to the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) for examination since 1957. An
alternative under consideration to performing spent naval nuclear fuel inspections at the INEL-ECF is
to construct a facility providing similar capabilities at the Hanford Site. Two options for relocating
an alternate ECF at the Hanford Site are to: (1) construct a new ECF between the 200 East and 200
West Areas adjacent to the proposed spent nuclear fuel storage facility, or (2) modify the currently
unused Fuels and Materials Examination Facility (FMEF), located in the 400 Area, to perform ECF operations (see Figure 4.4-1).

This section provides a brief summary of the affected environment at Hanford. A detailed discussion of the Hanford Site affected environment is contained in Volume 1, Appendix A. The reader should refer to the applicable sections therein for additional information.

4.4.2 Land Use

The Hanford Site (which has been designated a National Environmental Research Park) encompasses approximately 1450 square kilometers (560 square miles) and includes several Department of Energy (DOE) operational areas. Most of the site is open, vacant land with only about
6 percent of the land occupied by constructed facilities. Land uses in the surrounding area include
urban and industrial development, irrigated and dry-land farming, and grazing.

The Hanford Site includes some land-use resources that Native Americans have expressed an interest in, regarding the Treaty of 1855. DOE is assisting them in this effort. Details are provided
in Volume 1, Appendix A.

Figure 4.4-1. Hanford Site map. 4.4.3 Socioeconomics

The Hanford Site plays a dominant role in the socioeconomics of the Tri-Cities (Richland, Pasco, and Kennewick) and other parts of Benton and Franklin counties. Approximately 380,000 people live within an 80-kilometer (50-mile) radius of the site. The agricultural community also represents a sizeable part of the local economy. Any major changes in Hanford activity would potentially most affect the Tri-Cities and other areas of Benton and Franklin counties. These areas in particular, but generally the 10 counties surrounding the Hanford Site, constitute the designated region of influence (Volume 1, Appendix A).

Hanford employment accounted for nearly one-quarter of the total non-agricultural jobs in Benton and Franklin counties in 1991. Approximately 93 percent of the direct employment at Hanford consists of residents of Benton and Franklin counties; approximately 81 percent reside in the Tri-Cities area. Population in the two counties increased by about 4 percent from 1980 to 1990.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the Hanford Site, and are provided in Appendix A to this volume of the Environmental Impact Statement. These data were developed in a manner which ensures that they are consistent with the data on the total population provided in Appendix A.

4.4.4 Cultural Resources

The Hanford Site is rich in cultural resources. It contains numerous, well-preserved archaeological sites representing both the prehistoric and historical periods and is still thought of as a homeland by many Native American people. Two single sites and seven archaeological districts are included in the National Register of Historic Places. Management of Hanford's cultural resources follows the Hanford Cultural Management Plan and is conducted by the Hanford Cultural Resources Laboratory of Pacific Northwest Laboratory. DOE is assisting Native Americans who have expressed an interest in renewing their use of some Hanford land-use resources, in accordance with the Treaty of 1855. Details are provided in Volume 1, Appendix A.

4.4.5 Aesthetic and Scenic Resources

The land in the vicinity of the Hanford Site is generally flat. Rattlesnake Mountain forms the western boundary of the Site, and Gable Mountain and Gable Butte are the highest land forms within the Site. Both the Columbia River, flowing across the northern part of the Site and forming the eastern boundary, and the spring-blooming desert flowers provide a source of visual enjoyment to people. The White Bluffs, steep bluffs above the northern boundary of the river in this region, are a striking feature of the landscape.

4.4.6 Geology

The Hanford Site is located within the central part of the Pasco Basin of the Columbia Plateau. Its surface features were formed by catastrophic floods and have undergone little modification since, with the exception of more recently formed sand dunes. The elevation of the Site varies from about 105 meters (345 feet) above mean sea level in the southeast corner to about 245 meters (803 feet) in the northwest. Much of the Hanford Site is underlain by sand, gravel, and cobble deposits which could have economic value. The major geologic units and a description of them can be found in Volume 1, Appendix A.

Seismicity of the Columbia Plateau is relatively low when compared to other regions of the Pacific Northwest. There are several major volcanoes in the Cascade Range west of the Hanford Site. The nearest is Mount Adams which is about 165 kilometers (102 miles) from the Site. The most active volcano is Mount St. Helens which is about 220 kilometers (136 miles) west-southwest from Hanford.

4.4.7 Air Resources

The Hanford Site is located in a semi-arid region where the climate is mild and dry, with occasional periods of high winds. The summers are generally hot and dry; the winters are relatively cool and mild. Average monthly temperatures at the Hanford Site range from -1.5 degrees C (29.3 degrees F) in January to 24.7 degrees C (76.5 degrees F) in July. The annual average relative humidity is 54 percent and is usually highest in winter (approximately 75 percent) and lower in summer (about 35 percent). The Cascade Mountains west of the Hanford Site greatly influence the local climate by acting as a natural barrier to Pacific Ocean storm systems. This contributes to the Site's relatively low average annual precipitation of 16 centimeters (6.3 inches). This range also serves as a source of cold air drainage which has a considerable effect on the wind regime on the Hanford Site.

Air quality is within federal standards. Details of the non-radiological air quality and the radiological air quality are provided in Appendix A of Volume 1.

Information on severe weather, precipitation extremes, and air dispersion/stagnation characteristics is provided in Volume 1, Appendix A for the Hanford Site. The source of meteorological information used in analytical calculations is provided in Attachment F.

4.4.8 Water Resources

The major surface water features near the Hanford Site are the Columbia and Yakima Rivers. The Columbia River flows through the northern part of the Site at an average annual flow rate of about 3400 cubic meters per second (120,000 cubic feet per second). The Yakima River, which has a low annual flow rate compared to the Columbia River, flows along the southern portion of the Hanford Site at an average annual rate of 104 cubic meters per second (3673 cubic feet per second).
The Hanford ECF site or the modified FMEF site would not be affected by a 500-year flood of the Columbia River. Details are provided in Volume 1, Appendix A.

The State of Washington Department of Ecology classifies the Columbia River as Class A (excellent) from the Grand Coulee Dam, past the Hanford Site, to the mouth of the river at the Pacific Ocean. The Hanford Reach of the Columbia River is the last free-flowing portion of the river in the United States. Radiological monitoring shows low levels of radionuclides in the Columbia River. Hydrogen-3 (tritium), iodine-129, and uranium are found in slightly higher concentrations downstream of the Hanford Site than upstream, but are well below concentration guidelines established by the DOE and the U.S. Environmental Protection Agency (EPA) drinking water standards.

Groundwater quality on the Hanford Site has been affected by defense-related activities to produce nuclear materials. While most of the Site does not have contaminated groundwater, large underlying areas of the Site do have elevated levels of both radiological and non-radiological constituents.
The liquid effluents, discharged into the ground, have carried with them certain radionuclides and chemicals which move through the soil column at varying rates, eventually entering the groundwater forming plumes of contamination. Groundwater monitoring is conducted on an annual basis. Results indicate that concentrations of various radionuclides in some wells in or near operating areas exceeded drinking water standards. Tritium continues to slowly migrate with the groundwater flow where it enters the Columbia River. Nitrate concentrations also exceeded drinking water standards at various locations around the Hanford Site. More information on groundwater quality can be found in Volume 1, Appendix A.

4.4.9 Ecological Resources

The Hanford Site is a relatively large, undisturbed area of shrub-steppe vegetation that contains numerous plant and animal species adapted to the region's semi-arid environment. The vegetation at the Hanford Site consists of 10 major kinds of plant communities, with cheatgrass the dominant plant on fields. More than 300 species of insects, 12 species of amphibians and reptiles, and about 39 species of mammals are found on the Hanford Site. The horned-lark and western meadowlark are the most abundant nesting birds. A more thorough treatment of the topic of ecological resources at the Hanford Site is provided in Volume 1, Appendix A. Also presented therein is a description of threatened and endangered species. These include four species of plants, six species of birds, and one species each of mammals and insects.

4.4.10 Noise

Hanford measurements of the propagation of noise have been concerned primarily with occupational noise at work sites. Environmental noise levels have not been extensively evaluated because of the remoteness of most Hanford activities. Most industrial facilities on the Hanford Site are located far enough away from the site boundary that noise levels at the boundary are not measurable or are barely distinguishable from background noise levels. Some field activities, such as well drilling and sampling, have the potential for producing noise in the field apart from major permanent facilities that could be disruptive to wildlife.

4.4.11 Traffic and Transportation

The area is serviced by a system of interstate highways and state roads. Personnel and most material shipments are transported by road. Bulk materials or large items are shipped by barge. Rail transportation is used to move irradiated fuel and certain high-level radioactive solid wastes and to transport equipment and materials.

Hanford's on-site road network consists of rural arterial routes. Only 65 of the 288 miles of paved roads at Hanford are accessible to the public. On-site rail transport is provided by a short-line railroad owned and operated by the DOE. This line connects just south of the Yakima River with the Union Pacific, which in turn interchanges with the Washington Central and Burlington Northern Railroads at Kennewick. The Hanford Site infrequently uses the Port of Benton dock facilities on the Columbia River for off-loading large shipments. Overland trailers are then used to transport those shipments to the Site.

4.4.12 Occupational and Public Health and Safety

Programs are in place at the Hanford Site to protect workers from radiological and non-radiological hazards. In 1989, about 9000 individuals were monitored at the Hanford Site, of which 6000 received a measurable radiation dose equivalent to an average annual dose of 0.1 rem per person. This is well below the regulatory dose limit of 5 rem per year and the DOE administrative control level of 2 rem per year.

Doses and exposures to the public from airborne releases at the Hanford Site are calculated and reported annually. It is calculated that the maximally exposed off-site individual would receive an exposure of 0.02 millirem per year of radioactive emissions, while the average exposure to the public would be 0.002 millirem per year.

4.4.13 Utilities and Energy

The principal source of water in the Tri-Cities and at the Hanford Site is the Columbia River. Electrical power for the Hanford Site is purchased wholesale from the Bonneville Power Administration, a federal power marketing agency. Hydropower, and to a lesser extent coal and nuclear power, are used to generate the region's electricity.

4.4.14 Materials and Waste Management

The Hanford Site contains several waste areas associated with nuclear defense-related materials. These areas are scheduled for remediation in accordance with the Hanford Federal Facility Agreement and Consent Order.

The following discussion briefly describes the current waste disposal practices at the Hanford Site. For more detailed information, and information on historical waste disposal practices, refer to Volume 1, Appendix A.

Wastes at the Hanford Site are generated by both facility operations and environmental restoration activities. Non-dangerous solid waste is disposed of at the Solid Waste Landfill located in the 200 Area. The existing capacity of this landfill will be expended by the mid to late 1990s. Newly generated non-radioactive hazardous waste is shipped off-site for treatment, recycling, recovery, and/or disposal.

Low-level mixed waste contains low-level radioactive materials and hazardous wastes. These wastes are either stored until technology is modified or verified to allow treatment or are evaporated through an evaporator. Solid low-level radioactive waste is placed in unlined, shallow trenches at the 200 Area Low-Level Waste Burial Grounds. Hanford also receives low-level waste from off-site generators for disposal. High-level wastes are being stored in single-shell and double-shell tanks until a treatment facility is constructed to allow treatment and disposal of the waste.

Transuranic waste is stored in above-ground storage facilities in the Hanford Central Waste Complex and Transuranic Waste Storage and Assay Facility. This waste is planned to be shipped to the Waste Isolation Pilot Plant in New Mexico for final disposal.

4.5 OAK RIDGE RESERVATION

4.5.1 Overview

As mentioned previously, naval spent nuclear fuel has been shipped to the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) for examination since 1957. An alternative to continuing naval spent nuclear fuel operations at the ECF at INEL is to construct a facility providing similar capabilities at the Oak Ridge Reservation (ORR). The new ECF would be sited near the K-25 Site which is located on the western portion of the ORR (see Figure 4.5-1). A separate security area would be established specifically to enclose the ECF at ORR, with all access controlled by the Naval Reactors Program as has always been the case at the ECF at INEL.

This section provides a brief summary of the affected environment at the Oak Ridge Reservation. A detailed discussion of the ORR affected environment is contained in Volume 1, Appendix F. The reader should refer to the applicable sections of that appendix for additional information and for information source references.

4.5.2 Land Use

The ORR is located on approximately 54 square miles (140 square kilometers) of federal land within Anderson and Roane Counties, Tennessee, with Knox and Loudon Counties to the south. Most of the ORR is located within the corporate limits of the city of Oak Ridge. Knoxville is located approximately 30 miles (48 kilometers) southeast of Oak Ridge and is the largest city in the area. The ORR includes three intensively developed industrial areas at the Y-12 Plant, the Oak Ridge National Laboratory (ORNL), and the K-25 Site separated by mostly undeveloped forest land. Surrounding land uses include residential, commercial, public, and industrial areas in the city of Oak Ridge and rural areas characterized by residences, small farms, forest, and pastures. Approximately 21 square miles (54 square kilometers) of undeveloped ORR land have been designated as a National Environmental Research Park.

Figure 4.5-1. Oak Ridge Reservation site map.

4.5.3 Socioeconomics

Socioeconomic parameters are defined in this Environmental Impact Statement for a region of influence encompassing Anderson, Knox, Roane, and Loudon Counties, Tennessee. About 92 percent of ORR employees presently live in this region of influence. The employment level at the ORR in 1990 was 17,082 persons. The 1990 population of 489,230 in the region of influence is expected to increase at less than 1 percent annually through the year 2004, to 538,820 people. The housing stock, with a 1990 vacancy rate of 1.5 percent, is expected to grow in proportion to the population.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the ORR, and are provided in Appendix F to this volume of the Environmental Impact Statement. These data were developed in a manner which ensures that they are consistent with the data on the total population provided in Appendix F.

4.5.4 Cultural Resources

A cultural resources survey conducted in 1975 did not identify any cultural resources on the proposed Oak Ridge ECF site. Therefore, no prehistoric or historic resources are expected to be located on the proposed Oak Ridge ECF site. There are no known Native American resources on the proposed site of the Oak Ridge ECF. Further discussion is provided in Appendix F of Volume 1.

4.5.5 Aesthetic and Scenic Resources

The view on and near the ORR consists mainly of rural land. Views are limited by hilly terrain, forest cover, and frequent haziness. The three main developed areas at the Y-12 Plant, ORNL, and K-25 Site have low vulnerability to visual impacts (visual sensitivity); undeveloped ORR lands range from low to moderate visual sensitivity.

4.5.6 Geology

The ORR lies within the western portion of the Valley and Ridge Province, near the boundary with the Cumberland Plateau. The Valley and Ridge Province is characterized by numerous linear ridges and valleys which extend northeast-southwest. Local geology is characterized by sedimentary rocks of Cambrian and Ordovician age. Areas of the ORR underlain by limestones and dolomites contain sinkholes and caves ("karst" geology). Soils generally belong to the Ultisol order, characterized as moderately acidic soils that exhibit severe mineral weathering with precipitation of iron oxides. No prime or unique farmlands are located on the ORR.

From 1811 to 1975, five earthquakes or earthquake series with Modified Mercalli Intensity (MMI) of V to VI have affected the ORR area. No MMI VII earthquakes have been recorded in the ORR during this period. An MMI VII earthquake does not typically cause severe damage, but rather causes breaking of weak chimneys at the roof line, cracks in masonry, and the falling of plaster, loose bricks, and stones. MMI VII earthquakes generally occur one order of magnitude less frequently than MMI V to VI earthquakes. Seismic records indicate that the ORR is located in a region of moderate seismic activity having an average of one to two earthquakes per year with seismic activity occurring in bursts followed by long periods of no activity. No deformation of recent surface deposits has been detected, and seismic shocks from the surrounding, more seismically active areas are dissipated by distance from the epicenter. The ORR is located in Uniform Building Code Zone 2A.

4.5.7 Air Resources

Climate at the ORR is characterized by moderate temperatures (low daily average of 36.7yF in January and high daily average of 76.6yF in July), ample precipitation (annual average of 54.0 inches), and frequent summer thunderstorms. Although infrequently subjected to tornadoes, the ORR did experience a tornado from a severe thunderstorm in February 1993. The tornado passed the Y-12 Plant and ended just north of Knoxville. Wind speeds along the tornado path ranged from 40 miles per hour (18 meters per second) to nearly 130 miles per hour (58 meters per second). As of 1991, the areas within the Air Quality Control Region which includes the ORR were designated as in attainment with respect to all National Ambient Air Quality Standards. Great Smoky Mountains National Park, a Prevention of Significant Deterioration Class I area, is located roughly 30 miles to the southeast. The estimated 50-year effective dose equivalent to any member of the public due to airborne radiological emissions from the ORR is approximately 3.3 millirem. This level is well under regulatory limits.

4.5.8 Water Resources

The ORR is drained by the Clinch River and its network of tributaries. The Clinch River, a tributary of the Tennessee River, extends roughly 350 miles and drains roughly 4,410 square miles. The section of the river bordering the ORR is impounded by Melton Hill Dam and is a navigable component of the inland waterway system. The average discharge from Melton Hill Dam between 1963 and 1979 was 150 cubic meters (5,300 cubic feet) per second. The Clinch River is the principal source of water withdrawn to meet operational demands on the ORR. The only groundwater beneath the ORR suitable for withdrawal is found in the Knox Aquifer, but withdrawals are few due to the abundance of surface water. Concentrations of radiological and non-radiological contaminants above applicable water standards have been observed at a number of groundwater monitoring wells within the ORR. Such concentrations are probably a result of past waste disposal practices (such as the discharge of radioactive material to ponds and impoundments). However, data indicate that generally the contamination remains close to the source. Further discussion concerning the water quality at ORR is provided in Appendix F of Volume 1.

4.5.9 Ecological Resources

Most undeveloped land on the ORR supports forest, including naturally established second growth forest and pine plantations that have been established on former agricultural lands. Aquatic habitats on the ORR include tailwaters, impoundments, reservoir embayments, large streams, small perennial streams, and wetlands. Wetlands on the ORR include shallow embayments on the Clinch River impoundments, narrow strips of forested wetlands along groundwater seeps and creeks, and abandoned farm ponds. Twenty-five plant and animal species known to be present on the ORR are listed by the Tennessee Department of Environment and Conservation as either endangered, threatened, or of special concern.

4.5.10 Noise

Noise from the operation of industrial facilities and equipment on the ORR is primarily limited to the developed areas at the Y-12 Plant, ORNL, and K-25 Site. Noise from other parts of the ORR is generally limited to vehicular and rail traffic. Noise at the ORR boundary is generally indistinguishable from background noise.

4.5.11 Traffic and Transportation

Segments of some arterial roads in the vicinity of the ORR operate close to design capacity at certain times. Several arterial roads that are open to the public traverse ORR lands. The Clinch River is a navigable component of the inland waterway system but primarily serves only recreational boaters. Airports in the vicinity of the ORR include the McGhee Tyson Airport in Knoxville and numerous smaller private airfields.

4.5.12 Occupational and Public Health and Safety

Health impacts to the public are minimal due to administrative and design controls at ORR facilities that keep releases of radioactive or otherwise hazardous materials to the environment in compliance with applicable regulatory standards. Occupational doses to persons working at ORR facilities also fall within regulatory limits. Refer to Appendix F of this volume for detailed information in this area.

4.5.13 Utilities and Energy

The Clinch River and Melton Hill Reservoirs provide all water resources to the ORR and the city of Oak Ridge through two pumping stations. The ORR uses an average of 69.3 million liters (18.3 million gallons) per day. Total potable water capacity available to the ORR is 152 million liters (40.2 million gallons) per day, obtained through the K-25 and Y-12 treatment plants. Electric power is provided to the ORR by the Tennessee Valley Authority. The current ORR power demand is approximately 115 megawatts, while the connected capacity of ORR facilities is approximately 920 megawatts. The average usage of natural gas at the ORR in 1994 was 3.6 billion Btu per day, compared to a contractual capacity of 7.6 billion Btu per day.

4.5.14 Materials and Waste Management

Each of the three main areas of the ORR is responsible for its own air and wastewater discharges and the associated treatment facilities. Non-radioactive hazardous wastes are also handled by each area, typically by shipment to off-site commercial treatment or disposal enterprises. Facilities for managing radioactive wastes, radioactive mixed wastes, and sanitary and industrial wastes generally involve more than one of the areas or involve land/facilities outside the area boundaries. Solid sanitary and industrial wastes are disposed of on the ORR. Most radioactive and mixed wastes are stored on-site pending future disposal actions. The Toxic Substance Control Act Incinerator, located at the K-25 Site, is used to incinerate uranium-contaminated polychlorinated biphenyl wastes and other mixed wastes.

4.6 NEVADA TEST SITE

4.6.1 Overview

As mentioned previously, naval spent nuclear fuel has been shipped to the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) for examination since 1957. Two of the alternatives under consideration result in the creation of a facility similar to ECF at the DOE-owned Nevada Test Site (NTS) in Nevada. A detailed description of the environment at the NTS is provided in Volume 1, Appendix F. This section provides a summary of some of the highlights from that volume. Therefore, specific source references for information contained in this section are omitted here but can be found in Volume 1, Appendix F.

A site has been identified as a possible location for the construction of a full-capability ECF at the Nevada Test Site. The potential location for the Nevada ECF is in Area 5 in the southeast section of the NTS, adjacent to Mercury Highway and south of the NFS High Explosive Assembly/ Disassembly Unit (see Figure 4.6-1). A separate security area would be established specifically to enclose the Nevada Test Site ECF, with all access controlled by the Naval Reactors Program as has always been the case at the Idaho ECF. This would place the Nevada ECF in close proximity to the location being proposed under one of the Centralization alternatives for construction and operation of an interim spent nuclear fuel storage facility.

4.6.2 Land Use

The NTS occupies an area of approximately 3,500 square kilometers (1,350 square miles) in southern Nevada in a remote area about 104 kilometers (65 miles) northwest of Las Vegas, Nevada. The southern two-thirds of the NTS is dominated by three large valleys or basins: Yucca, Frenchman, and Jackass flats. Mountain ridges and hills rise above gradually sloping stream-deposited soil fans, enclosing these basins. The northern and northwestern sections of the NTS are dominated by Pahute Mesa and Ranier Mesa. The NTS does not contain any public recreation facilities and only a very small percentage of the land is occupied by constructed facilities. The NTS is almost entirely surrounded by other federally owned lands which buffer it from lands open to the public. The NTS is Figure 4.6-1. Candidate site for an Expended Core Facility at the Nevada Test Site. bordered by the Nellis Air Force Range on the north, east, and west, and by the Bureau of Land Management on the south and southwest.

4.6.3 Socioeconomics

Socioeconomic parameters defined in this Environmental Impact Statement are for a two-county region of influence encompassing Clark and Nye Counties, Nevada. Ninety-eight percent of NTS employees live in Clark County (88 percent) or Nye County (10 percent). Economic conditions have continued to improve in Southern Nevada since the mid-1980s. Economic growth has been accelerated relative to the national trends because of the expansion in hotel and gaming markets. Appendix F of Volume 1 provides a complete description of the affected environment at the NTS in this category.

Executive Order 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," requires federal agencies to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs and activities on minority and low-income populations. An adverse environmental impact is a deleterious environmental impact determined to be unacceptable or above generally accepted norms. A disproportionately high impact refers to an impact (or risk of an impact) in a low-income or minority community that significantly exceeds that on the larger community. Data available from the U. S. Census of 1990 have been used to develop information on the locations of minority and low-income populations within approximately 50 miles of the NTS, and are provided in Appendix F to this volume of the Environmental Impact Statement. These data were developed in a manner which ensures that they are consistent with the data on the total population provided in Appendix F.

4.6.4 Cultural Resources

People have inhabited the NTS site for approximately 12,000 years. The area of the NTS was inhabited by Shoshone and Southern Paiute Native American tribes prior to European settlement. These tribes are known to be affiliated with sites located in the northern portions of the NTS including the Pahute and Rainier Mesas. No prehistoric or historic resources are expected to be located on the proposed site for the ECF facilities. Also, there are no areas contained in the site that are subject to Native American Treaty rights. Appendix F of Volume 1 provides a complete description of the affected environment at the NTS in this category.

4.6.5 Aesthetic and Scenic Resources

The view across the NTS comprises a mixture of open desert, mountain ranges, and industrial features. Areas on and surrounding the NTS are generally of low to moderate vulnerability to visual impact (visual sensitivity). Appendix F of Volume 1 provides a more complete description of the affected environment at the NTS in this category.

4.6.6 Geology

The NTS lies in the southern part of the Great Basin Section of the Basin and Range Physiographic Province. Local geology is characterized by sediment-filled topographically closed valleys surrounded by ranges composed of sedimentary rocks and compacted volcanic ash and lava. Appendix F of Volume 1 provides a complete description of the affected environment at the NTS in this category.

4.6.7 Air Resources

The climate at lower elevations at the NTS is characterized by bright sunlight, limited precipitation, low relative humidity, and large daily temperature ranges. Climatological parameters change markedly at higher elevations. In Pahute Mesa at an elevation of 2,000 meters (6,560 feet) above mean sea level, the average daily maximum/minimum temperatures are 4.4yC/2.2yC (40yF/28yF) in January and 26.7yC/16.7yC (80yF/62yF) in July. At Yucca Flat, at an elevation of 1,200 meters (3,920 feet) above mean sea level, the average daily maximum/minimum temperatures are 10.6yC/-6.1yC (51yF/21yF) in January and 35.6yC/13.9y- C (96yF/57yF) in July.

The NTS is located in an attainment area for all criteria pollutants, and air quality in the region presently meets all applicable federal and Nevada regulations. For all activities on the NTS, the estimated effective dose equivalent to any member of the public from all airborne radionuclide emissions is approximately 0.01 millirem per year, which is well under regulatory limits.

4.6.8 Water Resources

Perennial surface water in the vicinity of the NTS is mostly limited to widely scattered springs, short river reaches, and playas (seasonally inundated lakes). Intermittent surface water bodies include ephemeral streams which briefly flow following heavy rainfall and playa lakes which contain standing water for brief periods following storms. Localized flash floods following rare heavy rainfalls can be destructive. Aquifers underlying the NTS are generally deep and between 660 and 1640 feet. Due to the scarcity of surface water, groundwater is the principal water source for NTS activities and surrounding communities. Appendix F of Volume 1 provides a complete description of the affected environment at the NTS in the general category of water resources, including both surface water and groundwater.

4.6.9 Ecological Resources

The NTS lies in an ecological transition area between the Mojave and Great Basin deserts. Terrestrial habitats on the NTS comprise desert scrub-shrub plant communities and a mountain, hill, and mesa community dominated by pinion pine and juniper. Aquatic habitats and wetlands on the NTS are limited to widely scattered springs, ephemeral stream channels, and playa lakes. Twenty-five federally and state listed threatened, endangered, or other special status species have been identified on or near the NTS. Of particular concern is the federally listed (threatened) desert tortoise, which is vulnerable to physical injury from construction and human activities, and the federally listed (endangered) Devils Hole pupfish, which is vulnerable to declining water levels.

4.6.10 Noise

Major noise sources at the NTS occur primarily in developed operational areas and include various facilities, equipment, and machines (e.g., cooling towers, transformers, engines, pumps, boilers, steam vents, paging systems, construction and materials-handling equipment, and vehicles), aircraft operations, and testing. No NTS environmental noise survey data are available. At the boundary, away from most facilities, noise from most sources is barely distinguishable from background noise levels.

4.6.11 Traffic and Transportation

Arterial roads in the vicinity of the NTS, including Nevada Route 375 and U.S. Route 95, generally support free flow of traffic. Airports in the vicinity of the NTS include McCarran International Airport in Las Vegas and numerous smaller private airports. Additional information in this category can be found in Volume 1, Appendix F.

4.6.12 Occupational and Public Health and Safety

Health impacts to the public are minimal due to administrative and design controls at the NTS facilities that keep releases of radioactive or other hazardous materials to the environment in compliance with applicable regulatory standards. Occupational doses to persons working at NTS facilities also fall within regulatory limits. Appendix F of Volume 1 provides a complete description of the affected environment at the NTS in this category.

4.6.13 Utilities and Energy

Water is presently supplied to NTS facilities at a rate of 6139 gallons per minute by 12 active wells that tap underlying groundwater (aquifers). Between 40 and 45 megawatts of electrical power is presently available to the NTS from the Nevada Power Company. Proposed expansion will bring capacity to approximately 200 megawatts.

4.6.14 Materials and Waste Management

Numerous surface and subsurface contamination sites from previously conducted nuclear tests and ancillary operations have been identified on the NTS. Non-radiological contamination on the NTS is minimal because there have been no industrial-type production operations on the NTS.

A "Mixed Waste Management Unit" is located just north of the Radioactive Waste Management Station and will be part of routine disposal operations in the near future. In May 1990, mixed waste disposal operations ceased due to Environmental Protection Agency issuance of the Land Disposal Restrictions of the Resource Conservation and Recovery Act for the Third Thirds Wastes. Active mixed waste disposal operations will commence upon completion of a National Environmental Policy Act documentation and issuance of a State of Nevada Part B permit.

Appendix F of Volume 1 provides additional documentation on materials and waste management practices at the Nevada Test Site.

WASHINGTON

5.1.1.1 Overview of Environmental Impacts

The following sections discuss the major differences in potential environmental consequences associated with the choice of alternatives that include storage of naval spent nuclear fuel and inspection of high priority naval spent nuclear fuel at Puget Sound Naval Shipyard. The environmental consequences associated with storage of naval spent nuclear fuel at Puget Sound Naval Shipyard are based on the estimates of naval spent nuclear fuel that would be stored at Puget Sound Naval Shipyard through the year 2035 and current knowledge of the design features associated with spent fuel storage systems. The review of the environmental consequences associated with these alternatives has shown that the impact on the environment associated with these activities would be very small. There would be no impact to the Puget Sound Naval Shipyard regional environment associated with any alternatives that do not involve the Puget Sound Naval Shipyard.

5.1.1.2 Land Use

Construction of a storage area at Puget Sound Naval Shipyard for temporary naval spent nuclear fuel storage would require a modest change in the current land in use by the shipyard. A description of the alternate storage containers and water pools and approximate storage locations is provided in Attachment D. Attachment C provides a comparison of spent nuclear fuel storage in new water pools versus dry container storage. The shipyard area is already an industrial site; therefore, there would be no impact on land use. No additional land outside the naval complex would be required. The alternative of storing naval spent nuclear fuel in water pools would require that a water pool facility be constructed in the vicinity of the area that is designated for dry container storage or modification of the existing water pool to provide additional space. The water pool would have sufficient capacity to accommodate storage of all spent nuclear fuel expected to be stored at the shipyard.

In addition to the alternative involving storage at naval facilities of spent nuclear fuel generated in the future, the existing water pool facility would be used for the alternative where inspections of high priority naval spent nuclear fuel would be conducted at Puget Sound Naval Shipyard. A description of the Puget Sound Naval Shipyard water pool facility and the inspection operations under the alternative of inspecting high priority spent nuclear fuel at Puget Sound Naval Shipyard are also provided in Attachment D.

Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.1.1.3 Socioeconomics

The calculated number of direct construction and operating jobs that would be required for the 10-year period between 1995 and 2004 for each storage alternative at the shipyard is provided in **Table 5.1.1-1.** Since there would be no naval spent nuclear fuel storage or inspection activities at the shipyard under the 1992/1993 Planning Basis and Centralization alternatives, no additional jobs would be required at the shipyard under these alternatives.

Table 5.1.1-1. Number of construction and operating jobs created at Puget Sound Naval Shipyard for each alternative.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Railcar(1)	1	1	8	1	1	1	1	1	1	1
Immobile Containers on Pads(2)	1	1	1	1	2	6	8	8	8	8
Shipping Containers on Pads (3)	1	1	1	1	2	6	2	2	2	2
Water Pool Storage(2)	16	16	73	113	138	99	106	40	40	40
Water Pool Inspection(3)	0	0	82	123	142	60	60	60	60	60

---

(1) Storage mode under the No Action and Decentralization alternatives.

(2) Storage mode under the Decentralization alternative.
(3) Inspection at Puget Sound would occur under the Decentralization B alternative.

The only discernible socioeconomic consequence of storing naval spent nuclear fuel at Puget Sound Naval Shipyard is that a relatively small number of construction workers (ranging from a few to a maximum of several hundred) would be required for construction of the storage area. The work force would consist of skilled craftsmen and unskilled laborers. This work force would be needed during the storage facility expansion and water pool modification and would be available from within the area.

The operation of the spent fuel storage area using dry storage containers would require additional workers to secure the fuel in the storage area and to support surveillance and monitoring activities. For the alternative involving storing fuel in immobile dry storage containers, about 20 workers would be required to handle the spent nuclear fuel when it is placed into the storage containers. This work force would normally only be needed when fuel is being inserted into the containers. For the alternative involving shipping containers, fewer workers would be needed to handle and secure the containers in the storage area. The operation of a water pool facility for the alternative involving storing naval spent nuclear fuel in a water pool would require approximately 40 additional workers. The operation of a water pool facility for the alternative involving inspection of spent nuclear fuel would require approximately 60 workers. The number required for any of the shipyard and prototype site storage alternatives would be small and is expected to be supplied from either within the existing shipyard work force or from the local work force. Considering that the Department of Defense employs approximately 10,200 civilians at the shipyard, the addition of workers to support the alternatives would have no discernible impact on the local socioeconomic conditions of the Puget Sound Naval Shipyard site and Bremerton area.

For the alternatives where dry storage containers would be manufactured, some additional jobs would be created in the locations where the containers are made. The process of selecting the container manufacturer is subject to federal procurement requirements and would be initiated after the Record of Decision. Consequently, the specific socioeconomic impacts from container fabrication cannot be specified. The net effect of container fabrication would be to create additional jobs and bolster the local economy of the area(s) where containers are made. It is considered unlikely that the selection of the contractor would depend on the alternative storage site selected, so the jobs associated with construction of casks provide no basis for selection of a storage site.

5.1.1.4 Cultural Resources

The action considered would not affect any site that is listed on the National Register of Historic Places (NPS 1991), any known archaeological areas, or any other cultural resources. Therefore, there would be no impacts to cultural resources associated with the alternative of storing or inspecting naval spent nuclear fuel at this location.

None of the alternatives considered would impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.1.1.5 Aesthetic and Scenic Resources

The naval spent nuclear fuel storage area would be located within the Puget Sound Naval Shipyard and would not affect the visual quality of the area since it is compatible with the landscape character of the site. Physical changes to the site resulting from the expansion of a spent nuclear fuel storage area would not alter this industrial setting. There are no particulate air emissions associated with storage of naval spent nuclear fuel and thus no visibility impacts are expected. No aesthetic or scenic resources in the vicinity of the shipyard would be affected by the construction and operation of the storage facility.

5.1.1.6 Geology

The expansion and operation of the naval spent nuclear fuel storage facility at this location is not expected to affect the geologic character or resources of the region. If an alternative were selected which required the storage area to be constructed, the ground would be excavated as necessary to prepare the surface. This would not affect the geologic characteristics of the underlying layers nor the characteristics of the aquifer or vadose zone.

5.1.1.7 Air Resources

5.1.1.7.1 Radiological Consequences.

If the alternative where naval spent fuel would be stored in dry storage containers were to be selected, no airborne radioactivity releases would be expected to occur as a result of normal storage operations. The fuel would be contained such that at least two barriers exist to prevent fission products from becoming airborne. These barriers would retain the spent nuclear fuel in an air-tight containment until it is moved to a permanent storage site and there would be no airborne radioactive material released from routine operations for this method of storage. The only radiation exposure would be direct radiation from the array of filled storage containers. The filled storage containers would be fenced off and shielded if necessary such that there would be no distinguishable effect on the current radiation readings at the site perimeter.

For the alternatives where naval spent nuclear fuel would be stored in a water pool and the alternative where fuel would be inspected in the Puget Sound Naval Shipyard water pool, airborne radioactivity would be emitted beyond current emissions. The airborne releases are expected to be less than the emissions from the Idaho National Engineering Laboratory (INEL) Expended Core Facility (ECF) because the water pool size and the number of inspections performed would be smaller at the shipyard and the shipyard would not conduct the shielded cell operations that are performed at ECF. To conservatively estimate the radiological consequences, airborne releases based on ECF releases from 1991 are used. The radiological source term used and the detailed calculations performed to determine expected normal releases are provided in Attachment F.

The radiation exposures to human beings due to estimated radionuclide releases to the atmosphere plus direct radiation from the stored spent nuclear fuel at the shipyards for both the alternative involving water pool storage and the alternative involving dry storage were calculated as described in Attachment F. Postulated releases were calculated for wet storage of spent nuclear fuel in a water pool plus inspection of naval spent nuclear fuel.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from the stored spent fuel. The population data used to calculate population doses were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F. Estimated exposures to workers were also calculated.

The hypothetical exposures calculated are based on an exposure to the estimated average effluents and the direct radiation exposure for one year from the naval spent nuclear fuel stored at the shipyard. The calculations include the external effective exposure equivalent from the ground deposition, deposition to surface water, and air immersion pathways and the 50-year committed effective exposure equivalent from internal exposure through the ingestion and inhalation pathways. All pathways were considered for persons potentially exposed, except that the ingestion pathway was omitted for the workers because they do not grow their food on-site. Solubilities which would produce the highest calculated exposures were chosen for internal exposure factors. Values for human dietary consumption patterns were taken from "Age Dependent Values of Dietary Intake for Assessing Human Exposures to Environmental Pollutants" (Rupp 1980). The hypothetical exposures calculated can be converted into a risk of fatal cancer or a risk of non-fatal health detriments (e.g., non-fatal cancers, hereditary defects) based on recommendations of the International Commission on

Radiological Protection (ICRP 1991).

Attachment F summarizes the calculated exposures and fatal cancers to the worker, maximally exposed off-site individual (MOI), nearest public access (NPA), and the population from releases of radioactivity and direct radiation exposure in one year for each location and storage mode. Section 3.7 provides a comparison of the annual number of fatal cancers calculated for the general population for each location and alternative.

The number of fatal cancers calculated is so small that there would be essentially no fatal cancers resulting from the storage of naval spent nuclear fuel during the time it could reasonably be expected to continue to be stored. Putting this into perspective, it could be stated that one member of the population might experience a fatal cancer due to incident-free storage of naval spent nuclear fuel at the Puget Sound Naval Shipyard if operations continued for 15,400 years.

5.1.1.7.2 Non-radiological Consequences.

As noted in Attachment F, no increase in non-radioactive airborne emissions would be expected to result from spent nuclear fuel storage or examination facility operations. Storage and examination facility operations would not involve use of carcinogenic toxins, criteria pollutants, or other hazardous or toxic chemicals except that small quantities of industrial cleaning agents and paint thinner may be used for housekeeping and cleanliness control and these would be the same as those already used at the shipyard. Consequently, there would be no impact on ambient air quality as a result of implementing any of the alternatives at the shipyard.

If an alternative were to be selected that required a storage facility to be constructed or renovated, fugitive dust emissions would be expected to result from excavation operations. The quantity of dust generated would be small, consistent with typical excavation activities, and controlled within local requirements for dust control.

5.1.1.8 Water Resources

5.1.1.8.1 Radiological Consequences.

Spent nuclear fuel storage and inspection operations at the shipyard would not result in discharges of radioactivity in liquid effluents during routine operation regardless of the alternative selected for storage or inspection of spent nuclear fuel. The health effect due to fallout of nuclides released to the air onto the surface water is included in the analysis results discussed in Section 5.1.1.7. The air fallout impact is so small that there would be no distinguishable radiation levels in the water.

Puget Sound Naval Shipyard does not reside in the 100 or 500 year floodplain. Consequently, the floodplain would not be impacted by spent naval nuclear fuel storage and examination activities at the shipyard.

5.1.1.8.2 Non-radiological Consequences.

Other than chemicals used to maintain the storage area, no hazardous wastes would be generated by the storage of naval spent nuclear fuel at the shipyard. Any hazardous liquid effluents that may be generated at the storage area would be disposed of at an Environmental Protection Agency approved disposal site.

The only source for liquid discharges from the naval spent nuclear fuel storage operations to the environment consists of storm water runoff which would be consistent with the type of discharges associated with common light industrial facilities and related activities. It can be concluded that there would be no impact to the human environment due to runoff water from the naval spent nuclear fuel storage area.

The increased water usage associated with any alternative would be negligible compared to the existing shipyard demand.

5.1.1.9 Ecological Resources

Construction and operation of a spent fuel storage area would not impact any known habitats for threatened or endangered species and no major changes to the industrial environment are planned. Therefore, no major ecological impacts to the region would result from selection of any of the alternatives.

The conceptual location where naval spent nuclear fuel would be stored is illustrated in Attachment D. This location is within an existing industrial complex and is surrounded by buildings and paved areas. The industrial nature of the shipyard and the fact that the land has already been disturbed from its natural state by earlier activities mean that plant or animal species sensitive to disturbance by human activities would not be expected to be present. Therefore, there would be no ecological impacts associated with construction or operation of a spent nuclear fuel storage area at this location. The radiological controls that are in effect at the shipyard ensure that the radiation levels in the vicinity of the shipyard are maintained at or near natural background. Since these same controls would be applied to spent nuclear fuel activities, no ecological effects due to radioactive material would be expected to occur.

5.1.1.10 Noise

Puget Sound Naval Shipyard is an existing industrial-type environment characterized by noise from truck and automobile traffic; ship loading cranes and related diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related pumping systems for those and other liquids. No ambient noise level increases are expected to occur as a result of any of the alternatives. Therefore, no noise impacts would be expected to occur.

5.1.1.11 Traffic and Transportation

Shipments of radioactive materials in the Naval Nuclear Propulsion Program are required to be made in accordance with applicable regulations of the U. S. Department of Transportation, U.S. Department of Energy, and the U.S. Nuclear Regulatory Commission. The purpose of these regulations is to ensure that shipments of radioactive material are adequately controlled to protect the environment and the health and safety of the general public. These regulations are applicable to all radioactive material shipments and provide requirements for the container design, certification, and identification as applicable for the specific quantity, type, and form of radioactive material being shipped. Naval shipping container design requirements invoke shielding and integrity specifications and meet all regulatory requirements. They provide for testing of container designs, training and qualification of workers who construct containers, and quality control inspections during fabrication to ensure that the containers will meet their design requirements. A detailed description of the shipping containers used for naval spent nuclear fuel shipments is provided in Attachment A. A description of the impacts associated with normal and accident conditions associated with transportation of naval spent nuclear fuel is provided in Attachment A.

5.1.1.11.1 Regional Infrastructure.

The alternatives under consideration are described in Section 3. The No Action alternative or the first variation of the Decentralization alternative would store the naval spent nuclear fuel on-site. This alternative would reduce the number of rail shipments from the shipyard or prototype site compared to the past practice of transporting all naval spent nuclear fuel to INEL. The second variation of the Decentralization alternative would ship about 10 percent of the naval spent nuclear fuel to Puget Sound. This would have some transportation impact, but not as much as transporting all naval spent nuclear fuel off-site. The third Decentralization alternative ships all naval spent nuclear fuel to INEL, examines it, and returns it to the original shipyard or prototype site. This alternative involves more transportation than the previous practice of transporting naval spent nuclear fuel to INEL, since the naval spent nuclear fuel is not returned from INEL to the original site. The 1992/1993 Planning Basis alternative, the Regionalization at INEL alternative, or the Centralization at INEL alternative would involve the same transportation as has been required in the past, namely transportation to INEL and retention there. The Centralization alternative at the Hanford Site would result in more transportation impact than any of the previous alternatives, due to the distances and population distribution between Hanford and the shipyards and prototypes. The Centralization alternative at the Savannah River Site would result in the most transportation impact of naval spent nuclear fuel of any of the alternatives.

5.1.1.11.2 Site Infrastructure.

The alternatives associated with naval spent nuclear fuel storage and inspection at Puget Sound Naval Shipyard would create some small amount of additional site highway traffic because any additional employees needed to operate the water pool facility under the inspection or storage alternatives would need to travel to and from work. This impact is expected to be very small considering the total number of employees at the Puget Sound Naval Shipyard and the fact that the additional workers might be provided from the existing work force. Spent fuel storage and inspection activities would increase the internal traffic in the shipyard in the short-term; however, the total impact on shipyard traffic would not be detectable.

5.1.1.12 Occupational and Public Health and Safety

Detailed analyses of incident-free naval spent nuclear fuel transportation and storage and handling impacts on worker and public health are described in Attachment A (transportation) and Attachment F (storage and inspection). The transportation analysis results, and the storage and handling analysis are summarized separately in the following subsections.

5.1.1.12.1 Incident-free Transportation Occupational and Public Health and Safety.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.1.12.2 Incident-free Occupational and Public Health and Safety During Naval Spent Nuclear Fuel Storage and Handling.

The public health and safety impacts of radioactivity releases and direct radiation from storage of naval spent nuclear fuel were analyzed as discussed in Section 5.1.1.7 and Attachment F. Attachment F summarizes the results of the analysis of radioactivity releases and direct radiation from stored naval spent nuclear fuel. This analysis shows that the exposure to the workers, maximally exposed off-site individual, and nearest public access from stored naval spent nuclear fuel would result in far less than one fatality per year. For perspective, it could be stated that one member of these population groups might experience a fatal cancer due to storage of naval spent nuclear fuel at Puget Sound Naval Shipyard if operations continued for 15,400 years.

Projections of the number of occupational accidents that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

No public or occupational radiological health and safety impacts would be expected to result from naval spent nuclear fuel storage area construction activities since the construction would not involve radioactive work.

Attachment F also discusses toxic chemical issues for naval spent nuclear fuel handling and storage. Attachment F concludes that there would be no additional types or volumes of chemicals required at the shipyards or prototype site for naval spent nuclear fuel storage. Therefore, there is no incident-free non-radiological impact resulting from storage of naval spent nuclear fuel at the shipyards or prototype site.

5.1.1.12.3 Incident-free Occupational and Public Health and Safety Effects on Environmental Justice Due to Naval Spent Nuclear Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the management of naval spent nuclear fuel at the Puget Sound Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the Puget Sound Naval Shipyard do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game since environmental monitoring in the vicinity of this relatively small and restricted site has shown no detectable difference in the amounts of radioactivity present in the environment from levels in similar parts of the region.

To place the impacts on environmental justice in perspective, the risk associated with routine naval spent nuclear fuel management operations under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.1.1.13 Utilities and Energy

If an alternative associated with storage of spent nuclear fuel at Puget Sound Naval Shipyard were to be selected, construction and operation of the storage area would not be expected to require a large expenditure of utilities and energy resources. Construction activities would require quantities of water and electricity typical of any small to medium size construction project. Operation of a dry container spent fuel storage facility would likely require only minimal electricity for security lighting and to support industrial equipment necessary to move spent fuel.

Alternatives associated with water pool storage and inspection would require heating, ventilation, water, and electrical systems suitable for a work environment and to properly filter and exhaust the airborne discharges to the atmosphere. The utility and energy demands and impact would be less than that identified in Section 5.2.13 for operation of ECF (10,000 MWh per year) since the water pool facility at Puget is smaller and the scope of operations would be less.

The amount of utilities and energy expected to be consumed would be a small incremental increase in the total amount of utilities and energy used at the shipyard and would not result in any discernible environmental consequence.

5.1.1.14 Facility and Transportation Accidents

5.1.1.14.1 Facility Accidents. There has never been an accident in the history of the Naval

Nuclear Propulsion Program that resulted in a significant release of radioactivity to the environment or that resulted in radiation exposure to workers in excess of abnormal occurrence limits on exposures as defined by the U.S. Nuclear Regulatory Commission. A description of potential accidents considered and a summary of the accident analyses that were conducted with regard to the inspection and storage of naval spent nuclear fuel are contained in Attachment F.

5.1.1.14.1.1 Radiological Accidents. Section 3.7.3 provides a summary of the impacts

due to the most severe accidents considered for each site. The facility accident with the greatest potential impact at Puget Sound Naval Shipyard involves accidental drainage of the water pool. An accident of this magnitude would result in less than one fatal cancer to the general population over 50 years, as described in Attachment F. The likelihood of such an accident occurring is 1 x 10-5, which is very small. For perspective, an accident such as this would not be expected to occur unless the facility operated for about 100,000 years.

5.1.1.14.1.2 Non-radiological Accidents. As discussed in detail in Attachment F, the

limiting hypothetical non-radiological accident for naval spent nuclear fuel storage in a water pool at a shipyard or prototype location would be a diesel fuel spill and fire. A catastrophic failure of a diesel fuel storage tank that might be used for an emergency diesel generator to provide backup electrical power was postulated to occur, resulting in the spilling of the entire quantity of diesel fuel with a subsequent fire. The fire would generate the following toxic chemicals:

- Carbon monoxide
- Oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide)
- Lead
- Sulfur dioxide.

Measures would be taken to reduce the health impacts of potential releases of toxic materials. These measures would involve controls to protect both workers and the general public. The naval shipyard and prototype sites have emergency planning, emergency preparedness, and emergency response programs in place to protect both workers and the public, and involve established resources such as warning communications, fire departments, and emergency command centers.

The airborne concentrations of the combustion products listed above, resulting from the fire, were calculated at the locations of the on-site individuals, an individual at the site boundary, and the general population within a 50-mile radius of the facility. Detailed results are presented in Attachment F. If the accidental fire that has been hypothesized were to actually occur, the safety measures that would be in place would ensure no adverse health impacts to the general public and minimal health impacts to the workers.

5.1.1.14.2 Transportation Accidents.

Shipments of radioactive materials associated with naval spent nuclear fuel have never resulted in any measurable release of radioactivity to the environment (NNPP 1994a). There have never been any significant accidents involving release of radioactive material during shipment since the Naval Nuclear Propulsion Program began. The effects of potential transportation accidents during the various stages of transportation of naval spent nuclear fuel are presented in Attachment A.

The health effects associated with accidents during shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. Details of the transportation analysis are provided in Attachment A.

5.1.1.14.3 Other Impacts of Accidents.

In addition to the possible human health effects associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives.

The analyses described in Attachment F showed that an area ranging from about 8 acres extending approximately a quarter mile (for an inadvertent criticality accident) to about 110 acres extending approximately 0.9 mile (for a large airplane crashing into a dry storage container) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who live in this area might be evacuated or otherwise experience restrictions in their daily activities for a brief period, and those who work at locations within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure. It should be noted that all of the affected area within approximately a half mile from the spent nuclear fuel facility would be inside the boundaries of the federally owned site.

An accident might result in short-term restrictions on access to a relatively small area, but there would be no enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area impacted would only vary slightly among the alternatives. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with any of the alternatives would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on plant and animal species in the area would also be small for all alternatives considered. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. There are no endangered or threatened species unique to the area surrounding the federally owned site, so an accident would not be expected to result in destruction of any species for any of the alternatives considered. The effects of accidents related to any of the alternatives and any associated cleanup which might be performed would be localized in a small area which extends only a short distance beyond the boundaries of the federally owned site and thus would not be expected to appreciably affect the potential for survival of any species in the area. Based on these considerations, evaluation of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.1.1.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear

Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the Puget Sound Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is because the consequences of any accident would depend on the random conditions in effect at the time an accident occurred, and the wind directions at the Puget Sound Naval Shipyard are highly variable with no strongly dominant direction.

To place the impacts on environmental justice in perspective, the risk associated with accidents caused by naval spent nuclear fuel management under any of the alternatives considered would amount to less than one additional fatality per year for the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.1.1.15 Waste Management

The alternative in which naval spent nuclear fuel is stored at Puget Sound Naval Shipyard would produce limited amounts of solid municipal waste, solid low-level radioactive wastes, and hazardous wastes.
In addition, no transuranic or high-level radioactive wastes would be generated by spent nuclear fuel activities at the site under any alternative. The quantity of industrial wastes generated would be small and most likely consist of industrial cleaning agents of the type normally encountered at the site. Small quantities of sanitary wastes would result from the additional work force but this volume would be small. The wastes produced from the storage of naval spent nuclear fuel would be controlled and minimized in accordance with the existing waste management programs at the shipyard. The amount of additional wastes generated would be minimal compared to the existing baseline and would not cause any adverse impacts to public health and safety and the environment in the vicinity of the shipyard.

5.1.1.16 Cumulative Impacts

5.1.1.16.1 Radiological Cumulative Impacts. Spent nuclear fuel storage and examination at

Puget Sound would not result in discharges of radioactivity in liquid effluents during routine operations regardless of the alternative selected. Therefore, there would be no incremental addition of radioactivity to surface or ground water as a result of normal operations for any alternative. For alternatives involving the storage of spent nuclear fuel in dry storage and shipping containers, no airborne radioactivity emissions are expected, so there would be no cumulative air quality impacts associated with these storage methods. Consequently, the only radiological cumulative impacts that would result from dry storage alternatives would be due to direct radiation exposure from the stored containers of spent nuclear fuel.

For alternatives involving the storage and examination at Puget Sound of naval spent nuclear fuel in water pools, there would be no discernible direct radiation exposure to the public from the fuel elements due to the shielding provided by the water in the pool. Therefore, any cumulative impacts which would result from water pool storage (and examination at Puget Sound) would be primarily due to airborne emissions, and the addition of these emissions would cause an indiscernible change in the emissions in the area (see Section 5.1.1.7). Current operations at the site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

A summary of the cumulative radiological impacts is provided in the following section.

An overview of the historical radiological impacts from naval nuclear operations at the Puget Sound Naval Shipyard and from transportation of naval spent nuclear fuel is provided in Section 4.1.1.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The radiological impacts associated with the alternatives where naval spent nuclear fuel would be inspected or stored at Puget Sound Naval Shipyard are very small and are described in Section 5.1.1.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the population in the vicinity of the Puget Sound Naval Shipyard from all of the alternatives considered would be approximately 5.30 person-rem. This means that there would be much less than one fatal cancer from these operations over the entire 40-year period evaluated. The total exposure to a theoretical maximally exposed off-site individual living at the shipyard boundary for the entire 40-year period would be 7.0 x 10-3 rem due to the alternative resulting in the largest exposure. This maximally exposed off-site individual would have a 3.5 x 10-6 risk of contracting a fatal cancer during his or her lifetime due to storage of spent nuclear fuel. When existing site radiological impacts due to naval nuclear operations are added to the impacts of the most limiting spent nuclear fuel alternative, the exposure to the population would be 6.1 person-rem and to the maximally exposed off-site individual would be 7.6 x 10-3 rem. This still results in much less than one fatal cancer in the population and the risk of the maximally exposed off-site individual contracting a fatal cancer during his or her lifetime is 3.8 x 10-6.

The total exposure related to naval spent nuclear fuel activities to a worker assumed to be working continually 100 meters from the spent nuclear fuel under the alternative resulting in the largest exposure is 0.22 rem accumulated over 40 years. That corresponds to a fatal cancer risk of 8.8 x 10-5 during the worker's lifetime. The exposure to the same worker when existing site radiological impacts due to naval nuclear operations are added to the spent nuclear fuel exposure is 0.222 rem over 40 years which corresponds to a fatal cancer risk of 8.9 x 10-5 during the worker's lifetime. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

Sections 4.1.1.14 and 5.1.1.15 describe the management of low-level radioactive waste and mixed waste at the site. The volume of low-level radioactive wastes which would be generated under the alternatives has not been calculated. However, considering the nature of radiological work that would be associated with spent nuclear fuel storage (and examination) activities, the amount of low-level radioactive waste produced during spent nuclear fuel activities would be much less than 20 percent of the current site generation rate (651 m3 per year). This additional radioactive waste would not introduce any changes to the site's waste management practices. The small amount of additional material involved would not impose any discernible additional stress on the capacity of the radioactive waste burial ground. Therefore, any cumulative impacts associated with the generation and disposal of additional low-level wastes would be very small.

Since no mixed, transuranic, or high-level radioactive wastes would be generated by spent nuclear fuel activities at this site under any alternative, there would be no cumulative impacts associated with these materials.

5.1.1.16.2 Non-radiological Cumulative Impacts.

An overview of the historical non-radiological impacts from naval nuclear operations at the Puget Sound Naval Shipyard and from transportation of naval spent nuclear fuel is provided in Section 4.1.1.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no non-radiological cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The non-radiological impacts associated with the alternative where naval spent nuclear fuel would be inspected or stored at Puget Sound Naval Shipyard are described in Section 5.1.1.12, with the detailed results of analyses provided in Attachment F. As summarized in Section 5.1.1.12, there would be no additional chemicals required at the shipyard for naval spent nuclear fuel storage and therefore no non-radiological impacts from normal operations. Consequently, no cumulative impacts to air quality or water resources would result since the incremental addition of chemicals at the shipyard that might result from naval spent fuel activities would be very small. There are no current environmental problems associated with these materials.

The non-radiological cumulative transportation impacts for the population from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A. The non-radiological impacts associated with the transportation and storage of naval spent nuclear fuel for all of the alternatives considered would be low.

No cumulative land use impacts would be expected to occur as a result of spent nuclear fuel storage and examination at Puget Sound. The land that would be dedicated for this purpose is on existing federal property and situated in an industrial setting which has already been disturbed from its natural state (approximately 327 acres are developed land). The conversion of this space for storage of spent nuclear fuel would not result in the need to disturb undeveloped land or for additional land to be added to the federally owned property in the foreseeable future.

From a socioeconomic perspective, the introduction of naval spent nuclear fuel activities at the site would create a small number of additional jobs and could have a very small cumulative socioeconomic impact. The site currently employs approximately 10,200 civilian personnel. No shipyard employment has been associated with spent nuclear fuel activities in the past since spent nuclear fuel activities have not been conducted at the site. An average of approximately 1 to 100 additional jobs might be added as a result of possible spent nuclear fuel activities in the future. The peak number of additional jobs created at the site in any given year would be approximately 280, which is associated with construction and operation of a water pool facility for storage of spent nuclear fuel and modification of the existing water pool for limited examination of fuel. Considering that the regional labor force consists of approximately 527,000 workers, the additional number of added jobs under any alternative would have little or no discernible socioeconomic impact. These jobs would be filled either from within the existing site work force or from the available regional labor force without discernible effect. There are no foreseeable future projects planned at the site and no known projects planned in the region that would cause the small number of workers involved in naval spent nuclear fuel activities to become an important impact.

The cumulative impacts associated with non-radiological waste management are likewise expected to be small. As stated previously, any industrial wastes generated from naval spent nuclear fuel storage and examination at Puget Sound would be small and limited to industrial cleaning agents of the type normally encountered at the site. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of additional non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of waste.

5.1.1.17 Unavoidable Adverse Effects

There are no discernible unavoidable adverse effects associated with the implementation of any of the alternatives and none which would help to choose among the alternatives.

The alternative in which naval spent nuclear fuel is inspected or stored at the Puget Sound Naval Shipyard would cause the public to be exposed to small amounts of radiation, described in Section 5.1.1.12, and would result in less than one health effect in the entire population surrounding the shipyard. Similarly, continued operation of the storage facility would produce limited amounts of solid municipal waste and solid low-level radioactive waste. These amounts of waste would not produce any major impacts in the vicinity of the Puget Sound Naval Shipyard. There will be no changes to the ecological, cultural, geological, and aesthetic resources due to the implementation of any of the alternatives. There will also be no impact on ambient noise levels.

5.1.1.18 Irreversible and Irretrievable Commitments of Resources

The only irreversible and irretrievable commitment of resources that results from the alternative in which naval spent nuclear fuel would be stored at the shipyard would be the money which would be spent by the federal government to construct the necessary facilities. The total cost of storing spent naval nuclear fuel at the shipyards and prototype ranges from approximately $1.5 billion to $5.7 billion. This cost represents the total cumulative cost over the 40-year period for all of the shipyards and prototype. This cost includes construction costs of the new storage facilities, and, depending on the alternative selected, the operation of a limited examination facility at Puget Sound Naval Shipyard combined with the costs associated with shutting down ECF, or the operational costs of the INEL-ECF. The major expense in the highest cost alternatives is the procurement of shipping containers. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

5.1.2 NORFOLK NAVAL SHIPYARD: PORTSMOUTH, VIRGINIA

5.1.2.1 Overview of Environmental Impacts

The following sections discuss the major differences in potential environmental consequences associated with the choice of alternatives that include storage of naval spent nuclear fuel at Norfolk Naval Shipyard. The environmental consequences associated with storage of naval spent nuclear fuel at Norfolk Naval Shipyard are based on the estimates of naval spent nuclear fuel that would be stored at Norfolk Naval Shipyard through the year 2035 and current knowledge of the design features associated with spent fuel storage containers. The review of the environmental consequences associated with these alternatives has shown that the impact on the environment at Norfolk Naval Shipyard associated with all activities is very small. There would be no impact to the Norfolk Naval Shipyard regional environment associated with any alternatives that do not involve the Norfolk Naval Shipyard.

5.1.2.2 Land Use

Norfolk Naval Shipyard has identified a centrally located area within the controlled industrial area as a potential site for spent nuclear fuel storage. The site is located approximately 1500 feet from the southern branch of the Elizabeth River. Public access to the 900 feet of river nearest the site evaluated is restricted. There are no known existing adverse environmental conditions at this site. The area is already an industrial site; therefore, there would be no impact on land use. The area identified should be sufficient depending on the type of storage mode ultimately chosen. A description of storage containers and water pools and their approximate storage locations is provided in Attachment D. Attachment C provides a comparison of spent nuclear fuel storage in new water pools versus dry container storage.

The alternative of storing naval spent nuclear fuel in water pools would require that a water pool facility be constructed in the vicinity of the area that is designated for dry container storage. The water pool would have sufficient capacity to accommodate storage of all spent nuclear fuel expected to be stored at the shipyard.

No additional land use outside the shipyard would be required.

Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.1.2.3 Socioeconomics

The calculated number of direct construction and operating jobs that would be required for the 10-year period between 1995 and 2004 for each storage alternative at the shipyard is provided in **Table 5.1.2-1.** Since there would be no naval spent nuclear fuel storage or inspection activities at the shipyard under the 1992/1993 Planning Basis and Centralization alternatives, no additional jobs would be required at the shipyard under these alternatives.

Table 5.1.2-1. Number of construction and operating jobs created at Norfolk Naval Shipyard for each alternative.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Railcar(1)	1	1	8	1	1	1	1	1	1	1
Immobile Containers on Pads(2)	1	1	1	1	2	6	8	8	8	8
Shipping Containers on Pads (2)	1	1	1	1	2	6	2	2	2	2
Water Pools(2)	16	16	70	107	132	94	103	40	40	40

---

(1) Storage mode under the No Action and Decentralization alternatives.
(2) Storage mode under the Decentralization alternative.

The only discernible socioeconomic consequence of storing naval spent nuclear fuel at Norfolk Naval Shipyard is that a relatively small number of construction workers (ranging from a few to a maximum of several hundred would be required for construction of the storage area). The work force would consist of skilled craftsmen and unskilled laborers. This work force would be needed during the storage facility construction and would be available from within the area.

The operation of the spent fuel storage area using dry storage containers would require additional workers to support surveillance and monitoring activities. For the alternative involving storing fuel in immobile dry storage containers, about 20 workers would be required to handle the spent nuclear fuel when it is placed into the storage containers. This work force would normally only be needed when fuel is being inserted into the containers. For the alternative involving shipping containers, fewer workers would be needed to handle and secure the containers in the storage area. The operation of a water pool facility for the alternative involving storing naval spent nuclear fuel in a water pool would require approximately 40 additional workers. The number required for any of the shipyard and prototype site storage alternatives would be small and is expected to be supplied from either within the existing shipyard work force or from the local work force. Considering that the Department of Defense employs approximately 8,500 civilians at the shipyard, the addition of workers to support the alternatives would have no discernible impact on the local socioeconomic conditions of the Norfolk Naval Shipyard site.

For the alternatives where dry storage containers would be manufactured, some additional jobs would be created in the locations where the containers are made. The process of selecting the container manufacturer is subject to federal procurement requirements and would be initiated after the Record of Decision. Consequently, the specific socioeconomic impacts from container fabrication cannot be specified. The net effect of container fabrication would be to create additional jobs and bolster the local economy of the area(s) where containers are made. It is considered unlikely that the selection of the contractor would depend on the alternative storage site selected, so the jobs

associated
with construction of casks provide no basis for selection of a storage site.

5.1.2.4 Cultural Resources

The action considered would not affect any site that is listed on the National Register of Historic Places (NPS 1991), any known archaeological areas, or any other cultural resources. Therefore, there would be no impacts to cultural resources associated with the alternative of storing
naval spent nuclear fuel at this location.

None of the alternatives considered would impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.1.2.5 Aesthetic and Scenic Resources

The naval spent nuclear fuel storage area would be located within the Norfolk Naval Shipyard
which is an existing industrial setting and would not affect the visual quality of the area since it is
compatible with the landscape character of the site. Physical changes to the site resulting from the
construction of a spent nuclear fuel storage area would not alter this setting. There are no particulate
air emissions associated with storage of naval spent nuclear fuel and thus no visibility impacts are
expected. No aesthetic or scenic resources in the vicinity of the shipyard would be affected by the
construction and operation of the storage facility.

5.1.2.6 Geology

The construction and operation of the naval spent nuclear fuel storage facility at the Norfolk
Naval Shipyard is not expected to affect the geologic character or resources of the region. If an
alternative were selected which required a storage facility to be constructed, the ground would only be
excavated as necessary to prepare the surface. This would not affect the geological characteristics of the underlying layers nor the characteristics of the aquifer or vadose zone. For the alternative of
storing fuel in a water pool facility, the ground surface would need to be excavated to a depth of
approximately 40 feet. This excavation would not affect the geological characteristics of the area.
Since the Columbia aquifer is at a depth of 3 to 5 feet throughout the shipyard, the hydraulic considerations make a water pool facility more difficult and expensive than an above-ground storage
facility. However, if water pools were selected, all precautions necessary to protect the aquifer would
be taken.

5.1.2.7 Air Resources

5.1.2.7.1 Radiological Consequences.

If the alternative where naval spent fuel would be stored
in dry storage containers were to be selected, no airborne radioactivity releases would be expected to
occur as a result of normal storage operations. The fuel would be contained such that at least two
barriers exist to prevent fission products from becoming airborne. These barriers would retain the
spent nuclear fuel in an air-tight containment until it is moved to a permanent storage site and there

would be no airborne radioactive material released from routine operations for this method of storage. The only radiation exposure would be direct radiation from the array of filled storage containers. The filled storage containers would be fenced off and shielded if necessary such that there would be no distinguishable effect on the current radiation readings at the site perimeter.

For the alternative where naval spent nuclear fuel would be stored in a water pool, airborne radioactivity would be emitted beyond current emissions. The airborne releases for this alternative are expected to be less than the emissions from the Idaho National Engineering Laboratory (INEL) Expended Core Facility (ECF) because the water pool size and the number of inspections performed would be smaller at the shipyard and the shipyard would not conduct the shielded cell operations that are performed at ECF. To conservatively estimate the radiological consequences, airborne releases based on ECF releases from 1991 are used. The radiological source term used and the detailed calculations performed to determine expected normal releases are provided in Attachment F.

The radiation exposures to human beings due to estimated radionuclide releases to the atmosphere plus direct radiation from the stored spent nuclear fuel at the shipyards for both the alternative involving water pool storage and the alternative involving dry storage were calculated as described in Attachment F. Postulated releases were calculated for wet storage of spent nuclear fuel in a water pool plus inspection of naval spent nuclear fuel.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from the stored spent fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F. Estimated exposures to workers were also calculated.

The hypothetical exposures calculated are based on an exposure to the estimated average effluents and the direct radiation exposure for one year from the naval spent nuclear fuel stored at the shipyard. The calculations include the external effective exposure equivalent from the ground deposition, deposition to surface water, and air immersion pathways and the 50-year committed effective exposure equivalent from internal exposure through the ingestion and inhalation pathways. All pathways were considered for persons potentially exposed, except that the ingestion pathway was omitted for the workers because they do not grow their food on-site. Solubilities which would produce the highest calculated exposures were chosen for internal exposure factors. Values for human dietary consumption patterns were taken from "Age Dependent Values of Dietary Intake for Assessing Human Exposures to Environmental Pollutants" (Rupp 1980). The hypothetical exposures calculated can be converted into a risk of fatal cancer or a risk of non-fatal health detriments (e.g., non-fatal cancers, hereditary defects) based on recommendations of the International Commission on Radiological Protection (ICRP 1991).

Attachment F summarizes the calculated exposures and fatal cancers to the worker, maximally exposed off-site individual (MOI), nearest public access (NPA), and the population from airborne releases of radioactivity and direct radiation exposure in one year for each location and storage mode. Section 3.7 provides a comparison of the annual number of fatal cancers calculated for the general population for each location and alternative.

The number of fatal cancers calculated is so small that there would be essentially no fatal cancers resulting from the storage of naval spent nuclear fuel during the time it could reasonably be expected to continue to be stored. Putting this into perspective, it could be stated that one member of the population might experience a fatal cancer due to incident-free storage of naval spent nuclear fuel at the Norfolk Naval Shipyard if operations continued for 7,100 years.

If a water pool facility would be constructed at the Norfolk Naval Shipyard and used for storage of spent nuclear fuel, the airborne emissions from the facility would be less than that identified for the Puget Sound Naval Shipyard because no spent nuclear fuel inspection operations beyond visual examinations would be conducted in the water pools.

5.1.2.7.2 Non-radiological Consequences.

As noted in Attachment F, no increase in non-radioactive airborne emissions would be expected to result from spent nuclear fuel storage facility operations. Storage facility operations would not involve use of carcinogenic toxins, criteria pollutants, or other hazardous or toxic chemicals except for small quantities of industrial cleaning agents and paint thinner that may be used for housekeeping and cleanliness control and these would be the same as those already used at the shipyard. Consequently, there would be no impact on ambient air quality as a result of implementing any of the alternatives at the shipyard.

If an alternative were to be selected that required a storage facility to be constructed or renovated, fugitive dust emissions would be expected to result from excavation operations. The quantity of dust generated would be small, consistent with typical excavation activities, and controlled within local requirements for dust control.

5.1.2.8 Water Resources

5.1.2.8.1 Radiological Consequences.

Spent nuclear fuel storage operations at the shipyard would not result in discharges of radioactivity in liquid effluents during routine operation regardless of the particular alternative chosen for storage of spent nuclear fuel. The health effect due to fallout of nuclides released to the air onto the surface water is included in the analysis results discussed in Section 5.1.2.7. The air fallout impact is so small that there would be no distinguishable radiation levels in the water.

Most of the Norfolk Naval Shipyard, including the location considered for the interim storage of naval spent nuclear fuel, is in the 100-year floodplain. However, the location considered for naval spent nuclear fuel is not in a high-hazard area (as defined by Title 10, Part 1022 of The Code of Federal Regulations for floodplains) which is an area where frequent flooding occurs. Since the majority of the shipyard is already developed and covered with impervious material, construction and operation of a naval spent nuclear fuel storage facility at the shipyard would produce no discernible impacts on the floodplain.

Flooding in the area where shipping and immobile dry storage containers are stored would not result in any adverse environmental consequences. These containers are completely sealed such that no radioactivity would be released from the interior even if they were completely submerged. In addition, the massive nature of these containers prevents them from floating or moving during a flood.

Since the shipyard resides in a floodplain, the design of the facility and equipment would minimize the potential for flooding and damage to the facility. However, in the event a water pool facility would be flooded, the exchange of pool water with the flood waters could occur. As discussed in Attachment F, Section F.1.4.2.1.6.2, the radioactivity concentration in the ECF water pool is below the Nuclear Regulatory Commission limits specified in Title 10, Part 20 of The Code of Federal Regulations for liquid effluent except for Co-60 which is slightly higher (water pools used for storage or examination of naval spent nuclear fuel would be maintained to comparable concentrations). Any release of radioactivity would have to result from the exchange of floodwater with the pool water. This exchange would reduce the level of radioactivity even further. Consequently, no adverse environmental impacts would result from flooding of water pools at naval spent nuclear fuel storage sites.

5.1.2.8.2 Non-radiological Consequences.

Other than chemicals used to maintain the storage area, no hazardous wastes would be generated by the storage of naval spent nuclear fuel at Norfolk Naval Shipyard. Any hazardous liquid effluents that may be generated at the storage area would be disposed of at an Environmental Protection Agency approved disposal site.

The only source for liquid discharges from the naval spent nuclear fuel storage operations to the environment consists of storm water runoff which would be consistent with the type of discharges associated with common light industrial facilities and related activities. It can be concluded that there would be no impact to the human environment due to runoff water from the naval spent nuclear fuel storage area.

The increased water usage under any of the alternatives would be negligible compared to the existing shipyard demand.

5.1.2.9 Ecological Resources

There are no threatened or endangered species known to exist within the shipyard and no major changes to the industrial environment are planned. Therefore, no major ecological impacts to the region would result from selection of any of the alternatives.

The conceptual location where naval spent nuclear fuel would be stored is illustrated in Attachment D. This location is within an existing industrial complex and is surrounded by buildings and paved areas. The industrial nature of the shipyard and the fact that the land has already been disturbed from its natural state by earlier activities mean that plant or animal species sensitive to disturbance by human activities would not be expected to be present. Therefore, there would be no ecological impacts associated with construction or operation of a spent nuclear fuel storage area at this location. The radiological controls that are in effect at the shipyard ensure that the radiation levels in the vicinity of the shipyard are maintained at or near natural background. Since these same controls would be applied to spent nuclear fuel activities, no ecological effects due to radioactive material would be expected to occur.

5.1.2.10 Noise

Norfolk Naval Shipyard is an existing industrial-type environment characterized by noise from truck and automobile traffic; ship loading cranes and related diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related pumping systems for those and other liquids. No ambient noise level increases are expected to occur as a result of any of the alternatives. Therefore, no noise impacts would be expected to occur.

5.1.2.11 Traffic and Transportation

Shipments of radioactive materials in the Naval Nuclear Propulsion Program are required to be made in accordance with applicable regulations of the U. S. Department of Transportation, U.S. Department of Energy, and the U.S. Nuclear Regulatory Commission. The purpose of these regulations is to ensure that shipments of radioactive material are adequately controlled to protect the environment and the health and safety of the general public. These regulations are applicable to all radioactive material shipments and provide requirements for the container design, certification, and identification as applicable for the specific quantity, type, and form of radioactive material being shipped. Naval shipping container design requirements invoke shielding and integrity specifications and meet all regulatory requirements. They provide for testing of container designs, training and qualification of workers who construct containers, and quality control inspections during fabrication to ensure that the containers will meet their design requirements. A detailed description of the shipping containers used for naval spent nuclear fuel shipments is provided in Attachment A. A description of the impacts associated with normal and accident conditions associated with transportation of naval spent nuclear fuel is provided in Attachment A.

5.1.2.11.1 Regional Infrastructure.

The alternatives under consideration are described in Section 3. The No Action alternative or the first variation of the Decentralization alternative would store the naval spent nuclear fuel on-site. This alternative would reduce the number of rail shipments from the shipyard or prototype site compared to the past practice of transporting all naval spent nuclear fuel to INEL. The second variation of the Decentralization alternative would ship about 10 percent of the naval spent nuclear fuel to Puget Sound. This would have some transportation impact, but not as much as transporting all naval spent nuclear fuel off-site. The third Decentralization alternative ships all naval spent nuclear fuel to INEL, examines it, and returns it to the original shipyard or prototype site. This alternative involves more transportation than the previous practice of transporting naval spent nuclear fuel to INEL, since the naval spent nuclear fuel is not returned from INEL to the original site. The 1992/1993 Planning Basis alternative, the Regionalization at INEL alternative, or the Centralization at INEL alternative would involve the same transportation as has been required in the past, namely transportation to INEL and retention there. The Centralization alternative at the Hanford Site would result in more transportation impact than any of the previous alternatives, due to the distances and population distribution between Hanford and the shipyards and prototypes. The Centralization alternative at the Savannah River Site would result in the most transportation impact of naval spent nuclear fuel of any of the alternatives.

5.1.2.11.2 Site Infrastructure.

If the alternative of storing naval spent nuclear fuel at Norfolk Naval Shipyard were to be selected, operation of a naval spent nuclear fuel storage facility would not noticeably affect site highway traffic because any increase in the work force would represent a very small incremental increase in overall traffic to and from the shipyard. Internal traffic in the Norfolk Naval Shipyard would increase in the short-term; however, the total impact on shipyard and surrounding area traffic would be very small.

5.1.2.12 Occupational and Public Health and Safety

Detailed analyses of incident-free naval spent nuclear fuel transportation and storage and handling impacts on worker and public health are described in Attachment A (transportation) and Attachment F (storage and inspection).
The transportation analysis results, and the storage and handling analysis are summarized separately in the following subsections.

5.1.2.12.1 Incident-free Transportation Occupational and Public Health and Safety.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.2.12.2 Incident-free Occupational and Public Health and Safety During Naval Spent Nuclear Fuel Storage and Handling.

The public health and safety impacts of radioactivity releases and direct radiation from storage of naval spent nuclear fuel were analyzed as discussed in Section 5.1.2.7 and Attachment F. Attachment F summarizes the results of the analysis of radioactivity releases and direct radiation from stored naval spent nuclear fuel. This analysis shows that the exposure to the worker, maximally exposed off-site individual, and nearest public access from stored naval spent nuclear fuel would result in far less than one fatality per year. For perspective, it could be stated that one member of these population groups might experience a fatal cancer due to storage of naval spent nuclear fuel at Norfolk Naval Shipyard if operations continued for 7,100 years.

Projections of the number of occupational accidents that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

No public or occupational radiological health and safety impacts would be expected to result from naval spent nuclear fuel storage area construction activities since the construction would not involve radioactive work.

Attachment F also discusses toxic chemical issues for naval spent nuclear fuel handling and storage. Attachment F concludes that there would be no additional types or volumes of chemicals required at the shipyards or prototype site for naval spent nuclear fuel storage. Therefore, there is no incident-free non-radiological impact resulting from storage of naval spent nuclear fuel at the shipyards or prototype site.

5.1.2.12.3 Incident-free Occupational and Public Health and Safety Effects on Environmental Justice Due to Naval Spent Nuclear Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the management of naval spent nuclear fuel at the Norfolk Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the Norfolk Naval Shipyard do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game since environmental monitoring in the vicinity of this relatively small and restricted site has shown no detectable difference in the amounts of radioactivity present in the environment from levels in similar parts of the region.

To place the impacts on environmental justice in perspective, the risk associated with routine naval spent nuclear fuel management operations under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.1.2.13 Utilities and Energy

If an alternative associated with storage of spent nuclear fuel at Norfolk Naval Shipyard were to be selected, construction and operation of the storage facility would not be expected to require a large expenditure of utilities and energy resources. Construction activities would require quantities of water and electricity typical of any small to medium size construction project. Operation of a dry container spent fuel storage facility would likely require only a small amount of electricity for lighting and to support industrial equipment necessary to move spent nuclear fuel. Alternatives associated with water pool storage would require heating, ventilation, water, and electrical systems suitable for a work environment and to properly filter and exhaust the airborne discharges to the atmosphere. The utility and energy demands would be less than those required to operate ECF (10,000 MWh per year) (Section 5.2.13) since the water pool used for spent fuel storage would be smaller and no spent fuel operations beyond visual examinations would be conducted in the water pool.

The amount of utilities and energy expected to be consumed would be a small incremental increase in the total amount of utilities and energy used at the shipyard and would not result in any discernible environmental consequence.

5.1.2.14 Facility and Transportation Accidents

5.1.2.14.1 Facility Accidents. There has never been an accident in the history of the Naval

Nuclear Propulsion Program that resulted in a significant release of radioactivity to the environment or that resulted in radiation exposure to workers in excess of abnormal occurrence limits on exposures as defined by the U.S. Nuclear Regulatory Commission. A description of potential accidents considered and a summary of the accident analyses that were conducted with regards to the storage of naval spent nuclear fuel are contained in Attachment F.

5.1.2.14.1.1 Radiological Accidents. Section 3.7.3 provides a summary of the impacts

due to the most severe accidents considered for each site. The facility accident with the greatest potential impact at Norfolk Naval Shipyard involves an airplane crash. An accident of this magnitude would result in a calculated 16 fatal cancers to the general population over 50 years, as described in Attachment F. The likelihood of such an accident occurring is 1 x 10-6, which is very small. For perspective, an accident such as this would not be expected to occur unless the facility operated for about 1,000,000 years.

5.1.2.14.1.2 Non-radiological Accidents. As discussed in detail in Attachment F, the

limiting hypothetical non-radiological accident for naval spent nuclear fuel storage in a water pool at a shipyard or prototype location would be a diesel fuel spill and fire. A catastrophic failure of a diesel fuel storage tank that might be used for an emergency diesel generator to provide backup electrical power was postulated to occur, resulting in the spilling of the entire quantity of diesel fuel with a subsequent fire. The fire would generate the following toxic chemicals:

- Carbon monoxide
- Oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide)
- Lead
- Sulfur dioxide.

Measures would be taken to reduce the health impacts of potential releases of toxic materials. These measures would involve controls to protect both workers and the general public. The naval shipyard and prototype sites have emergency planning, emergency preparedness, and emergency response programs in place to protect both workers and the public, and involve established resources such as warning communications, fire departments, and emergency command centers.

The airborne concentrations of the combustion products listed above, resulting from the fire, were calculated at the locations of the on-site individuals, an individual at the site boundary, and the general population within a 50-mile radius of the facility. Detailed results are presented in Attachment F. If the accidental fire that has been hypothesized were to actually occur, the safety measures that would be in place would ensure no adverse health impacts to the general public and minimal health impacts to the workers.

5.1.2.14.2 Transportation Accidents.

Shipments of radioactive materials associated with naval spent nuclear fuel have never resulted in any measurable release of radioactivity to the environment (NNPP 1994a). There have never been any significant accidents involving release of radioactive material during shipment since the Naval Nuclear Propulsion Program began. The effects of potential transportation accidents during the various stages of transportation of naval spent nuclear fuel are presented in Attachment A.

The health effects associated with accidents during shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. Details of the transportation analysis are provided in Attachment A.

5.1.2.14.3 Other Impacts of Accidents.

In addition to the possible human health effects associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives. The analyses described in Attachment F showed that an area ranging from about 8 acres extending approximately a quarter mile (for an inadvertent criticality accident) to about 110 acres extending approximately 0.9 mile (for a large airplane crashing into a dry storage container) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who live in this area might be evacuated or otherwise experience restrictions in their daily activities for a brief period, and those who work at locations within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure. It should be noted that all of the affected area within about a quarter of a mile from the spent nuclear fuel facility would be inside the boundaries of the federally owned site.

An accident might result in short-term restrictions on access to a relatively small area, but there would be no enduring impacts on cultural or similar resources, partially because the area involved would be small and partly because the remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area impacted would vary only slightly among the alternatives. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with any of the alternatives would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for all alternatives considered. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. There are no endangered or threatened species unique to the area surrounding the federally owned site and an accident would not be expected to result in destruction of any species for any of the alternatives considered. The effects of accidents related to any of the alternatives and any associated cleanup which might be performed would be localized in a small area extending only a short distance beyond the boundaries of the federally owned site and would not be expected to appreciably affect threatened or endangered species in the area. Based on these considerations, evaluation of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.1.2.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear

Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the Norfolk Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is because the consequences of any accident would depend on the random conditions in effect at the time an accident occurred, and the wind directions at the Norfolk Naval Shipyard are highly variable with no strongly dominant direction.

To place the impacts on environmental justice in perspective, the risk associated with accidents caused by naval spent nuclear fuel management under any of the alternatives considered would amount to less than one additional fatality per year for the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.1.2.15 Waste Management

The alternative in which naval spent nuclear fuel is stored at Norfolk Naval Shipyard would produce limited amounts of solid municipal waste, solid low-level radioactive wastes, and hazardous wastes.
In addition, no transuranic or high-level radioactive wastes would be generated by spent nuclear fuel activities at the site under any alternative. The quantity of industrial wastes generated would be small and most likely consist of industrial cleaning agents of the type normally encountered at the site. Small quantities of sanitary wastes would result from the additional work force but this volume would be small. The wastes produced from the storage of naval spent nuclear fuel would be controlled and minimized in accordance with the existing waste management programs at the shipyard. The amount of additional wastes generated would be minimal compared to the existing baseline and would not cause any adverse impacts to public health and safety and the environment in the vicinity of the shipyard.

5.1.2.16 Cumulative Impacts

5.1.2.16.1 Radiological Cumulative Impacts. Spent nuclear fuel storage at the site would not

result in discharges of radioactivity in liquid effluents during routine operations regardless of the alternative selected. Therefore, there would be no incremental addition of radioactivity to surface or ground water as a result of normal operations for any alternative. For alternatives involving the storage of spent nuclear fuel in dry storage and shipping containers, no airborne radioactivity emissions are expected, so there would be no cumulative air quality impacts associated with these storage methods. Consequently, the only radiological cumulative impacts that would result from dry storage alternatives would be due to direct radiation exposure from the stored containers of spent nuclear fuel.

For alternatives involving the storage of naval spent nuclear fuel in water pools, there would be no discernible direct radiation exposure to the public from the fuel elements due to the shielding provided by the water in the pool. Therefore, any cumulative impacts which would result from water pool storage would be primarily due to airborne emissions, and the addition of these emissions would cause an indiscernible change in the emissions in the area (see Section 5.1.2.7). Current operations at the site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

A summary of the cumulative radiological impacts is provided in the following section.

An overview of the historical radiological impacts from naval nuclear operations at the Norfolk Naval Shipyard and from transportation of naval spent nuclear fuel is provided in Section

4.1.2.12 and detailed analyses are provided in Attachments F and A.

Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The radiological impacts associated with the alternatives where naval spent nuclear fuel would be stored at Norfolk Naval Shipyard are very small and are described in Section 5.1.2.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the population in the vicinity of the Norfolk Naval Shipyard from all of the alternatives considered would be approximately 11.2 person-rem. This means that there would be much less than one fatal cancer from these operations over the entire 40-year period evaluated. The total exposure to a theoretical maximally exposed off-site individual living at the shipyard boundary for the entire 40-year period would be 0.12 rem due to the alternative resulting in the largest exposure. This maximally exposed off-site individual would have a 6.0 x 10-5 risk of contracting a fatal cancer during his or her lifetime due to storage of spent nuclear fuel. When existing site radiological impacts due to naval nuclear operations are added to the impacts of the most limiting spent nuclear fuel alternative, the exposure to the population would be 13.6 person-rem and to the maximally exposed off-site individual would remain at 0.12 rem. This still results in much less than one fatal cancer in the population and the risk of the maximally exposed off-site individual contracting a fatal cancer during his or her lifetime is essentially unchanged.

The total exposure related to naval spent nuclear fuel activities to a worker assumed to be working continually 100 meters from the spent nuclear fuel under the alternative resulting in the largest exposure is 0.23 rem accumulated over 40 years. That corresponds to a fatal cancer risk of 9.2 x 10-5 during the worker's lifetime. The exposure to the same worker when existing site radiological impacts due to naval nuclear operations are added to the spent nuclear fuel exposure is 0.232 rem over 40 years which corresponds to a fatal cancer risk of 9.3 x 10-5 during the worker's lifetime. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

Sections 4.1.2.14 and 5.1.2.15 describe the management of low-level radioactive waste and mixed waste at the site. The volume of low-level radioactive wastes which would be generated under the alternatives has not been calculated. However, considering the nature of radiological work that would be associated with spent nuclear fuel storage activities, the amount of low-level radioactive waste produced during spent nuclear fuel activities would be much less than 20 percent of the current site generation rate (1019 m3 per year). This additional radioactive waste would not introduce any changes to the site's waste management practices. The small amount of additional material involved would not impose any discernible additional stress on the capacity of the radioactive waste burial ground. Therefore, any cumulative impacts associated with the generation and disposal of additional low-level wastes would be very small.

Since no mixed, transuranic, or high-level radioactive wastes would be generated by spent nuclear fuel activities at this site under any alternative, there would be no cumulative impacts associated with these materials.

5.1.2.16.2 Non-radiological Cumulative Impacts.

An overview of the historical non-radiological impacts from naval nuclear operations at the Norfolk Naval Shipyard and from transportation of naval spent nuclear fuel is provided in Section 4.1.2.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no non-radiological cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The non-radiological impacts associated with the alternative where naval spent nuclear fuel would be inspected or stored at Norfolk Naval Shipyard are described in Section 5.1.2.12, with the detailed results of analyses provided in Attachment F. As summarized in Section 5.1.2.12, there would be no additional chemicals required at the shipyard for naval spent nuclear fuel storage and therefore no non-radiological impacts from normal operations. Consequently, no cumulative impacts to air quality or water resources would result since the incremental addition of chemicals at the shipyard that might result from naval spent fuel activities would be very small. There are no current environmental problems associated with these materials.

The non-radiological cumulative transportation impacts for the population from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A. The non-radiological impacts associated with the transportation and storage of naval spent nuclear fuel for all of the alternatives considered would be low.

No cumulative land use impacts would be expected to occur as a result of spent nuclear fuel storage. The land that would be dedicated for this purpose is on existing federal property and situated in an industrial setting which has already been disturbed from its natural state (over 1100 acres are developed land). The conversion of this space for storage of spent nuclear fuel would not result in the need to disturb undeveloped land or for additional land to be added to the federally owned property in the foreseeable future.

From a socioeconomic perspective, the introduction of naval spent nuclear fuel activities at the site would create a small number of additional jobs and could have a very small cumulative socioeconomic impact. The site currently employs approximately 8500 civilian personnel. No shipyard employment has been associated with spent nuclear fuel activities in the past since spent nuclear fuel activities have not been conducted at the site. An average of approximately 1 to 40 additional jobs might be added as a result of possible spent nuclear fuel activities in the future. The peak number of additional jobs created at the site in any given year would be approximately 132, which is associated with construction and operation of a water pool facility for storage of spent nuclear fuel. Considering that the regional labor force consists of approximately 533,000 workers, the additional number of added jobs under any alternative would have little or no discernible socioeconomic impact. These jobs would be filled either from within the existing site work force or from the available regional labor force without discernible effect. There are no foreseeable future projects planned at the site and no known projects planned in the region that would cause the small number of workers involved in naval spent nuclear fuel activities to become an important impact.

The cumulative impacts associated with non-radiological waste management are likewise expected to be small. As stated previously, any industrial wastes generated from naval spent nuclear fuel storage would be small and limited to industrial cleaning agents of the type normally encountered at the site. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of additional non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of waste.

5.1.2.17 Unavoidable Adverse Effects

There are no discernible unavoidable adverse effects associated with the implementation of any of the alternatives and none which would help to choose among the alternatives. The alternative in which naval spent nuclear fuel is stored at the Norfolk Naval Shipyard would cause the public to be exposed to small amounts of radiation, described in Section 5.1.2.12, and would result in less than one health effect in the entire population surrounding the shipyard. Similarly, continued operation of the storage facility would produce limited amounts of solid municipal waste and solid low-level radioactive waste. These amounts of waste would not produce any major impacts in the vicinity of the shipyard. There will be no changes to the ecological, cultural, geological, and aesthetic resources due to the implementation of any of the alternatives. There would also be no expected impact on ambient noise levels.

5.1.2.18 Irreversible and Irretrievable Commitments of Resources

The only irreversible and irretrievable commitment of resources that results from the alternative in which naval spent nuclear fuel would be stored at the Norfolk Naval Shipyard would be the money which would be spent by the federal government to construct the necessary facilities. The total cost of storing spent naval nuclear fuel at the shipyards and prototype ranges from approximately $1.5 billion to $5.7 billion. This cost represents the total cumulative cost over the 40-year period for all of the shipyards and prototype. This cost includes construction costs of the new storage facilities, and, depending on the alternative selected, the operation of a limited examination facility at Puget Sound Naval Shipyard combined with the costs associated with shutting down ECF, or the operational costs of the INEL-ECF. The major expense in the highest cost alternatives is the procurement of shipping containers. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

5.1.3 PORTSMOUTH NAVAL SHIPYARD: KITTERY, MAINE

5.1.3.1 Overview of Environmental Impacts

The following sections discuss the major differences in potential environmental consequences associated with the choice of alternatives that include storage of naval spent nuclear fuel at Portsmouth Naval Shipyard. The environmental consequences associated with storage of naval spent nuclear fuel at Portsmouth Naval Shipyard are based on the estimates of naval spent nuclear fuel that will be stored at Portsmouth Naval Shipyard through the year 2035 and current knowledge of the design features associated with spent fuel shipping containers, immobile storage containers, and storage systems. The review of the environmental consequences associated with each of these alternatives has shown that the associated impact on the environment is very small. There would be no impact to the Portsmouth Naval Shipyard regional environment associated with any alternatives that do not involve the Portsmouth Naval Shipyard.

5.1.3.2 Land Use

Construction of a storage area at Portsmouth Naval Shipyard would require a modest change in the current land use by the shipyard. A description of the alternative storage containers and their approximate storage locations is provided in Attachment D. Attachment C provides a comparison of spent nuclear fuel storage in new water pools versus dry container storage.

The alternative of storing naval spent nuclear fuel in water pools would require that a water pool facility be constructed in the vicinity of the area that is designated for dry container storage. The water pool would have sufficient capacity to accommodate storage of all naval spent nuclear fuel expected to be stored at the shipyard.

No additional land outside the shipyard would be required.

Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.1.3.3 Socioeconomics

The calculated number of direct construction and operating jobs that would be required for the 10-year period between 1995 and 2004 for each storage alternative at the shipyard is provided in **Table 5.1.3-1.** Since there would be no naval spent nuclear fuel storage or inspection activities at the shipyard under the 1992/1993 Planning Basis and Centralization alternatives, no additional jobs would be required at the shipyard under these alternatives.

Table 5.1.3-1. Number of construction and operating jobs created at Portsmouth Naval Shipyard for each alternative.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Railcar(1)	1	1	6	1	1	1	1	1	1	1
Immobile Containers on Pads(2)	1	1	1	1	2	6(3)	4	4	4	4
Shipping Containers on Pads (2)	1	1	1	1	2	6(3)	1	1	1	1
Water Pools(2)	16	16	47	72	89	63	77	35	35	35

---

(1) Storage mode under the No Action and Decentralization alternatives.
(2) Storage mode under the Decentralization alternative.
(3) The construction jobs would last less than one year.

The only discernible socioeconomic consequence of storing naval spent nuclear fuel at Portsmouth Naval Shipyard is that a relatively small number of construction workers (ranging from a few to a maximum of several hundred would be required for construction of the area). The work force would consist of skilled craftsmen and unskilled laborers. This work force would be needed during the storage facility construction and would be available from within the area.

The operation of the spent fuel storage area using dry storage containers would require additional workers to secure the fuel in the storage area and to support surveillance and monitoring activities. For the alternative involving storing fuel in immobile dry storage containers, about 20 workers would be required to handle the spent nuclear fuel when it is placed into the storage containers. This work force would normally only be needed when fuel is being inserted into the containers. For the alternative involving shipping containers, fewer workers would be needed to handle and secure the containers in the storage area. The operation of a water pool facility for the alternative involving storing naval spent nuclear fuel in a water pool would require approximately 40 additional workers. The number required for any of the shipyard and prototype site storage alternatives would be small and is expected to be supplied from either within the existing shipyard work force or from the local work force. Considering that the shipyard employs approximately 5000 naval and civilian personnel, the addition of workers to support the alternatives would have no discernible impact on the local socioeconomic conditions of the Portsmouth Naval Shipyard site.

For the alternatives where dry storage containers would be manufactured, some additional jobs would be created in the locations where the containers are made. The process of selecting the container manufacturer is subject to federal procurement requirements and would be initiated after the Record of Decision. Consequently, the specific socioeconomic impacts from container fabrication cannot be specified. The net effect of container fabrication would be to create additional jobs and bolster the local economy of the area(s) where containers are made. It is considered unlikely that the selection of the contractor would depend on the alternative storage site selected, so the jobs associated with construction of casks provide no basis for selection of a storage site.

5.1.3.4 Cultural Resources

All construction contracts for the shipyard contain a clause such that if artifacts are uncovered, appropriate measures must be taken to ensure the safe recovery of such items. In most cases, these items are then placed in the shipyard museum.

The shipyard's historic district is considered a valued cultural resource and many buildings are listed on the historic register. The implementation of storage alternatives will not affect any site that is listed on the National Register of Historic Places (NPS 1991), any known archaeological areas, or any other cultural resources. Therefore, there would be no impacts to cultural resources associated with the alternative of storing naval spent nuclear fuel at the shipyard.

None of the alternatives considered would impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.1.3.5 Aesthetic and Scenic Resources

The naval spent nuclear fuel storage area would be located within the Portsmouth Naval Shipyard which is an existing industrial setting and would not affect the visual quality of the area since it is compatible with the landscape character of the site. Physical changes to the site resulting from the construction of a naval spent nuclear fuel storage facility will not alter this setting. There are no particulate air emissions associated with storage of naval spent nuclear fuel and thus no visibility impacts are expected. No aesthetic or scenic resources in the vicinity of the shipyard would be affected by the construction and operation of the storage facility.

5.1.3.6 Geology

If an alternative were to be selected which required naval spent nuclear fuel to be stored at Portsmouth Naval Shipyard, the construction and operation of the naval spent nuclear fuel storage facility would not be expected to affect the geologic character or resources of the region. During the storage facility construction phase, the ground would need to be excavated as necessary to prepare the surface. This would not affect the geological characteristics of the underlying layers. For the alternative of storing naval spent nuclear fuel in a storage pool facility, the ground surface would need to be excavated to a depth of approximately 40 feet. This excavation would not affect the geological characteristics of the area.

5.1.3.7 Air Resources

5.1.3.7.1 Radiological Consequences.

No airborne radionuclide releases from normal operations are expected to occur as a result of the alternatives involving naval spent nuclear fuel being stored in dry storage containers. The fuel would be contained such that at least two barriers exist to prevent fission products from becoming airborne. These barriers would retain the spent nuclear fuel in an air-tight containment until moved to a permanent storage site and there would be no airborne radioactive material released from routine operations for this method of storage. The only radiation exposure would be direct radiation from the array of filled storage containers. The filled storage containers would be fenced off and shielded if necessary such that there would be no distinguishable effect on the current radiation readings at the site perimeter.

For the alternative where naval spent nuclear fuel would be stored in a water pool, airborne radionuclide releases are expected to be less than the emissions from the Idaho National Engineering Laboratory (INEL) Expended Core Facility (ECF) because the water pool size and number of inspections performed would be smaller at the shipyard and the shipyard would not conduct the shielded cell operations that are performed at ECF. To conservatively estimate the radiological consequences, airborne releases based on ECF releases from 1991 are used. The radiological source term used and the detailed calculations performed to determine expected normal releases are provided in Attachment F.

The radiation exposures to human beings due to estimated radionuclide releases to the atmosphere plus direct radiation from the stored spent nuclear fuel at the shipyards for both the alternative involving water pool storage and the alternative involving dry storage were calculated as described in Attachment F.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from the stored fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F. Estimated exposures to workers were also calculated.

The hypothetical exposures calculated are based on an exposure to the estimated average effluents and the direct radiation exposure for one year from the fuel stored at the shipyard. The calculations include the external effective equivalent exposure from the ground deposition, deposition to surface water, and air immersion pathways and the 50-year committed effective equivalent exposure from internal exposure through the ingestion and inhalation pathways. All pathways were considered for persons potentially exposed, except that the ingestion pathway was omitted for the workers because they do not grow their food on-site. Solubilities which would produce the highest calculated exposures were chosen for internal exposure factors. Values for human dietary consumption patterns were taken from "Age Dependent Values of Dietary Intake for Assessing Human Exposures to Environmental Pollutants" (Rupp 1980). The hypothetical exposures calculated can be converted into a risk of fatal cancer or a risk of non-fatal health detriments (e.g., non-fatal cancers, hereditary defects) based on the "1990 Recommendations of the International Commission on Radiological Protection" (ICRP 1991).

Attachment F summarizes the calculated exposures and fatal cancers to the worker, maximally exposed off-site individual (MOI), nearest public access (NPA), and the population from releases of radioactivity and direct radiation exposure in one year for each location and storage mode. Section 3.7 provides a comparison of the annual number of fatal cancers calculated for the general population for each location and alternative.

The number of fatal cancers calculated is so small that there would be essentially no fatal cancers resulting from the storage of naval spent nuclear fuel during the time it could reasonably be expected to continue to be stored. Putting this into perspective, it could be stated that one member of the population might experience a fatal cancer due to incident-free storage of naval spent nuclear fuel at the Portsmouth Naval Shipyard if operations continued for 43,500 years.

If a water pool facility would be constructed at the Portsmouth Naval Shipyard and used for storage of naval spent nuclear fuel, the airborne emissions from the facility would be less than that identified for the Puget Sound Naval Shipyard because no naval spent nuclear fuel inspection operations beyond visual examination would be conducted in the water pool facility.

5.1.3.7.2 Non-radiological Consequences.

As noted in Attachment F, no increase in non-radioactive airborne emissions would be expected to result from spent nuclear fuel storage facility operations. Storage facility operations would not involve use of carcinogenic toxins, criteria pollutants, or other hazardous or toxic chemicals except that small quantities of industrial cleaning agents and paint thinner may be used for housekeeping and cleanliness control and these would be the same as those already used at the shipyard. Consequently, there would be no impact on ambient air quality as a result of implementing any of the alternatives at the shipyard.

If an alternative were to be selected that required a storage facility to be constructed or renovated, fugitive dust emissions would be expected to result from excavation operations. The quantity of dust generated would be small, consistent with typical excavation activities, and controlled within local requirements for dust control.

5.1.3.8 Water Resources

5.1.3.8.1 Radiological Consequences.

Spent nuclear fuel storage at the shipyard would not result in discharges of radioactivity to liquid effluents during routine operation regardless of the alternative selected for storage of spent nuclear fuel. The health effect due to fallout of nuclides released to the air onto the surface water is included in the analysis results discussed in Section 5.1.3.7. The air fallout impact is so small that there would be no distinguishable radiation levels in the water.

Portsmouth Naval Shipyard does not reside in the 100 or 500 year floodplain. Consequently, the floodplain would not be impacted by spent naval nuclear fuel storage and examination activities at the shipyard.

5.1.3.8.2 Non-radiological Consequences.

Other than chemicals used to maintain the storage area, no hazardous wastes would be generated by the storage of naval spent nuclear fuel at Portsmouth Naval Shipyard. Any hazardous liquid effluents that may be generated at the storage area would be disposed of at an Environmental Protection Agency approved disposal site.

The only source for liquid discharges from the naval spent nuclear fuel storage operations to the environment consists of storm water runoff which would be consistent with the type of discharges associated with common light industrial facilities and related activities. It can be concluded that there would be no impact to the human environment due to runoff water from the proposed naval spent nuclear fuel storage area.

The increased water usage under any alternative would be negligible compared to the existing shipyard demand.

5.1.3.9 Ecological Resources

Both Maine and New Hampshire officials were consulted and have determined that there is no evidence to suggest that any threatened or endangered species reside on the Portsmouth Naval Shipyard (Appendix V.B. of the Navy's Natural Resources Management Plan (Navy 1993)). No major changes to the industrial environment are planned. None of the alternatives would affect the areas surrounding the shipyard. Therefore, no major ecological impacts to the region would result from selection of any of the alternatives.

The conceptual location where naval spent nuclear fuel would be stored is illustrated in Attachment D. This location is within an existing industrial complex and is surrounded by buildings and paved areas. The industrial nature of the shipyard and the fact that the land has already been disturbed from its natural state by earlier activities mean that plant or animal species sensitive to disturbance by human activities would not be expected to be present. Therefore, there would be no ecological impacts associated with construction or operation of a spent nuclear fuel storage area at this location. The radiological controls that are in effect at the shipyard ensure that the radiation levels in the vicinity of the shipyard are maintained at or near natural background. Since these same controls would be applied to spent nuclear fuel activities, no ecological effects due to radioactive material would be expected to occur.

5.1.3.10 Noise

Portsmouth Naval Shipyard is an existing industrial-type environment characterized by noise from truck and automobile traffic; ship loading cranes and related diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related pumping systems for those and other liquids. No ambient noise level increases are expected to occur as a result of any of the alternatives. Therefore, no noise impacts would be expected to occur.

5.1.3.11 Traffic and Transportation

Shipments of radioactive materials in the Naval Nuclear Propulsion Program are required to be made in accordance with applicable regulations of the U. S. Department of Transportation, U.S. Department of Energy, and the U.S. Nuclear Regulatory Commission. The purpose of these regulations is to ensure that shipments of radioactive material are adequately controlled to protect the environment and the health and safety of the general public. These regulations are applicable to all radioactive material shipments and provide requirements for the container design, certification, and identification as applicable for the specific quantity, type, and form of radioactive material being shipped. Naval shipping container design requirements invoke shielding and integrity specifications and meet all regulatory requirements. They provide for testing of container designs, training and qualification of workers who construct containers, and quality control inspections during fabrication to ensure that the containers will meet their design requirements. A detailed description of the shipping containers used for naval spent nuclear fuel shipments is provided in Attachment A. A description of the impacts associated with normal and accident conditions associated with transportation of naval spent nuclear fuel is provided in Attachment A.

5.1.3.11.1 Regional Infrastructure.

The alternatives under consideration are described in Section 3. The No Action alternative or the first variation of the Decentralization alternative would store the spent nuclear fuel on-site. This alternative would reduce the number of rail shipments from the shipyard or prototype site compared to the past practice of transporting all spent nuclear fuel to INEL. The second variation of the Decentralization alternative would ship about 10 percent of the spent nuclear fuel to Puget Sound. This would have some transportation impact, but not as much as transporting all spent nuclear fuel off-site. The third Decentralization alternative ships all spent nuclear fuel to INEL, examines it, and returns it to the original shipyard or prototype site. This alternative involves more transportation than the previous practice of transporting spent nuclear fuel to INEL, since the spent nuclear fuel is not returned from INEL to the original site. The 1992/1993 Planning Basis alternative, the Regionalization at INEL alternative, or the Centralization at INEL alternative would involve the same transportation as has been required in the past, namely transportation to INEL and retention there. The Centralization alternative at the Hanford Site would result in more transportation impact than any of the previous alternatives, due to the distances and population distribution between Hanford and the shipyards and prototypes. The Centralization alternative at the Savannah River Site would result in the most transportation impact of spent nuclear fuel of any of the alternatives.

5.1.3.11.2 Site Infrastructure.

The alternative associated with naval spent nuclear fuel storage at Portsmouth Naval Shipyard would not noticeably affect site highway traffic because any increase in the work force would represent a very small incremental increase in overall traffic to and from the shipyard. There would be no noticeable change in the internal traffic in the shipyard because fuel is held temporarily even when it is transported off-site.

5.1.3.12 Occupational and Public Health and Safety

Detailed analyses of incident-free spent nuclear fuel transportation and storage and handling impacts on worker and public health are described in Attachment A (transportation) and Attachment F (storage and inspection). The transportation analysis results, and the storage and handling analysis are summarized separately in the following subsections.

5.1.3.12.1 Incident-free Transportation Occupational and Public Health and Safety.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.3.12.2 Incident-free Occupational and Public Health and Safety During Spent Nuclear

Fuel Storage and Handling.

The public health and safety impacts of radioactivity releases and direct radiation from storage of spent nuclear fuel were analyzed as discussed in Section 5.1.3.7 and Attachment F. Attachment F summarizes the results of the analysis of radioactivity releases and direct radiation from stored spent nuclear fuel. This analysis shows that the exposure to the worker, maximally exposed off-site individual, and nearest public access from stored naval spent nuclear fuel would result in far less than one fatality per year. For perspective, it could be stated that one member of these population groups might experience a fatal cancer due to storage of naval spent nuclear fuel at Portsmouth Naval Shipyard if operations continued for 43,500 years.

Projections of the number of occupational accidents that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

No public or occupational radiological health and safety impacts would be expected to result from naval spent nuclear fuel storage area construction activities since the construction would not involve radioactive work.

Attachment F also discusses toxic chemical issues for spent nuclear fuel handling and storage. Attachment F concludes that there would be no additional types or volumes of chemicals required at the shipyards or prototype site for spent nuclear fuel storage. Therefore, there is no incident-free non-radiological impact resulting from storage of spent nuclear fuel at the shipyards or prototype site.

5.1.3.12.3 Incident-free Occupational and Public Health and Safety Effects on Environmental Justice Due to Naval Spent Nuclear Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the management of naval spent nuclear fuel at the Portsmouth Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the Portsmouth Naval Shipyard do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game since environmental monitoring in the vicinity of this relatively small and restricted site has shown no detectable difference in the amounts of radioactivity present in the environment from levels in similar parts of the region.

To place the impacts on environmental justice in perspective, the risk associated with routine naval spent nuclear fuel management operations under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.1.3.13 Utilities and Energy

If an alternative associated with the storage of naval spent nuclear fuel at Portsmouth Naval Shipyard were to be selected, construction and operation of the storage area would not be expected to require a large expenditure of utilities and energy resources. Construction activities will require quantities of water and electricity typical of any small to medium size construction project. Operation of the dry container naval spent nuclear fuel storage facility will likely require only a small amount of electricity for security lighting and to support industrial equipment necessary to move naval spent nuclear fuel (cranes, etc). Alternatives associated with water pool storage would require heating, ventilation, water, and electrical systems suitable for a work environment and to properly filter and exhaust the airborne discharges to the atmosphere. The utility and energy demands would be less than those required to operate ECF (10,000 MWh per year) (Section 5.2.13) since the water pool used for naval spent nuclear fuel storage would be smaller and no spent fuel operations beyond visual examinations would be conducted in the water pool.

The amount of utilities and energy expected to be consumed would be a small incremental increase in the total amount of utilities and energy used at the Portsmouth Naval Shipyard and will not result in any discernible environmental consequence.

5.1.3.14 Facility and Transportation Accidents

5.1.3.14.1 Facility Accidents. There has never been an accident in the history of the Naval

Nuclear Propulsion Program that resulted in a significant release of radioactivity to the environment or that resulted in radiation exposure to workers in excess of abnormal occurrence limits on exposures as defined by the U.S. Nuclear Regulatory Commission. A description of potential accidents considered and a summary of the accident analyses that were conducted with regards to the storage of naval spent nuclear fuel are contained in Attachment F.

5.1.3.14.1.1 Radiological Accidents. Section 3.7.3 provides a summary of the impacts

due to the most severe accidents considered for each site. The facility accident with the greatest potential impact at Portsmouth Naval Shipyard involves an airplane crash. An accident of this magnitude would result in 9 fatal cancers to the general population over 50 years, as described in Attachment F. The likelihood of an airplane crash is 1 x 10-7. The facility accident with the greatest risk involves accidental drainage of the water pool. The drained water pool accident would result in less than one fatality over 50 years, but the likelihood of occurrence is 1 x 10-5.

5.1.3.14.1.2 Non-radiological Accidents. As discussed in detail in Attachment F, the limiting

hypothetical non-radiological accident for spent nuclear fuel storage in a water pool at a shipyard or prototype location would be a diesel fuel spill and fire. A catastrophic failure of a diesel fuel storage tank that might be used for an emergency diesel generator to provide backup electrical power was postulated to occur, resulting in the spilling of the entire quantity of diesel fuel with a subsequent fire.

The fire would generate the following toxic chemicals:

- Carbon monoxide
- Oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide)
- Lead
- Sulfur dioxide.

Measures would be taken to reduce the health impacts of potential releases of toxic materials. These measures would involve controls to protect both workers and the general public. The naval shipyard and prototype sites have emergency planning, emergency preparedness, and emergency response programs in place to protect both workers and the public and involve established resources such as warning communications, fire departments, and emergency command centers.

The airborne concentrations of the combustion products listed above, resulting from the fire, were calculated at the locations of the on-site individuals, an individual at the site boundary, and the general population within a 50-mile radius of the facility. Detailed results are presented in

Attachment F. If the accidental fire that has been hypothesized were to actually occur, the safety measures that would be in place would ensure no adverse health impacts to the general public and minimal health impacts to the workers.

5.1.3.14.2 Transportation Accidents.

Shipments of radioactive materials associated with naval spent nuclear fuel have never resulted in any measurable release of radioactivity to the environment (NNPP 1994a). There have never been any significant accidents involving the release of radioactive material during shipment since the Naval Nuclear Propulsion Program began. The effects of potential transportation accidents during the various stages of transportation of naval spent nuclear fuel are presented in Attachment A.

The health effects associated with accidents during shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.3.14.3 Other Impacts of Accidents.

In addition to the possible human health effects associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives.
The analyses described in Attachment F showed that an area ranging from about 8 acres extending approximately a quarter mile (for an inadvertent criticality accident) to about 110 acres extending approximately 0.9 mile (for a large airplane crashing into a dry storage container) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who live in this area might be evacuated or otherwise experience restrictions in their daily activities for a brief period, and those who work at locations within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure. It should be noted that all of the affected area within about a quarter mile from the spent nuclear fuel facility would be inside the boundaries of the federally owned site.

An accident might result in short-term restrictions on access to a relatively small area, but there would be no enduring impacts on cultural or similar resources, partially because the area would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area impacted would vary only slightly among the alternatives considered. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with any of the alternatives would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for all alternatives considered. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. There are no endangered or threatened species unique to the area surrounding the federally owned site, so an accident would not be expected to result in destruction of any species for any of the alternatives considered. The effects of accidents related to any of the alternatives and any associated cleanup which might be performed would be localized in a small area extending only a short distance beyond the boundaries of the federally owned site and thus would not be expected to appreciably affect the potential for survival of endangered or threatened species in southeastern Maine or New Hampshire. Based on these considerations, evaluation of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.1.3.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear

Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the Portsmouth Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is because the consequences of any accident would depend on the random conditions in effect at the time an accident occurred, and the wind directions at the Portsmouth Naval Shipyard are highly variable with no strongly dominant direction.

To place the impacts on environmental justice in perspective, the risk associated with accidents caused by naval spent nuclear fuel management under any of the alternatives considered would amount to less than one additional fatality per year for the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.1.3.15 Waste Management

The alternative in which naval spent nuclear fuel is stored at Portsmouth Naval Shipyard would produce limited amounts of solid municipal waste, solid low-level radioactive wastes, and hazardous wastes.

In addition, no transuranic or high-level radioactive wastes would be generated by spent nuclear fuel activities at the site under any alternative. The quantity of industrial wastes generated would be small and most likely consist of industrial cleaning agents of the type normally encountered at the site. Small quantities of sanitary wastes would result from the additional work force but this volume would be small. The wastes produced from the storage of naval spent nuclear fuel would be controlled and minimized in accordance with the existing waste management programs at the Portsmouth Naval Shipyard. The amount of additional wastes generated would be minimal compared to the existing baseline and would not cause any adverse impacts to public health and safety and the environment in the vicinity of the Portsmouth Naval Shipyard.

5.1.3.16 Cumulative Impacts

5.1.3.16.1 Radiological Cumulative Impacts. Spent nuclear fuel storage at the site would not

result in discharges of radioactivity in liquid effluents during routine operations regardless of the alternative selected. Therefore, there would be no incremental addition of radioactivity to surface or ground water as a result of normal operations for any alternative. For alternatives involving the storage of spent nuclear fuel in dry storage and shipping containers, no airborne radioactivity emissions are expected, so there would be no cumulative air quality impacts associated with these storage methods. Consequently, the only radiological cumulative impacts that would result from dry storage alternatives would be due to direct radiation exposure from the stored containers of spent nuclear fuel.

For alternatives involving the storage of naval spent nuclear fuel in water pools, there would be no discernible direct radiation exposure to the public from the fuel elements due to the shielding provided by the water in the pool. Therefore, any cumulative impacts which would result from water pool storage would be primarily due to airborne emissions, and the addition of these emissions would cause an indiscernible change in the emissions in the area (see Section 5.1.3.7). Current operations at the site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

A summary of the cumulative radiological impacts is provided in the following section.

An overview of the historical radiological impacts from naval nuclear operations at the Portsmouth Naval Shipyard and from transportation of naval spent nuclear fuel is provided in Section 4.1.3.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The radiological impacts associated with the alternatives where naval spent nuclear fuel would be stored at Portsmouth Naval Shipyard are very small and are described in Section 5.1.3.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the population in the vicinity of the Portsmouth Naval Shipyard from all of the alternatives considered would be approximately 1.8 person-rem. This means that there would be much less than one fatal cancer from these operations over the entire 40-year period evaluated. The total exposure to a theoretical maximally exposed off-site individual living at the shipyard boundary for the entire 40-year period would be 2.2 x 10-3 rem due to the alternative resulting in the largest exposure. This maximally exposed off-site individual would have a 1.1 x 10-6 risk of contracting a fatal cancer during his or her lifetime due to storage of spent nuclear fuel. When existing site radiological impacts due to naval nuclear operations are added to the impacts of the most limiting spent nuclear fuel alternative, the exposure to the population would be 2.2 person-rem and to the maximally exposed off-site individual would be 2.5 x 10-3 rem. This still results in much less than one fatal cancer in the population and the risk of the maximally exposed off-site individual contracting a fatal cancer during his or her lifetime is 1.3 x 10-6.

The total exposure related to naval spent nuclear fuel activities to a worker assumed to be working continually 100 meters from the spent nuclear fuel under the alternative resulting in the largest exposure is 0.11 rem accumulated over 40 years. That corresponds to a fatal cancer risk of 4.4 x 10-5 during the worker's lifetime. The exposure to the same worker when existing site radiological impacts due to naval nuclear operations are added to the spent nuclear fuel exposure is essentially the same over 40 years. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

Sections 4.1.3.14 and 5.1.3.15 describe the management of low-level radioactive waste and mixed waste at the site. The volume of low-level radioactive wastes which would be generated under the alternatives has not been calculated. However, considering the nature of radiological work that would be associated with spent nuclear fuel storage activities, the amount of low-level radioactive waste produced during spent nuclear fuel activities would be much less than 20 percent of the current site generation rate (57 m3 per year). This additional radioactive waste would not introduce any changes to the site's waste management practices. The small amount of additional material involved would not impose any discernible additional stress on the capacity of the radioactive waste burial ground. Therefore, any cumulative impacts associated with the generation and disposal of additional low-level wastes would be very small.

Since no mixed, transuranic, or high-level radioactive wastes would be generated by spent nuclear fuel activities at this site under any alternative, there would be no cumulative impacts associated with these materials.

5.1.3.16.2 Non-radiological Cumulative Impacts.

An overview of the historical non-radiological impacts from naval nuclear operations at the Portsmouth Naval Shipyard and from transportation of naval spent nuclear fuel is provided in Section 4.1.3.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no non-radiological cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The non-radiological impacts associated with the alternative where naval spent nuclear fuel would be inspected or stored at Portsmouth Naval Shipyard are described in Section 5.1.3.12, with the detailed results of analyses provided in Attachment F. As summarized in Section 5.1.3.12, there would be no additional chemicals required at the shipyard for naval spent nuclear fuel storage and therefore no non-radiological impacts from normal operations. Consequently, no cumulative impacts to air quality or water resources would result since the incremental addition of chemicals at the shipyard that might result from naval spent fuel activities would be very small. There are no current environmental problems associated with these materials.

The non-radiological cumulative transportation impacts for the population from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A. The non-radiological impacts associated with the transportation and storage of naval spent nuclear fuel for all of the alternatives considered would be low.

No cumulative land use impacts would be expected to occur as a result of spent nuclear fuel storage. The land that would be dedicated for this purpose is on existing federal property and situated in an industrial setting which has already been disturbed from its natural state (approximately 227 acres are developed land). The conversion of this space for storage of spent nuclear fuel would not result in the need to disturb undeveloped land or for additional land to be added to the federally owned property in the foreseeable future.

From a socioeconomic perspective, the introduction of naval spent nuclear fuel activities at the site would create a small number of additional jobs and could have a very small cumulative socioeconomic impact. The site currently employs approximately 4900 civilian personnel. No shipyard employment has been associated with spent nuclear fuel activities in the past since spent nuclear fuel activities have not been conducted at the site. An average of approximately 1 to 35 additional jobs might be added as a result of possible spent nuclear fuel activities in the future. The peak number of additional jobs created at the site in any given year would be approximately 89, which is associated with construction and operation of a water pool facility for storage of spent nuclear fuel. Considering that the regional labor force consists of approximately 121,550 workers, the additional number of added jobs under any alternative would have little or no discernible socioeconomic impact. These jobs would be filled either from within the existing site work force or from the available regional labor force without discernible effect. There are no foreseeable future projects planned at the site and no known projects planned in the region that would cause the small number of workers involved in naval spent nuclear fuel activities to become an important impact.

The cumulative impacts associated with non-radiological waste management are likewise expected to be small. As stated previously, any industrial wastes generated from naval spent nuclear fuel storage would be small and limited to industrial cleaning agents of the type normally encountered at the site. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of additional non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of waste.

5.1.3.17 Unavoidable Adverse Effects

There are no discernible unavoidable adverse effects associated with the implementation of any of the alternatives and none which would help to choose among the alternatives. The alternative in which naval spent nuclear fuel is stored at the Portsmouth Naval Shipyard would cause the public to be exposed to small amounts of radiation, described in Section 5.1.3.12, and would result in less than one health effect in the entire population surrounding the shipyard. Similarly, continued operation of the storage facility would produce limited amounts of solid municipal waste and solid low-level radioactive waste. These amounts of waste would not produce any major impacts in the vicinity of the shipyard. There will be no changes to the ecological, cultural, geological, and aesthetic resources due to the implementation of any of the alternatives. There will also be no impact on ambient noise levels.

5.1.3.18 Irreversible and Irretrievable Commitments of Resources

The only irreversible and irretrievable commitment of resources that results from the alternative in which naval spent nuclear fuel would be stored at the Portsmouth Naval Shipyard would be the money which would be spent by the federal government to construct the necessary facilities. The total cost of storing spent naval nuclear fuel at the shipyards and prototype ranges from approximately $1.5 billion to $5.7 billion. This cost represents the total cumulative cost over the 40-year period for all of the shipyards and prototype. This cost includes construction costs of the new storage facilities, and, depending on the alternative selected, the operation of a limited examination facility at Puget Sound Naval Shipyard combined with the costs associated with shutting down ECF, or the operational costs of the INEL-ECF. The major expense in the highest cost alternatives is the procurement of shipping containers. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

5.1.4 PEARL HARBOR NAVAL SHIPYARD: PEARL HARBOR, HAWAII

5.1.4.1 Overview of Environmental Impacts

The following sections discuss the major differences in potential environmental consequences associated with the choice of alternatives that include storage of naval spent nuclear fuel at Pearl Harbor Naval Shipyard (hereafter referred to as Pearl Harbor). The environmental consequences associated with storage of naval spent nuclear fuel at Pearl Harbor are based on the estimates of naval spent nuclear fuel that will be stored at Pearl Harbor through the year 2035 and the current knowledge of the design features associated with spent fuel storage systems. The review of the environmental consequences associated with these alternatives has shown that the impact on the environment at Pearl Harbor associated with all activities is very small. There would be no impact to the environment in the vicinity of Pearl Harbor associated with any alternatives that do not involve Pearl Harbor.

5.1.4.2 Land Use

Construction of a storage area at Pearl Harbor for temporary naval spent nuclear fuel storage would require a modest change in the current land in use by the shipyard. A description of the alternate storage containers and water pools and their approximate storage locations is provided in Attachment D. Attachment C provides a comparison of naval spent nuclear fuel storage in water pools versus dry container storage. The area is already an industrial site; therefore, there will be no impact on land use.

The alternative of storing naval spent nuclear fuel in water pools would require that a water pool facility be constructed in the vicinity of the area that is designated for dry container storage. The water pool would have sufficient capacity to accommodate storage of all naval spent nuclear fuel expected to be stored at the shipyard.

No additional land use outside the shipyard would be required.

Native Hawaiian rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.1.4.3 Socioeconomics

The calculated number of direct construction and operating jobs that would be required for the 10-year period between 1995 and 2004 for each storage alternative at the shipyard is provided in

Table 5.1.4-1. Since there would be no naval spent nuclear fuel storage or inspection activities at the shipyard under the 1992/1993 Planning Basis and Centralization alternatives, no additional jobs would be required at the shipyard under these alternatives.

Table 5.1.4-1. Number of construction and operating jobs created at Pearl Harbor Naval Shipyard for each alternative.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Railcar(1)	1	1	6	1	1	1	1	1	1	1
Immobile Containers on Pads(2)	1	1	1	1	2	6(3)	4	4	4	4
Shipping Containers on Pads (2)	1	1	1	1	2	6(3)	1	1	1	1
Water Pools(2)	16	16	46	71	88	62	77	35	35	35

---

(1) Storage mode under the No Action and Decentralization alternatives.
(2) Storage mode under the Decentralization alternative.
(3) The construction jobs would last less than one year.

The only discernible socioeconomic consequence from the alternative of storing naval spent nuclear fuel at Pearl Harbor is that a relatively small number of construction workers (ranging from a few to a maximum of several hundred would be required for construction of the storage area). The work force would consist of skilled craftsmen and unskilled laborers. This work force would be needed during the storage facility construction and would be provided from within the area.

The operation of the naval spent nuclear fuel storage area using dry storage containers would require additional workers to secure the fuel in the storage area and to support surveillance and monitoring activities. For the alternative involving storing fuel in immobile dry storage containers, about 20 workers would be required to handle the naval spent nuclear fuel when it is placed into the storage containers. This work force would normally only be needed when fuel is being inserted into the containers. For the alternative involving shipping containers, fewer workers would be needed to handle and secure the containers in the storage area. The operation of a water pool facility for the alternative involving storing naval spent nuclear fuel in a water pool would require approximately 40 additional workers. The number required for any of the shipyard and prototype site storage alternatives would be small and would be expected to be supplied from either within the existing shipyard work force or the local work force. Considering that the Department of Defense employs approximately 10,900 civilians at the Pearl Harbor naval base, the addition of workers to support the alternatives would have no discernible impact on the local socioeconomic conditions of the Pearl Harbor site.

For the alternatives where dry storage containers would be manufactured, some additional jobs would be created in the locations where the containers are made. The process of selecting the container manufacturer is subject to federal procurement requirements and would be initiated after the Record of Decision. Consequently, the specific socioeconomic impacts from container fabrication cannot be specified. The net effect of container fabrication would be to create additional jobs and bolster the local economy of the area(s) where containers are made. It is considered unlikely that the selection of the contractor would depend on the alternative storage site selected, so the jobs associated with construction of casks provide no basis for selection of a storage site.

5.1.4.4 Cultural Resources

The action considered will not affect any site that is listed on the National Register of Historic Places (NPS 1991), any known archaeological areas, or any other cultural resources. Therefore, there would be no impacts to cultural resources associated with the alternative of storing naval spent nuclear fuel at this location.

None of the alternatives considered would impact known archaeological or Native Hawaiian sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.1.4.5 Aesthetic and Scenic Resources

The naval spent nuclear fuel storage area would be located within the Pearl Harbor site which is an existing industrial setting and would not affect the visual quality of the area since it is compatible with the landscape character of the site. Physical changes to the Pearl Harbor site resulting from storage area construction will not alter this setting. There are no particulate air emissions associated with storage of naval spent nuclear fuel and thus no visibility impacts are expected. No aesthetic or scenic resources in the vicinity of the shipyard would be affected by the construction and operation of the storage facility.

5.1.4.6 Geology

The construction and operation of the naval spent nuclear fuel storage facility at Pearl Harbor is not expected to affect the geologic character or resources of the region. If an alternative were selected which required a storage area to be constructed, the ground surface would be excavated as necessary to prepare the surface. This would not affect the geological characteristics of the underlying layers nor the characteristics of the Koolou and Wainae aquifers or vadose zone. For the alternative of storing fuel in a water pool facility, the ground surface would need to be excavated to a depth of approximately 40 feet. This excavation would not affect the geological characteristics of the area.

5.1.4.7 Air Resources

5.1.4.7.1 Radiological Consequences.

No airborne radionuclide releases from normal operations are expected to occur as a result of naval spent nuclear fuel being stored in dry storage containers. The fuel would be contained such that at least two barriers exist to prevent fission products from becoming airborne. These barriers would retain the naval spent nuclear fuel in an air-tight containment until it is moved to a permanent storage site and there would be no airborne radioactive material released from routine operations for this method of storage. The only radiation exposure would be direct radiation from the array of filled storage containers. The filled storage containers would be fenced off and shielded if necessary such that there would be no distinguishable effect on normal background radiation levels at the site perimeter.

For the alternative where naval spent nuclear fuel would be stored in a water pool, airborne radionuclide releases are expected to be less than the emissions from the Idaho National Engineering Laboratory (INEL) Expended Core Facility (ECF) because the water pool size would be smaller, no naval spent nuclear fuel inspection operations beyond visual examinations would be conducted, and no shielded cell operations would be conducted at Pearl Harbor. To conservatively estimate the radiological consequences, airborne releases based on ECF releases from 1991 are used. The radiological source term used and the detailed calculations performed to determine expected normal releases are provided in Attachment F.

The radiation exposures to human beings due to estimated radionuclide releases to the atmosphere plus direct radiation from the stored naval spent nuclear fuel at the shipyards for both the alternative involving water pool storage and the alternative involving dry storage were calculated as described in Attachment F.

A person on the shipyard boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from the stored naval spent nuclear fuel. The population data used to calculate population exposures were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F. Estimated exposures to workers were also calculated.

The hypothetical exposures calculated are based on an exposure to the estimated average effluents and the direct radiation exposure for one year from the naval spent nuclear fuel stored at the shipyard. The calculations include the external effective equivalent exposure from the ground deposition, deposition to surface water, and air immersion pathways and the 50-year committed effective equivalent exposure from internal exposure through the ingestion and inhalation pathways. All pathways were considered for persons potentially exposed, except that the ingestion pathway was omitted for the workers because they do not grow their food on-site. Solubilities which would produce the highest calculated exposures were chosen for internal exposure factors. Values for human dietary consumption patterns were taken from "Age Dependent Values of Dietary Intake for Assessing Human Exposures to Environmental Pollutants" (Rupp 1980). The hypothetical exposures calculated can be converted into a risk of fatal cancer or a risk of non-fatal health detriments (e.g., non-fatal cancers, hereditary defects) based on recommendations of the International Commission on Radiological Protection (ICRP 1991).

Attachment F summarizes the calculated exposures and fatal cancers to the worker, the maximally exposed off-site individual (MOI), nearest public access (NPA), and the population from releases of radioactivity and direct radiation exposure in one year for each location and storage mode. Section 3.7 provides a comparison of the annual number of fatal cancers calculated for the general population for each location and alternative.

The number of fatal cancers calculated is so small that there would be essentially no fatal cancers resulting from the storage of naval spent nuclear fuel during the time it could reasonably be expected to continue to be stored. Putting this into perspective, it could be stated that one member of the population might experience a fatal cancer due to incident-free storage of naval spent nuclear fuel at Pearl Harbor if operations continued for 14,300 years.

5.1.4.7.2 Non-radiological Consequences.

As noted in Attachment F, no increase in non-radioactive airborne emissions would be expected to result from naval spent nuclear fuel storage facility operations. Storage facility operations would not involve use of carcinogenic toxins, criteria pollutants, or other hazardous or toxic chemicals except that small quantities of industrial cleaning agents and paint thinner may be used for housekeeping and cleanliness control and these would be the same as those already used at the shipyard. Consequently, there would be no impact on ambient air quality as a result of implementing any of the alternatives at the shipyard.

If an alternative were to be selected that required a storage facility to be constructed or renovated, fugitive dust emissions would be expected to result from excavation operations. The quantity of dust generated would be small, consistent with typical excavation activities, and controlled within local requirements for dust control.

5.1.4.8 Water Resources

5.1.4.8.1 Radiological Consequences.

Naval spent nuclear fuel storage operations at Pearl Harbor would not result in discharges of radioactivity in liquid effluents during routine operation regardless of the alternative selected for storage of naval spent nuclear fuel. The health effect due to fallout of nuclides released to the air onto the surface water is included in the analysis results discussed in Section 5.1.4.7. The air fallout impact is so small that there would be no distinguishable radiation levels in the water.

Based on FIRM and topographical maps of areas approximately three miles away, the location considered for the interim storage of naval spent nuclear fuel is in the 100-year floodplain. However, the location considered for naval spent nuclear fuel is not in a high-hazard area (as defined by Title 10, Part 1022 of The Code of Federal Regulations for floodplains) which is an area where frequent flooding occurs. Since the majority of the shipyard is already developed and covered with impervious material, construction and operation of a naval spent nuclear fuel storage facility at the shipyard would produce no discernible impacts on the floodplain.

Flooding in the area where shipping and immobile dry storage containers are stored would not result in any adverse environmental consequences. These containers are completely sealed such that no radioactivity would be released from the interior even if they were completely submerged. In addition, the massive nature of these containers prevents them from floating or moving during a flood.

Since the shipyard resides in close proximity to a floodplain, the design of the facility and equipment would minimize the potential for flooding and damage to the facility. However, in the event a water pool facility would be flooded, the exchange of pool water with the flood waters could occur. As discussed in Attachment F, Section F.1.4.2.1.6.2, the radioactivity concentration in the ECF water pool is below the Nuclear Regulatory Commission limits specified in Title 10, Part 20 of The Code of Federal Regulations for liquid effluent except for Co-60 which is slightly higher (water pools used for storage or examination of naval spent nuclear fuel would be maintained to comparable concentrations). Any release of radioactivity would have to result from the exchange of floodwater with the pool water. This exchange would reduce the level of radioactivity even further. Consequently, no adverse environmental impacts would result from flooding of water pools at naval spent nuclear fuel storage sites.

5.1.4.8.2 Non-radiological Consequences.

Other than chemicals used to maintain the storage area, no hazardous wastes would be generated by the storage of naval spent nuclear fuel at Pearl Harbor. Any hazardous liquid effluents that may be generated at the storage area would be disposed of at an Environmental Protection Agency approved disposal site.

The only source for liquid discharges from the naval spent nuclear fuel storage operations to the environment consists of storm water runoff which would be consistent with the type of discharges associated with common light industrial facilities and related activities. It can be concluded that there would be no impact to the human environment due to runoff water from the naval spent nuclear fuel storage area.

The increased water usage under any of the alternatives would be negligible compared to the existing shipyard demand.

5.1.4.9 Ecological Resources

There are no threatened or endangered species known to exist within the Pearl Harbor shipyard and no major changes to the industrial environment are planned. Therefore, no major ecological impacts to the region would result from selection of any of the alternatives.

The conceptual location where naval spent nuclear fuel would be stored is illustrated in Attachment D. This location is within an existing industrial complex and is surrounded by buildings and paved areas. The industrial nature of the shipyard and the fact that the land has already been disturbed from its natural state by earlier activities mean that plant or animal species sensitive to disturbance by human activities would not be expected to be present. Therefore, there would be no ecological impacts associated with construction or operation of a spent nuclear fuel storage area at this location. The radiological controls that are in effect at the shipyard ensure that the radiation levels in the vicinity of the shipyard are maintained at or near natural background. Since these same controls would be applied to spent nuclear fuel activities, no ecological effects due to radioactive material would be expected to occur.

5.1.4.10 Noise

Pearl Harbor is an existing industrial-type environment characterized by noise from truck and automobile traffic; ship loading cranes and related diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related pumping systems for those and other liquids. No ambient noise level increases are expected to occur as a result of any of the alternatives. Therefore, no noise impacts would be expected to occur.

5.1.4.11 Traffic and Transportation

Shipments of radioactive materials in the Naval Nuclear Propulsion Program are required to be made in accordance with applicable regulations of the U. S. Department of Transportation, U.S. Department of Energy, and the U.S. Nuclear Regulatory Commission. The purpose of these regulations is to ensure that shipments of radioactive material are adequately controlled to protect the environment and the health and safety of the general public. These regulations are applicable to all radioactive material shipments and provide requirements for the container design, certification, and identification as applicable for the specific quantity, type, and form of radioactive material being shipped. Naval shipping container design requirements invoke shielding and integrity specifications and meet all regulatory requirements. They provide for testing of container designs, training and qualification of workers who construct containers, and quality control inspections during fabrication to ensure that the containers will meet their design requirements. A detailed description of the shipping containers used for naval spent nuclear fuel shipments is provided in Attachment A. A description of the impacts from normal and accident conditions associated with transportation of naval spent nuclear fuel is provided in Attachment A.

5.1.4.11.1 Regional Infrastructure.

The alternatives under consideration are described in Section 3. The No Action alternative or the first variation of the Decentralization alternative would store the naval spent nuclear fuel on-site. This alternative would reduce the number of rail shipments from the shipyard or prototype site compared to the past practice of transporting all naval spent nuclear fuel to INEL. The second variation of the Decentralization alternative would ship about 10 percent of the naval spent nuclear fuel to Puget Sound. This would have some transportation impact, but not as much as transporting all naval spent nuclear fuel off-site. The third Decentralization alternative ships all naval spent nuclear fuel to INEL, examines it, and returns it to the original shipyard or prototype site. This alternative involves more transportation than the previous practice of transporting naval spent nuclear fuel to INEL, since the naval spent nuclear fuel is not returned from INEL to the original site. The 1992/1993 Planning Basis alternative, the Regionalization at INEL alternative, or the Centralization at INEL alternative would involve the same transportation as has been required in the past, namely transportation to INEL and retention there. The Centralization alternative at the Hanford Site would result in more transportation impact than any of the previous alternatives, due to the distances and population distribution between Hanford and the shipyards and prototypes. The Centralization alternative at the Savannah River Site would result in the most transportation impact of naval spent nuclear fuel of any of the alternatives.

5.1.4.11.2 Site Infrastructure.

The alternative associated with naval spent nuclear fuel storage at Pearl Harbor would not affect local highway traffic because any increase in the work force would represent a very small incremental increase in overall traffic to and from the shipyard. There would be no change in the internal traffic in the shipyard because naval spent nuclear fuel is held temporarily even when it is transported off-site.

5.1.4.12 Occupational and Public Health and Safety

Detailed analyses of incident-free naval spent nuclear fuel transportation and storage and handling impacts on worker and public health are described in Attachment A (transportation) and Attachment F (storage and inspection). The transportation analysis results, and the storage and handling analysis are summarized separately in the following subsections.

5.1.4.12.1 Incident-free Transportation Occupational and Public Health and Safety.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.4.12.2 Incident-free Occupational and Public Health and Safety During Naval Spent

Nuclear Fuel Storage and Handling. The public health and safety impacts of radioactivity releases and direct radiation from storage of naval spent nuclear fuel were analyzed as discussed in Section 5.1.4.7 and Attachment F. Attachment F summarizes the results of the analysis of radioactivity releases and direct radiation from stored naval spent nuclear fuel. This analysis shows that the exposure to the worker, maximally exposed off-site individual, and nearest public access from stored naval spent nuclear fuel would result in far less than one fatality per year. For perspective, it could be stated that one member of these population groups might experience a fatal cancer due to storage of naval spent nuclear fuel at Pearl Harbor if operations continued for 14,300 years.

Projections of the number of occupational accidents that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

No public or occupational radiological health and safety impacts would be expected to result from naval spent nuclear fuel storage area construction activities since the construction would not involve radioactive work.

Attachment F also discusses toxic chemical issues for naval spent nuclear fuel handling and storage. Attachment F concludes that there would be no additional types or volumes of chemicals required at the shipyards or prototype site for naval spent nuclear fuel storage. Therefore, there is no incident-free non-radiological impact resulting from storage of naval spent nuclear fuel at the shipyards or prototype site.

5.1.4.12.3 Incident-free Occupational and Public Health and Safety Effects on Environmental Justice Due to Naval Spent Nuclear Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the management of naval spent nuclear fuel at the Pearl Harbor Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred. The wind directions at Pearl Harbor are variable, but the wind direction which occurs most frequently is toward the southwest, away from land and residential areas. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game since environmental monitoring in the vicinity of this relatively small and restricted site has shown no detectable difference in the amounts of radioactivity present in the environment from levels in similar parts of the region.

To place the impacts on environmental justice in perspective, the risk associated with routine naval spent nuclear fuel management operations under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.1.4.13 Utilities and Energy

If an alternative associated with the storage of naval spent nuclear fuel at Pearl Harbor were to be selected, construction and operation of the storage area would not be expected to require a large expenditure of utilities and energy resources. Construction activities would require quantities of water and electricity typical of any small to medium size construction project. Operation of the storage facility would likely require only small amounts of electricity for lighting and to support industrial equipment necessary to move spent nuclear fuel (e.g., cranes). Alternatives associated with water pool storage would require heating, ventilation, water, and electrical systems suitable for a work environment and to properly filter and exhaust the airborne discharges to the atmosphere. The utility and energy demands would be less than those required to operate ECF (10,000 MWh per year) (Section 5.2.13) since the water pool used for spent fuel storage would be smaller and no spent fuel operations beyond visual examinations would be conducted in the water pool.

The amount of utilities and energy expected to be consumed would be a small incremental increase in the total amount of utilities and energy used at the shipyard and would not result in any discernible environmental consequence.

5.1.4.14 Facility and Transportation Accidents

5.1.4.14.1 Facility Accidents. There has never been an accident in the history of the Naval

Nuclear Propulsion Program that resulted in a significant release of radioactivity to the environment or that resulted in radiation exposure to workers in excess of abnormal occurrence limits on exposures as defined by the U.S. Nuclear Regulatory Commission. A description of potential accidents considered and a summary of the accident analyses that were conducted with regards to the storage of naval spent nuclear fuel is contained in Attachment F.

5.1.4.14.1.1 Radiological Accidents. Section 3.7.3 provides a summary of the impacts

due to the most severe accidents considered for each site. The facility accident with the greatest potential impact at Pearl Harbor involves an airplane crash. An accident of this magnitude would result in a calculated 26 fatal cancers to the general population over 50 years, as described in Attachment F. The likelihood of such an accident occurring is 1 x 10-5, which is very small. For perspective, an accident such as this would not be expected to occur unless the facility operated for about 100,000 years.

5.1.4.14.1.2 Non-radiological Accidents. As discussed in detail in Attachment F, the

limiting hypothetical non-radiological accident for naval spent nuclear fuel storage in a water pool at a shipyard or prototype location would be a diesel fuel spill and fire. A catastrophic failure of a diesel fuel storage tank that might be used for an emergency diesel generator to provide backup electrical power was postulated to occur, resulting in the spilling of the entire quantity of diesel fuel with a subsequent fire. The fire would generate the following toxic chemicals:

- Carbon monoxide
- Oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide)
- Lead
- Sulfur dioxide.

Measures would be taken to reduce the health impacts of potential releases of toxic materials. These measures would involve controls to protect both workers and the general public. The naval shipyard and prototype sites have emergency planning, emergency preparedness, and emergency response programs in place to protect both workers and the public, and involve established resources such as warning communications, fire departments, and emergency command centers.

The airborne concentrations of the combustion products listed above, resulting from the fire, were calculated at the locations of the on-site individuals, an individual at the site boundary, and the general population within a 50-mile radius of the facility. Detailed results are presented in Attachment F. If the accidental fire that has been hypothesized were to actually occur, the safety measures that would be in place would ensure no adverse health impacts to the general public and minimal health impacts to the workers.

5.1.4.14.2 Transportation Accidents.

Shipments of radioactive materials associated with naval spent nuclear fuel have never resulted in any measurable release of radioactivity to the environment (NNPP 1994a). There have never been any significant accidents involving release of radioactive material during shipment since the Naval Nuclear Propulsion Program began. The effects of potential transportation accidents during the various stages of transportation of naval spent nuclear fuel are presented in Attachment A.

The health effects associated with accidents during shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.4.14.3 Other Impacts of Accidents.

In addition to the possible human health effects associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives. The analyses described in Attachment F showed that an area ranging from about 8 acres extending approximately a quarter mile (for an inadvertent criticality accident) to about 110 acres extending approximately 0.9 mile (for a large airplane crashing into a dry storage container) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who live in this area might be evacuated or otherwise experience restrictions in their daily activities for a brief period, and those who work at locations within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure. It should be noted that all of the affected area within about three-quarters of a mile from the spent nuclear fuel facility would be within the boundaries of the federally owned site.

An accident might result in short-term restrictions on access to a relatively small area, but there would be no enduring impacts on cultural or similar resources or concerns such as Native Hawaiian rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area impacted would vary only slightly among the alternatives considered. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with any of the alternatives would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for all alternatives considered. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. There are no endangered or threatened species unique to the area surrounding the federally owned site, so an accident would not be expected to result in destruction of any species for any of the alternatives considered. The effects of accidents related to any of the alternatives and any associated cleanup which might be performed would be localized in a small area extending only a short distance beyond the boundaries of the federally owned site and thus would not be expected to appreciably affect the potential for survival of any endangered or threatened species which might occupy wetlands or other habitat in the area. Based on these considerations, evaluation of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.1.4.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear

Fuel Storage and Handling.
As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the Pearl Harbor Naval Shipyard would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is because the consequences of any accident would depend on the random conditions in effect at the time an accident occurred. The wind directions at Pearl Harbor are variable, but the wind direction which occurs most frequently is toward the southwest, away from land and residential areas.

To place the impacts on environmental justice in perspective, the risk associated with accidents caused by naval spent nuclear fuel management under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.1.4.15 Waste Management

The alternative in which naval spent nuclear fuel is stored at Pearl Harbor would produce limited amounts of solid municipal waste, solid low-level radioactive wastes, and hazardous wastes.
In addition, no transuranic or high-level radioactive wastes would be generated by spent nuclear fuel activities at the site under any alternative. The quantity of industrial wastes generated would be small and most likely consist of industrial cleaning agents of the type normally encountered at the site.
Small quantities of sanitary wastes would result from the additional work force but this volume would be small. The wastes produced from the storage of naval spent nuclear fuel would be controlled and minimized in accordance with the existing waste management programs at Pearl Harbor. The amount of additional wastes generated would be minimal compared to the existing baseline and would not cause any adverse impacts to public health and safety and the environment in the vicinity of Pearl Harbor.

5.1.4.16 Cumulative Impacts

5.1.4.16.1 Radiological Cumulative Impacts. Spent nuclear fuel storage at the site would not result in discharges of radioactivity in liquid effluents during routine operations regardless of the alternative selected. Therefore, there would be no incremental addition of radioactivity to surface or ground water as a result of normal operations for any alternative. For alternatives involving the storage of spent nuclear fuel in dry storage and shipping containers, no airborne radioactivity emissions are expected, so there would be no cumulative air quality impacts associated with these storage methods. Consequently, the only radiological cumulative impacts that would result from dry storage alternatives would be due to direct radiation exposure from the stored containers of spent nuclear fuel.

For alternatives involving the storage of naval spent nuclear fuel in water pools, there would be no discernible direct radiation exposure to the public from the fuel elements due to the shielding provided by the water in the pool. Therefore, any cumulative impacts which would result from water pool storage would be primarily due to airborne emissions, and the addition of these emissions would cause an indiscernible change in the emissions in the area (see Section 5.1.4.7). Current operations at the site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

A summary of the cumulative radiological impacts is provided in the following section.

An overview of the historical radiological impacts from naval nuclear operations at Pearl Harbor and from transportation of naval spent nuclear fuel is provided in Section 4.1.4.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The radiological impacts associated with the alternative where naval spent nuclear fuel would be stored at Pearl Harbor are very small and are described in Section 5.1.4.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the population in the vicinity of Pearl Harbor from all of the alternatives considered would be approximately 5.6 person-rem. This means that there would be much less than one fatal cancer from these operations over the entire 40-year period evaluated. The total exposure to a theoretical maximally exposed off-site individual living at the shipyard boundary for the entire 40-year period would be 8.0 x 10-4 rem due to the alternative resulting in the largest exposure. This maximally exposed off-site individual would have a 4.0 x 10-7 risk of contracting a fatal cancer during his or her lifetime due to storage of spent nuclear fuel. When existing site radiological impacts due to naval nuclear operations are added to the impacts of the most limiting spent nuclear fuel alternative, the exposure to the population would be 6.8 person-rem and to the maximally exposed off-site individual would be 9.2 x 10-4 rem. This still results in much less than one fatal cancer in the population and the risk of the maximally exposed off-site individual contracting a fatal cancer during his or her lifetime is 4.6 x 10-7.

The total exposure related to naval spent nuclear fuel activities to a worker assumed to be working continually 100 meters from the spent nuclear fuel under the alternative resulting in the largest exposure is 8.4 x 10-2 rem accumulated over 40 years. That corresponds to a fatal cancer risk of 3.4 x 10-5 during the worker's lifetime. The exposure to the same worker when existing site radiological impacts due to naval nuclear operations are added to the spent nuclear fuel exposure is essentially the same. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

Sections 4.1.4.14 and 5.1.4.15 describe the management of low-level radioactive waste and mixed waste at the site. The volume of low-level radioactive wastes which would be generated under the alternatives has not been calculated. However, considering the nature of radiological work that would be associated with spent nuclear fuel storage activities, the amount of low-level radioactive waste produced during spent nuclear fuel activities would be much less than 20 percent of the current site generation rate (84 m3 per year). This additional radioactive waste would not introduce any changes to the site's waste management practices. The small amount of additional material involved would not impose any discernible additional stress on the capacity of the radioactive waste burial ground. Therefore, any cumulative impacts associated with the generation and disposal of additional low-level wastes would be very small.

Since no mixed, transuranic, or high-level radioactive wastes would be generated by spent nuclear fuel activities at this site under any alternative, there would be no cumulative impacts associated with these materials.

5.1.4.16.2 Non-radiological Cumulative Impacts.

An overview of the historical non-radiological impacts from naval nuclear operations at Pearl Harbor and from transportation of naval spent nuclear fuel is provided in Section 4.1.4.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no non-radiological cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The non-radiological impacts associated with the alternative where naval spent nuclear fuel would be inspected or stored at Pearl Harbor are described in Section 5.1.4.12, with the detailed results of analyses provided in Attachment F. As summarized in Section 5.1.4.12, there would be no additional chemicals required at the shipyard for naval spent nuclear fuel storage and therefore no non-radiological impacts from normal operations. Consequently, no cumulative impacts to air quality or water resources would result since the incremental addition of chemicals at the shipyard that might result from naval spent fuel activities would be very small. There are no current environmental problems associated with these materials.

The non-radiological cumulative transportation impacts for the population from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A. The non-radiological impacts associated with the transportation and storage of naval spent nuclear fuel for all of the alternatives considered would be low.

No cumulative land use impacts would be expected to occur as a result of spent nuclear fuel storage. The land that would be dedicated for this purpose is on existing federal property and situated in an industrial setting which has already been disturbed from its natural state. The conversion of this space for storage of spent nuclear fuel would not result in the need to disturb undeveloped land or for additional land to be added to the federally owned property in the foreseeable future.

From a socioeconomic perspective, the introduction of naval spent nuclear fuel activities at the site would create a small number of additional jobs and could have a very small cumulative socioeconomic impact. The site currently employs approximately 5000 civilian personnel. No shipyard employment has been associated with spent nuclear fuel activities in the past since spent nuclear fuel activities have not been conducted at the site. An average of approximately 1 to 35 additional jobs might be added as a result of possible spent nuclear fuel activities in the future. The peak number of additional jobs created at the site in any given year would be approximately 88, which is associated with construction and operation of a water pool facility for storage of spent nuclear fuel. Considering that the regional labor force consists of approximately 407,530 workers, the additional number of added jobs under any alternative would have little or no discernible socioeconomic impact. These jobs would be filled either from within the existing site work force or from the available regional labor force without discernible effect. There are no foreseeable future projects planned at the site and no known projects planned in the region that would cause the small number of workers involved in naval spent nuclear fuel activities to become an important impact.

The cumulative impacts associated with non-radiological waste management are likewise expected to be small. As stated previously, any industrial wastes generated from naval spent nuclear fuel storage would be small and limited to industrial cleaning agents of the type normally encountered at the site. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of additional non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of waste.

5.1.4.17 Unavoidable Adverse Effects

There are no discernible unavoidable adverse effects associated with the implementation of any of the alternatives and none which would help to choose among the alternatives. The alternative in which naval spent nuclear fuel is stored at Pearl Harbor would cause the public to be exposed to small amounts of radiation, described in Section 5.1.4.12, and would result in less than one health effect in the entire population surrounding the shipyard. Similarly, continued operation of the storage facility would produce limited amounts of solid municipal waste and solid low-level radioactive waste. These amounts of waste would not produce any major impacts in the vicinity of the shipyard. There will be no changes to the ecological, cultural, geological, and aesthetic resources due to the implementation of any of the alternatives. There would also be no expected impact on ambient noise levels.

5.1.4.18 Irreversible and Irretrievable Commitments of Resources

The only irreversible and irretrievable commitment of resources that results from the alternative in which naval spent nuclear fuel would be stored at Pearl Harbor would be the money which would be spent by the federal government to construct the necessary facilities. The total cost of storing spent naval nuclear fuel at the shipyards and prototype ranges from approximately $1.5 billion to $5.7 billion. This cost represents the total cumulative cost over the 40-year period for all of the shipyards and prototype. This cost includes construction costs of the new storage facilities, and, depending on the alternative selected, the operation of a limited examination facility at Puget Sound Naval Shipyard combined with the costs associated with shutting down ECF, or the operational costs of the INEL-ECF. The major expense in the highest cost alternatives is the procurement of shipping containers. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

5.1.5 KENNETH A. KESSELRING SITE: WEST MILTON, NEW YORK

5.1.5.1 Overview of Environmental Impacts

The following sections discuss the major differences in potential environmental consequences associated with the choice of the alternatives that include storage of naval spent nuclear fuel at the Kenneth A. Kesselring Site. The environmental consequences associated with the storage of naval spent nuclear fuel at the Kesselring Site are based on the estimates of naval spent nuclear fuel that would be stored at the Kesselring Site through the year 2035 and current knowledge of the design features associated with spent fuel storage systems. The review of the environmental consequences associated with these alternatives has shown that the impact on the environment at the Kesselring Site associated with these activities is very small. There would be no impact to the environment in the vicinity of the Kesselring Site associated with any alternatives that do not involve the Kesselring Site.

5.1.5.2 Land Use

Construction of a storage area at the Kesselring Site for temporary storage of naval spent nuclear fuel would require little rearrangement of existing on-site facilities. The area is already an industrial site; therefore, there would be no impact on land use. A description of the alternate storage containers and water pools and their approximate locations is provided in Attachment D. Attachment C provides a comparison of naval spent nuclear fuel storage in water pools versus dry container storage.

No additional land within or outside the Kesselring Site would be required for fuel storage.

Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.1.5.3 Socioeconomics

The calculated number of direct construction and operating jobs that would be required for the 10-year period between 1995 and 2004 for each storage alternative at the Kesselring Site is provided in Table 5.1.5-1. Since there would be no naval spent nuclear fuel storage or inspection activities at the Site under the 1992/1993 Planning Basis and Centralization alternatives, no additional jobs would be required at the Site under these alternatives.

Table 5.1.5-1. Number of construction and operating jobs created at the Kesselring Site for each alternative.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Railcar(1)	1	1	6	1	1	1	1	1	1	1
Immobile Containers on Pads(2)	1	1	1	1	2	6(3)	3	3	3	3
Shipping										

Containers on Pads (2)	1	1	1	1	2	6(3)	1	1	1	1
Water Pools(2)	16	16	43	66	81	58	62	24	24	24

---

(1) Storage mode under the No Action and Decentralization alternatives.
(2) Storage mode under the Decentralization alternative.
(3) The construction jobs would last less than one year.

The only discernible socioeconomic consequence from the alternative of storing naval spent nuclear fuel at the Kesselring Site is that a relatively small number of construction workers (ranging from a few to a maximum of several hundred would be required for construction of the storage area). The work force would consist of skilled craftsmen and unskilled laborers. This work force would be needed during the storage facility construction and would be available from within the area.

The operation of the naval spent nuclear fuel storage area using dry storage containers would require additional workers. Personnel are required to secure fuel in the storage area and to support surveillance and monitoring activities associated with naval spent nuclear fuel storage operations. For the alternative involving storing fuel in immobile dry storage containers, about 20 workers would be required to handle the spent nuclear fuel when it is placed into the storage containers. This work force would normally only be needed when fuel is being inserted into the containers. For the alternative involving shipping containers, fewer workers would be needed to handle and secure the containers in the storage area. If the alternative of storing naval spent nuclear fuel in water pools were selected, approximately 20 workers would be required. These workers would be expected to be supplied from either within the existing Kesselring Site work force or from the local work force. Considering that the Kesselring Site employs approximately 1450 workers, the addition of workers to support the alternatives would have no discernible impact on the local socioeconomic conditions of the Kesselring Site.

For the alternatives where dry storage containers would be manufactured, some additional jobs would be created in the locations where the containers are made. The process of selecting the container manufacturer is subject to federal procurement requirements and would be initiated after the Record of Decision. Consequently, the specific socioeconomic impacts from container fabrication cannot be specified. The net effect of container fabrication would be to create additional jobs and bolster the local economy of the area(s) where containers are made. It is considered unlikely that the selection of the contractor would depend on the alternative storage site selected, so the jobs associated with construction of casks provide no basis for selection of a storage site.

5.1.5.4 Cultural Resources

No site that is listed on the National Register of Historic Places (NPS 1991), any known archaeological areas, or any other cultural resources would be affected by the storage of naval spent nuclear fuel at the Kesselring Site. Therefore, there would be no impact to cultural resources from the alternative of storing naval spent nuclear fuel at the Kesselring Site.

None of the alternatives considered would impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.1.5.5 Aesthetic and Scenic Resources

The naval spent nuclear fuel storage area would be located in an existing area within the security perimeter of the Kesselring Site which is an existing light industrial setting. There would be minor changes to the Site resulting from the storage of spent fuel. No aesthetic or scenic resources in the vicinity of the Site or on the Site would be affected by the operation of the storage area because existing industrial use areas would be used to store the spent fuel. The visual quality of the area would not be affected since the storage area would be compatible with the landscape character of the Kesselring Site. There are no particulate air emissions associated with storage of naval spent nuclear fuel and thus no visibility impacts are expected.

5.1.5.6 Geology

The operation of the naval spent nuclear fuel storage area at the Kesselring Site is not expected to affect the geologic character or resources of the region. If an alternative were selected that required a dry container storage area to be constructed, the ground would only be excavated as necessary to prepare the surface. This would not affect the geological characteristics of the underlying layers nor the characteristics of an aquifer or vadose zone. For the alternative of storing fuel in a water pool facility, the ground surface would need to be excavated to a depth of approximately 40 feet. This excavation would not affect the geological characteristics of the area.

5.1.5.7 Air Resources

5.1.5.7.1 Radiological Consequences.

If the alternative where naval spent nuclear fuel would be stored in dry storage containers were to be selected, no airborne radioactivity releases would be expected to occur as a result of normal storage operations. The naval spent nuclear fuel would be contained such that at least two barriers exist to prevent fission products from becoming airborne. These barriers would retain the naval spent nuclear fuel in an air-tight containment until it is moved to a permanent storage site and there would be no airborne radioactive material released from routine operations for this method of storage. The only radiation exposure would be direct radiation from the array of filled storage containers. The filled storage containers would be fenced off and shielded if necessary such that there would be no distinguishable effect on the current radiation readings at the site perimeter.

For the alternative where naval spent nuclear fuel would be stored in a water pool, airborne radioactivity emissions are expected to be considerably less than that identified for the Idaho National Engineering Laboratory (INEL) Expended Core Facility (ECF) because the water pool size would be smaller, no naval spent nuclear fuel inspection operations beyond visual examinations would be conducted, and no shielded cell operations would be conducted at the Kesselring Site. To conservatively estimate the radiological consequences, airborne releases based on ECF releases from 1991 are used. The radiological source term used and the detailed calculations performed to determine normal releases are provided in Attachment F.

The radiation exposures to human beings due to estimated radionuclide releases to the atmosphere and direct radiation from the stored naval spent nuclear fuel at the Kesselring Site for both the alternative involving water pool storage and the alternative involving dry storage were calculated as described in Attachment F.

A person on the Kesselring Site boundary at the location where the largest exposures would be received was used as the hypothetical maximally exposed off-site individual (MOI) for postulated releases of radioactive material from the stored naval spent nuclear fuel. The population data used to calculate population doses were taken from 1990 census data provided by the U.S. Census Bureau. Meteorology data were obtained as described in Attachment F. Estimated exposures to workers were also calculated.

The hypothetical exposures calculated are based on an exposure to the estimated average effluents and the direct radiation exposure for one year from the naval spent nuclear fuel stored at the Kesselring Site. The calculations include the external effective exposure equivalent from the ground deposition, deposition to surface water, and air immersion pathways and the 50-year committed effective exposure equivalent from internal exposure through the ingestion and inhalation

pathways.
All pathways were considered for the persons potentially exposed, except that the ingestion pathway was omitted for the workers at Kesselring because they do not grow their food on-site. Solubilities which would produce the highest calculated exposures were chosen for internal exposure factors. Values for human dietary consumption patterns were taken from "Age Dependent Values of Dietary Intake for Assessing Human Exposures to Environmental Pollutants" (Rupp 1980). The hypothetical exposures calculated can be converted into a risk of fatal cancer or a risk of non-fatal health detriments (e.g., non-fatal cancers, hereditary defects) based on recommendations of the International Commission on Radiological Protection (ICRP 1991).

Attachment F summarizes the calculated exposures and fatal cancers to the workers, the maximally exposed off-site individual (MOI), and the population from airborne releases of radioactivity and direct radiation exposure in one year for each location and storage mode. Section 3.7 provides a comparison of the annual number of fatal cancers calculated for the general population for each location and alternative.

The number of fatal cancers calculated is so small that there would be essentially no fatal cancers resulting from the storage of naval spent nuclear fuel during the time it could reasonably be expected to continue to be stored. Putting this into perspective, it could be stated that one member of the population might experience a fatal cancer due to incident-free storage of naval spent nuclear fuel at the Kesselring Site if operations continued for 24,400 years.

5.1.5.7.2 Non-radiological Consequences.

As noted in Attachment F, no increase in non-radioactive airborne emissions would be expected to result from naval spent nuclear fuel storage area operations. Storage area operations would not involve use of carcinogenic toxins, criteria pollutants, or other hazardous toxic chemicals except for small quantities of industrial cleaning agents and paint thinner that may be used for housekeeping and cleanliness control and these would be the same as those already used at the Kesselring Site. Consequently, there would be no impact on ambient air quality as a result of implementing any of the alternatives at the Site.

If an alternative were to be selected that required a storage facility to be constructed or renovated, fugitive dust emissions would be expected to result from excavation operations. The quantity of dust generated would be small, consistent with typical excavation activities and controlled within local requirements for dust control.

5.1.5.8 Water Resources

5.1.5.8.1 Radiological Consequences.

Naval spent nuclear fuel storage operations at the Kesselring Site would not result in discharges of radioactive liquid effluents during routine operation regardless of the alternative selected for storage of naval spent nuclear fuel. The health effect due to fallout of nuclides released to the air onto the surface water is included in the analysis results discussed in Section 5.1.5.7. The air fallout impact is so small that there would be no distinguishable radiation levels in the water.

The Kesselring Site does not reside in the 100 or 500 year floodplain. Consequently, the floodplain would not be impacted by spent naval nuclear fuel storage and examination activities at the Site.

5.1.5.8.2 Non-radiological Consequences.

Other than chemicals used to maintain the storage area, no hazardous wastes would be generated by the storage of naval spent nuclear fuel at the Kesselring Site. Any hazardous liquid effluents that may be generated at the storage area would be disposed of at an Environmental Protection Agency approved disposal site.

The only source for liquid discharges from the naval spent nuclear fuel storage operations to the environment consists of storm water runoff which would be consistent with the type of discharges associated with common light industrial facilities and related activities. It can be concluded that there would be no impact to the human environment due to runoff water from the naval spent nuclear fuel storage area.

The increased water usage under any of the alternatives would be negligible compared to the existing Site demand.

5.1.5.9 Ecological Resources

There are no known habitats for threatened or endangered species within the Kesselring Site and no major changes to the industrial environment are planned. Therefore, no ecological impacts to the region would result from selection of any of the alternatives.

The conceptual location where naval spent nuclear fuel would be stored is illustrated in Attachment D. This location is within an existing industrial complex and is surrounded by buildings and paved areas. The industrial nature of the Kesselring Site and the fact that the land has already been disturbed from its natural state by earlier activities mean that plant or animal species sensitive to disturbance by human activities would not be expected to be present. Therefore, there would be no ecological impacts associated with construction or operation of a spent nuclear fuel storage area at this location. The radiological controls that are in effect at the Kesselring Site ensure that the radiation levels in the vicinity of the Site are maintained at or near natural background. Since these same controls would be applied to spent nuclear fuel activities, no ecological effects due to radioactive material would be expected to occur.

5.1.5.10 Noise

The Kesselring Site is an existing light industrial-type environment characterized by noise from truck and automobile traffic; diesel-powered equipment; and continuously operating transmission lines for steam, fuel, water, and related pumping systems for these and other liquids. There would be no increase in ambient noise associated with any of the alternatives. Therefore, no noise impacts would be expected to occur.

5.1.5.11 Traffic and Transportation

Shipments of radioactive materials in the Naval Nuclear Propulsion Program are required to be made in accordance with applicable regulations of the U. S. Department of Transportation, U.S. Department of Energy, and the U.S. Nuclear Regulatory Commission. The purpose of these regulations is to ensure that shipments of radioactive material are adequately controlled to protect the environment and the health and safety of the general public. These regulations are applicable to all radioactive material shipments and provide requirements for the container design, certification, and identification as applicable for the specific quantity, type, and form of radioactive material being shipped. Naval shipping container design requirements invoke shielding and integrity specifications and meet all regulatory requirements. They provide for testing of container designs, training and qualification of workers who construct containers, and quality control inspections during fabrication to ensure that the containers will meet their design requirements. A detailed description of the shipping containers used for naval spent nuclear fuel shipments is provided in Attachment A. A description of the impacts from normal and accident conditions associated with transportation of naval spent nuclear fuel is provided in Attachment A.

5.1.5.11.1 Regional Infrastructure.

The alternatives under consideration are described in Section 3. The No Action alternative or the first variation of the Decentralization alternative would store the naval spent nuclear fuel on-site. This alternative would reduce the number of rail shipments from the shipyard or prototype site compared to the past practice of transporting all naval spent nuclear fuel to INEL. The second variation of the Decentralization alternative would ship about 10 percent of the naval spent nuclear fuel to Puget Sound. This would have some transportation impact, but not as much as transporting all naval spent nuclear fuel off-site. The third Decentralization alternative ships all naval spent nuclear fuel to INEL, examines it, and returns it to the original shipyard or prototype site. This alternative involves more transportation than the previous practice of transporting naval spent nuclear fuel to INEL, since the naval spent nuclear fuel is not returned from INEL to the original site. The 1992/1993 Planning Basis alternative, the Regionalization at INEL alternative, or the Centralization at INEL alternative would involve the same transportation as has been required in the past, namely transportation to INEL and retention there. The Centralization alternative at the Hanford Site would result in more transportation impact than any of the previous alternatives, due to the distances and population distribution between Hanford and the shipyards and prototypes. The Centralization alternative at the Savannah River Site would result in the most transportation impact of naval spent nuclear fuel of any of the alternatives.

5.1.5.11.2 Site Infrastructure.

The alternatives associated with storage of naval spent nuclear fuel at the Kesselring Site would have no impact on local highway traffic because any increase in the work force would represent a very small incremental increase in overall traffic to and from the Site. There would be no change in the internal traffic at the Kesselring Site because naval spent nuclear fuel is temporarily held on-site even when it is transported off-site.

5.1.5.12 Occupational and Public Health and Safety

Detailed analyses of incident-free naval spent nuclear fuel transportation and storage and handling impacts on worker and public health are described in Attachment A (transportation) and Attachment F (storage and inspection). The transportation analysis results, and the storage and handling analysis are summarized separately in the following subsections.

5.1.5.12.1 Incident-free Transportation Occupational and Public Health and Safety.

The radiological and non-radiological effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.5.12.2 Incident-free Occupational and Public Health and Safety During Naval Spent

Nuclear Fuel Storage and Handling.
The public health and safety impacts of radioactivity releases and direct radiation from storage of naval spent nuclear fuel were analyzed as discussed in Section 5.1.5.7 and Attachment F. Attachment F summarizes the results of the analysis of radioactivity releases and direct radiation from stored naval spent nuclear fuel. This analysis shows that the exposure to the worker and maximally exposed off-site individual from stored naval spent nuclear fuel would result in far less than one fatality per year. For perspective, it could be stated that one member of these population groups might experience a fatal cancer due to storage of naval spent nuclear fuel at the Kesselring Site if operations continued for 24,400 years.

Attachment F also discusses toxic chemical issues for naval spent nuclear fuel handling and storage. Attachment F concludes that there would be no additional types or volumes of chemicals required at the shipyards or prototype site for naval spent nuclear fuel storage. Therefore, there is no incident-free non-radiological impact resulting from storage of naval spent nuclear fuel at the shipyards or prototype site.

Projections of the number of occupational accidents that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

No public or occupational radiological health and safety impacts would be expected to result from naval spent nuclear fuel storage area construction activities since the construction would not involve radioactive work.

5.1.5.12.3 Incident-free Occupational and Public Health and Safety Effects on Environ-

mental Justice Due to Naval Spent Nuclear Fuel Storage and Handling.
As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the management of naval spent nuclear fuel at the Kesselring Site would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the Kesselring Site do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game since environmental monitoring in the vicinity of this relatively small and restricted site has shown no detectable difference in the amounts of radioactivity present in the environment from levels in similar parts of the region.

To place the impacts on environmental justice in perspective, the risk associated with routine naval spent nuclear fuel management operations under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.1.5.13 Utilities and Energy

If an alternative associated with storage of naval spent nuclear fuel at the Kesselring Site were to be selected, construction and operation of a naval spent nuclear fuel storage facility would not be expected to require a large expenditure of utilities and energy resources. Operation of the storage facility would likely require only a small amount of electricity for lighting and to support industrial equipment necessary to move spent nuclear fuel containers (cranes etc.). Construction activities would require quantities of water and electricity typical of any small to medium size construction project. Alternatives associated with water pool storage would require heating, ventilation, water, and electrical systems suitable for a work environment and to properly filter and exhaust the airborne discharges to the atmosphere. The utility and energy demands would be less than that required to operate ECF (10,000 MWh per year) (Section 5.2.13) since the water pool for naval spent nuclear fuel storage would be smaller and no inspections would be performed. The amount of utilities and energy expected to be consumed as a result of dry storage would be a small incremental increase in the total amount of utilities and energy used at the Kesselring Site and would not result in any discernible environmental consequences.

5.1.5.14 Facility and Transportation Accidents

5.1.5.14.1 Facility Accidents. There has never been an accident in the history of the Naval

Nuclear Propulsion Program that resulted in a significant release of radioactivity to the environment or that resulted in radiation exposure to workers in excess of abnormal occurrence limits on exposures as defined by the U.S. Nuclear Regulatory Commission. A description of potential accidents considered and a summary of the accident analyses that were conducted with regards to the storage of naval spent nuclear fuel are contained in Attachment F.

5.1.5.14.1.1 Radiological Accidents. Section 3.7.3 provides a summary of the impacts

due to the most severe accidents considered for each site. The facility accident with the greatest potential impact at the Kesselring Site involves an airplane crash. An accident of this magnitude would result in 7.5 fatal cancers to the general population over 50 years, as described in Attachment F. The likelihood of an airplane crash is 1 x 10-7. The facility accident with the greatest risk involves accidental drainage of the water pool. The drained water pool accident would result in less than one fatality over 50 years, but the likelihood of occurrence is 1 x 10-5.

5.1.5.14.1.2 Non-radiological Accidents. As discussed in detail in Attachment F, the

limiting hypothetical non-radiological accident for naval spent nuclear fuel storage in a water pool at a shipyard or prototype location would be a diesel fuel spill and fire. A catastrophic failure of a diesel fuel storage tank that might be used for an emergency diesel generator to provide backup electrical power was postulated to occur, resulting in the spilling of the entire quantity of diesel fuel with a subsequent fire. The fire would generate the following toxic chemicals:

- Carbon monoxide
- Oxides of nitrogen (90% nitric oxide and 10% nitrogen dioxide)
- Lead
- Sulfur dioxide.

Measures would be taken to reduce the health impacts of potential releases of toxic materials. These measures would involve controls to protect both workers and the general public. The naval shipyard and prototype sites have emergency planning, emergency preparedness, and emergency response programs in place to protect both workers and the public, and involve established resources such as warning communications, fire departments, and emergency command centers.

The airborne concentrations of the combustion products listed above, resulting from the fire, were calculated at the locations of the on-site individuals, an individual at the site boundary, and the general population within a 50-mile radius of the facility. Detailed results are presented in Attachment F. If the accidental fire that has been hypothesized were to actually occur, the safety measures that would be in place would ensure no adverse health impacts to the general public and minimal health impacts to the workers.

5.1.5.14.2 Transportation Accidents.

Shipments of radioactive materials associated with naval spent nuclear fuel have never resulted in any measurable release of radioactivity to the environment (NNPP 1994a). There have never been any significant accidents involving the release of radioactive material during shipment since the Naval Nuclear Propulsion Program began. The effects of potential transportation accidents during the various stages of transportation of naval spent nuclear fuel are presented in Attachment A.

The health effects associated with accidents during shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.1.5.14.3 Other Impacts of Accidents.

In addition to the possible human health effects associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives. The analyses described in Attachment F showed that an area ranging from about 8 acres extending approximately a quarter mile (for an inadvertent criticality accident) to about 110 acres extending approximately 0.9 mile (for a large airplane crashing into a dry storage container) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who live in this area might be evacuated or otherwise experience restrictions in their daily activities for a brief period, and those who work at locations within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure. It should be noted that all of the affected area within about three-quarters of a mile from the spent nuclear fuel facility would be inside the boundaries of the Kesselring Site.

An accident might result in short-term restrictions on access to a relatively small area, but there would be no enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area would vary only slightly among the alternatives considered. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with any of the alternatives would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for all alternatives considered. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. There are no endangered or threatened species unique to the area surrounding the federally owned site, so an accident would not be expected to result in destruction of any species for any of the alternatives considered. The effects of any accident related to any of the alternatives and any cleanup which might be performed would be localized in a small area which extends only a short distance beyond the boundaries of the federally owned site and thus would not be expected to appreciably affect the potential for survival of endangered or threatened species which might occupy wetlands or other habitat in the Saratoga area. Consequently, evaluation of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.1.5.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear Fuel Storage and Handling.

As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the Kesselring Site would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is because the consequences of any accident would depend on the random conditions in effect at the time an accident occurred, and the wind directions at the Kesselring Site are highly variable with no strongly dominant direction.

To place the impacts on environmental justice in perspective, the risk associated with accidents caused by naval spent nuclear fuel management under any of the alternatives considered would amount to less than one additional fatality per year for the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.1.5.15 Waste Management

The alternative in which naval spent nuclear fuel is stored at the Kesselring Site would produce limited amounts of solid municipal waste, solid low-level radioactive wastes, and hazardous wastes.
In addition, no transuranic or high-level radioactive wastes would be generated by spent nuclear fuel activities at the Kesselring Site under any alternative. The quantity of industrial wastes generated would be small and most likely consist of industrial cleaning agents of the type normally encountered at the Site. Small quantities of sanitary wastes would result from the additional work force but this volume would be small. The wastes produced from the storage of naval spent nuclear fuel would be controlled and minimized in accordance with the existing waste management programs at the Kesselring Site. The amount of additional wastes generated would be minimal compared to the existing baseline and would not cause any adverse impacts to public health and safety and the environment in the vicinity of the Kesselring Site.

5.1.5.16 Cumulative Impacts

5.1.5.16.1 Radiological Cumulative Impacts. Spent nuclear fuel storage at the Kesselring Site

would not result in discharges of radioactivity in liquid effluents during routine operations regardless of the alternative selected. Therefore, there would be no incremental addition of radioactivity to surface or ground water as a result of normal operations for any alternative. For alternatives involving the storage of spent nuclear fuel in dry storage and shipping containers, no airborne radioactivity emissions are expected, so there would be no cumulative air quality impacts associated with these storage methods. Consequently, the only radiological cumulative impacts that would result from dry storage alternatives would be due to direct radiation exposure from the stored containers of spent nuclear fuel.

For alternatives involving the storage of naval spent nuclear fuel in water pools, there would be no discernible direct radiation exposure to the public from the fuel elements due to the shielding provided by the water in the pool. Therefore, any cumulative impacts which would result from water pool storage would be primarily due to airborne emissions, and the addition of these emissions would cause an indiscernible change in the emissions in the area (see Section 5.1.5.7). Current operations at the site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

A summary of the cumulative radiological impacts is provided in the following section.

An overview of the historical radiological impacts from naval nuclear operations at the Kesselring Site and from transportation of naval spent nuclear fuel is provided in Section 4.1.5.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The radiological impacts associated with the alternatives where naval spent nuclear fuel would be stored at the Kesselring Site are very small and are described in Section 5.1.5.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the population in the vicinity of the Kesselring Site from all of the alternatives considered would be approximately 3.28 person-rem. This means that there would be much less than one fatal cancer from these operations over the entire 40-year period evaluated. The total exposure to a theoretical maximally exposed off-site individual living at the shipyard boundary for the entire 40-year period would be 2.7 x 10-4 rem due to the alternative resulting in the largest exposure. This maximally exposed off-site individual would have a 1.4 x 10-7 risk of contracting a fatal cancer during his or her lifetime due to storage of spent nuclear fuel. When existing site radiological impacts due to naval nuclear operations are added to the impacts of the most limiting spent nuclear fuel alternative, the exposure to the population would be 5.6 person-rem and to the maximally exposed off-site individual would be 4.8 x 10-4 rem. This still results in much less than one fatal cancer in the population and the risk of the maximally exposed off-site individual contracting a fatal cancer during his or her lifetime is 2.4 x 10-7.

The total exposure related to naval spent nuclear fuel activities to a worker assumed to be working continually 100 meters from the spent nuclear fuel under the alternative resulting in the largest exposure is 2.4 x 10-2 rem accumulated over 40 years. That corresponds to a fatal cancer risk of 9.6 x 10-6 during the worker's lifetime. The exposure to the same worker when existing site radiological impacts due to naval nuclear operations are added to the spent nuclear fuel exposure is 2.6 x 10-2 rem over 40 years which corresponds to a fatal cancer risk of 1.1 x 10-5 during the worker's lifetime. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

Sections 4.1.5.14 and 5.1.5.15 describe the management of low-level radioactive waste and mixed waste at the site. The volume of low-level radioactive wastes which would be generated under the alternatives has not been calculated. However, considering the nature of radiological work that would be associated with spent nuclear fuel storage activities, the amount of low-level radioactive waste produced during spent nuclear fuel activities would be much less than 20 percent of the current site generation rate (215 m3 per year). This additional radioactive waste would not introduce any changes to the Site's waste management practices. The small amount of additional material involved would not impose any discernible additional stress on the capacity of the radioactive waste burial ground. Therefore, any cumulative impacts associated with the generation and disposal of additional low-level wastes would be very small.

Since no mixed, transuranic, or high-level radioactive wastes would be generated by spent nuclear fuel activities at the Kesselring Site under any alternative, there would be no cumulative impacts associated with these materials.

5.1.5.16.2 Non-radiological Cumulative Impacts.

An overview of the historical non-radiological impacts from naval nuclear operations at the Kesselring Site and from transportation of naval spent nuclear fuel is provided in Section 4.1.5.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no non-radiological cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The non-radiological impacts associated with the alternative where naval spent nuclear fuel would be inspected or stored at the Kesselring Site are described in Section 5.1.5.12, with the detailed results of analyses provided in Attachment F. As summarized in Section 5.1.5.12, there would be no additional chemicals required at the prototype site for naval spent nuclear fuel storage and therefore no non-radiological impacts from normal operations. Consequently, no cumulative impacts to air quality or water resources would result since the incremental addition of chemicals at the Site that might result from naval spent fuel activities would be very small. There are no current environmental problems associated with these materials.

The non-radiological cumulative transportation impacts for the population from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A. The non-radiological impacts associated with the transportation and storage of naval spent nuclear fuel for all of the alternatives considered would be low.

No cumulative land use impacts would be expected to occur as a result of spent nuclear fuel storage. The land that would be dedicated for this purpose is on existing federal property and situated in an industrial setting which has already been disturbed from its natural state (about 50 acres are developed land). The conversion of this space for storage of spent nuclear fuel would not result in the need to disturb undeveloped land or for additional land to be added to the federally owned property in the foreseeable future.

From a socioeconomic perspective, the introduction of naval spent nuclear fuel activities at the Kesselring Site would create a small number of additional jobs and could have a very small cumulative socioeconomic impact. The site currently employs approximately 1450 civilian personnel. No site employment has been associated with spent nuclear fuel activities in the past since spent nuclear fuel activities have not been conducted at the site. An average of approximately 1 to 24 additional jobs might be added as a result of possible spent nuclear fuel activities in the future. The peak number of additional jobs created at the site in any given year would be approximately 81, which is associated with construction and operation of a water pool facility for storage of spent nuclear fuel. Considering that the regional labor force consists of approximately 176,600 workers, the additional number of added jobs under any alternative would have little or no discernible socioeconomic impact. These jobs would be filled either from within the existing Site work force or from the available regional labor force without discernible effect. There are no foreseeable future projects planned at the Site and no known projects planned in the region that would cause the small number of workers involved in naval spent nuclear fuel activities to become an important impact.

The cumulative impacts associated with non-radiological waste management are likewise expected to be small. As stated previously, any industrial wastes generated from naval spent nuclear fuel storage would be small and limited to industrial cleaning agents of the type normally encountered at the Kesselring Site. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of additional non-radiological wastes generated would not introduce any changes to the Site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of waste.

5.1.5.17 Unavoidable Adverse Effects

There are no discernible unavoidable adverse effects associated with the implementation of any of the alternatives and none which would help to choose among the alternatives. The alternative in which naval spent nuclear fuel is stored at the Kesselring Site would cause the public to be exposed to small amounts of radiation, described in Section 5.1.5.12, and would result in less than one health effect in the entire population surrounding the Kesselring Site. Similarly, continued operation of the storage facility would produce limited amounts of solid municipal waste and solid low-level radioactive waste. These amounts of waste would not produce any major impacts in the vicinity of the Kesselring Site. There will be no changes to the ecological, cultural, geological, and aesthetic resources due to the implementation of any of the alternatives. There would also be no expected impact on ambient noise levels.

5.1.5.18 Irreversible and Irretrievable Commitments of Resources

The only irreversible and irretrievable commitment of resources that results from the alternative in which naval spent nuclear fuel would be stored at the Kesselring Site would be the money that would be spent by the federal government to construct the necessary facilities. The total cost of storing spent naval nuclear fuel at the shipyards and prototype ranges from approximately $1.5 billion to $5.7 billion. This cost represents the total cumulative cost over the 40-year period for all of the shipyards and prototype. This cost includes construction costs of the new storage facilities, and, depending on the alternative selected, the operation of a limited examination facility at Puget Sound Naval Shipyard combined with the costs associated with shutting down ECF, or the operational costs of the INEL-ECF. The major expense in the highest cost alternatives is the procurement of shipping containers. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

5.2 IDAHO NATIONAL ENGINEERING LABORATORY

5.2.1 Overview of Environmental Impacts

The following sections discuss the potential environmental consequences at the Idaho National Engineering Laboratory (INEL) associated with the choice of alternatives for naval spent nuclear fuel management at the Expended Core Facility (ECF). The environmental consequences are based on the fact that the ECF is currently in existence and operating within the perimeter of the Naval Reactors Facility (NRF) at INEL. Volume 1, Appendix B provides an assessment of the environmental impacts at INEL resulting from the full range of spent nuclear fuel activities. This includes the impacts resulting from "ECF-related" activities, which are discussed below (i.e., the impacts resulting from the transportation, receipt, handling, and examination of naval spent nuclear fuel), as well as the impacts associated with the spent nuclear fuel operations at the Idaho Chemical Processing Plant (i.e., the storage of both naval and non-naval spent nuclear fuel and other non-naval spent nuclear fuel operations).

Review of the environmental effects of operation of the Expended Core Facility at INEL for the receipt and examination of naval spent nuclear fuel has shown that the impact on the environment associated with this work is very small. The largest effect in the vicinity of INEL associated with the selection of any alternative for examination of naval fuel is the economic impact of the jobs which are retained or lost at ECF. The differences in all other impacts in the vicinity of INEL for the available alternatives are very small or non-existent.

5.2.2 Land Use

The plan for all three naval plant prototypes at NRF is that they will all be shut down, defueled, and placed in safe storage until they are decommissioned. Operations at the ECF could continue or cease, depending upon the alternative selected. None of the prototype plants or the ECF, if operations cease, is planned to be decommissioned during the next 10 years; therefore, this land will not be available for other uses in the near future. Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.2.3 Socioeconomics

Approximately 500 engineers, technicians, clerical, and maintenance personnel are employed in the receipt and examination of naval spent nuclear fuel at ECF or in direct support of these activities. Table 5.2-1 provides a summary of the direct jobs which would be associated with the ECF if an alternative is selected which closes ECF, while Table 5.2-2 provides a summary of the direct jobs associated with the continued operation of ECF. As shown in Table 5.2-1, there is an increase in workers in the first three years to handle the shipment of containers which had been in storage at the shipyards and prototype during the preparation of this Environmental Impact Statement. The number of workers then decreases steadily to a final caretaker work force of 10. The increase in work force in the first three years shown in Table 5.2-2 includes construction workers for the completion of the Dry Cell Facility in addition to the operations work force increase discussed above.

Table 5.2-1. Summary of direct jobs (closure of INEL-ECF).

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct Jobs	550	550	550	500	350	100	10	10	10	10

Table 5.2-2. Summary of direct jobs (operation of INEL-ECF).

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct Jobs	574	574	550	500	500	500	500	500	500	500

5.2.4 Cultural Resources

None of the alternatives considered would impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.2.5 Aesthetic and Scenic Resources

The entire Naval Reactors Facility is difficult to see from any point accessible to the public so aesthetic and scenic resources in the vicinity of INEL will not be affected by the alternative selected for receipt and handling of naval spent nuclear fuel at ECF. Even if NRF could be observed, the only action which would alter the landscape at NRF is the dry cell extension for spent fuel handling to ECF envisioned under the 1992/1993 Planning Basis alternative and this addition to the existing ECF building would be architecturally compatible with the NRF buildings.

5.2.6 Geology

The geology in the vicinity of the INEL will not be affected by the alternative selected for receipt and handling of naval spent nuclear fuel since no changes which could impact the geology would occur under any of the alternatives.

5.2.7 Air Resources

Small quantities of radioactivity are contained in the air released from ECF and prototype plant operations at NRF. The annual releases from ECF total approximately 1.1 curies, composed primarily of 0.30 curie of krypton-85, 0.70 curie of carbon-14, 0.094 curie of tritium, 0.000011 curie of combined strontium-90 and yttrium-90, and 0.0000048 curie of iodine-131. These releases at NRF would be reduced to near zero if an alternative which ends examination of naval spent nuclear fuel at ECF were selected. This reduction will occur approximately three years after the last fuel is received.

The principal sources of non-radioactive industrial gaseous effluents are air from offices, water vapor from cooling towers, and fuel combustion products from the three steam generating boilers used for heating. Since the boilers are used for generating steam for heating and it would be necessary to heat and maintain the ECF building whether naval spent nuclear fuel is shipped to INEL or not, the airborne effluents at NRF would be little affected by the alternative selected.

Asbestos-containing material is present at NRF, but, as a result of the well-controlled conditions with regard to asbestos at NRF, releases will be unaffected by the alternative selected.

5.2.8 Water Resources

No radioactive liquids are discharged to the environment at NRF. Consequently, the alternative selected would have no effect on releases of radioactive liquids at NRF.

Since the water released to the industrial waste ditch does not include any effluents from ECF, the discharges to the ditch would be unaffected by the choice of alternatives. Operation of ECF produces about 25% of the total NRF sewage discharge and the ECF discharge would be reduced to approximately zero if the people currently performing spent fuel examinations in that facility were no longer employed at NRF.

No hazardous wastes are disposed of at the NRF site and all solid and liquid hazardous wastes are transported by vendors to treatment, storage, and disposal facilities approved by the Environmental Protection Agency and operating under approvals or permits granted by state and federal regulatory agencies. The small amount of hazardous waste produced during ECF operation produces no effect on the environment in the vicinity of INEL, so the alternative selected would have no impact on water quality in this area.

Annual ECF water consumption is about 2.5 million gallons. The alternative selected would have no discernible effect on water usage, because the ground-water withdrawn for ECF operations is small in comparison to the total INEL water consumption. ECF operation has virtually no effect on surface waters.

A flood at ECF due to overflow of any surface water within the INEL boundaries is a low probability event. Flooding of the ECF building is possible should the Mackay Dam fail; however, there is adequate time following the dam break until the flood water reaches NRF to complete emergency procedure preparations. For more information refer to Attachment B.

5.2.9 Ecological Resources

Ecological resources (i.e., the terrestrial ecology, wetlands, aquatic ecology, and endangered and threatened species) in the vicinity of INEL will not be affected by any alternative selected since no additional land at the NRF site will be disturbed under any alternative.

5.2.10 Noise

The small amount of noise generated by work at ECF would cease several years after an alternative which stopped shipment of spent naval nuclear fuel were selected since ECF operations would cease. However, since this noise cannot be discerned beyond the site boundaries, the alternative selected would have no discernible impact on noise in the vicinity of INEL.

The similarly small amount of noise associated with railcar movement produced during shipment of the naval spent nuclear fuel from shipyards to ECF would cause the alternative selected to have no discernible impact on railcar noise generation. This is the case because the less than 50 railcars involved each year represent a minute fraction of the rail traffic in any area affected and the noise is indistinguishable from that produced by other rail traffic.

5.2.11 Traffic and Transportation

Traffic and transportation in the vicinity of INEL associated with naval spent nuclear fuel receipt, handling, and examination would essentially cease if an alternative which ended such operations at ECF were selected. This would cause approximately 400 truck deliveries per year to be eliminated. The reduction in personnel at ECF associated with cessation of these activities would cause approximately 22 fewer buses to be needed to transport them to and from the site each day. None of the alternatives considered would increase traffic or the need for transportation in the vicinity of INEL.

If the ECF operation continues at the INEL, routine shipments of naval spent nuclear fuel would be resumed to the site in certified shipping containers. Low-level waste generated at ECF and hazardous waste would continue to be moved from ECF to a disposal facility.

5.2.12 Occupational and Public Health and Safety

5.2.12.1 Occupational Health and Safety. Radiological and non-radiological impacts of ECF

operations on occupational health and safety are assessed separately in terms of radiological and non-radiological effects.

Radiation exposures to workers at ECF have averaged approximately 100 millirem per year, compared to the limit of 5000 millirem per year specified by The Code of Federal Regulations, Title 10, Part 20. The total radiation exposure to workers at ECF makes up about 30% of the occupational exposure to radiation experienced by workers at NRF. Since only about 280 workers at ECF work in radiological areas and the health risk per worker is estimated to be approximately 0.00040 occurrences of fatal cancer per rem of exposure, less than one fatal cancer (approximately 0.45 fatal cancer estimated) could be expected among all ECF workers throughout the rest of their lives due to operation of ECF for an additional 40 years. This means that radiation effects on the health of INEL workers would be virtually unchanged by the alternative selected for examination of naval spent nuclear fuel.

Operations at ECF have resulted in fewer than 210 days of work lost to injuries in the seven years between 1987 and 1993 out of 736 total lost days of work at NRF during that period. Recordable injuries at ECF represented about 12% of the total number of such injuries at NRF during the same period. Consequently, selection of an alternative which ended operation of ECF at INEL might be expected to reduce injuries to workers at NRF by about 10% to 25% due to the reduction in work force. Operation of a replacement for ECF at another Department of Energy (DOE) site would likely result in roughly the same number of injuries to workers at that facility since the safety record at ECF is very good and similar safe working conditions could be established at the new facility.

Projections of the number of occupational accidents that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

Limited quantities of some materials classified as hazardous chemicals are handled at ECF, but the precautions used during the work prevent exposure of the workers to these materials. Therefore, the alternative selected would not be expected to increase or decrease the exposure of

INEL workers to potentially hazardous chemicals.

5.2.12.2 Public Health and Safety. The impact of NRF operations on public health and safety

can also be assessed separately in terms of radiological and non-radiological effects.

The comprehensive INEL site radiation monitoring program (Hoff et al. 1992) shows that radiation exposure to persons who do not work at INEL resulting from all NRF operations is too small to be measured. In order to provide an estimate of the effects of radiation exposure which might be caused by INEL operations, calculations have been performed of the radiological exposures to the member of the general public who might receive the highest exposure (called the maximally exposed individual), to nearby (collocated) workers, to a worker at ECF located approximately 100 meters from the release point, and to the population surrounding the Idaho National Engineering Laboratory. These calculations include all types of radioactive particles or gases released into the atmosphere from the operation of all existing NRF facilities, including ECF. The calculation results and the analysis methods are provided in more detail in Attachment F.

The calculations indicate the risks are so small that there would be essentially no health effects resulting from radioactivity released by all operations at NRF, including ECF during the time it could reasonably be expected to operate. Putting the risk into perspective, it could be stated that one member of the population might experience a fatal cancer due to combined effects of operation of ECF if operations continued as in the past for 260 million years.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any health effects as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer or detrimental health effect for each alternative. The details of the transportation analysis are provided in Attachment A.

Results of all effluent monitoring confirm that the operation of NRF has no detectable impact on the environment from non-radiological releases (WECNRF 1993). Operations at NRF have had no effect on the groundwater of the Snake River Plain Aquifer, and monitoring results indicate no detectable toxic chemicals, solvents, or laboratory chemicals in the groundwater in the vicinity of NRF. No constituent measured in groundwater in the vicinity of NRF exceeds applicable drinking water standards. The alternative selected for examination of naval spent nuclear fuel would therefore have no effect on non-radiological public health and safety in the vicinity of INEL.

5.2.12.3 Incident-free Occupational and Public Health and Safety Effects on Environ-

mental Justice Due to Naval Spent Nuclear Fuel Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the examination of naval spent nuclear fuel at the INEL would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of activities associated with naval spent nuclear fuel examination under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the INEL do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game because of the very small impacts associated with examination of naval spent nuclear fuel.

To place the impacts on environmental justice in perspective, the risk associated with routine operations for naval spent nuclear fuel examination under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.2.13 Utilities and Energy

Operations at ECF currently consume approximately 10,000 MWh of electricity each year. However, since the ECF building and associated facilities would have to be maintained during the period covered by this Environmental Impact Statement whether ECF is used for naval spent nuclear fuel examination or not and the spent fuel examinations do not consume particularly large amounts of energy, the consumption of electricity and other energy would not be appreciably affected by the alternative selected. None of the alternatives considered would increase the consumption of energy at INEL.

5.2.14 Facility and Transportation Accidents

5.2.14.1 Facility Accidents. There has never been an accident in the history of the Naval

Nuclear Propulsion Program that resulted in a significant release of radioactivity to the environment or that resulted in radiation exposure to workers in excess of normal limits on exposure. Attachment F provides a description of radiological accidents which could occur during water pool and dry cell handling of naval spent nuclear fuel as well as accidents involving toxic chemicals used at ECF. The radiological accidents analyzed for ECF included: (1) an inadvertent criticality caused by an earthquake or similar event, (2) accidental loss of large amounts of water containing radioactive material from a water pool into the ground and then into water sources, and (3) severe damage of spent fuel if it were dropped from a crane during handling or had a heavy object dropped on it. The probability of an accident caused by an airplane crash was calculated for ECF and was determined to be less than 10-7. Due to the low probability, no consequences were calculated for this accident. Calculations of the cancer fatalities which might occur as a result of all the postulated accidents are provided in Attachment F. A comparison of the accident consequences for all alternatives is provided in Section 3.7.

The most limiting of the postulated accidents at ECF was water pool drainage, ultimately resulting in fuel overheating. The exposure to the entire population from this accident is calculated to cause 0.017 cancer fatalities over 50 years, as described in Attachment F.

The exposures to collocated workers following all accidents are well below the naval and DOE 5-rem standard for occupational exposure. However, exposures to the worker located at the ECF site 100 meters from the radiation release point would exceed this standard following an accident resulting in an inadvertent criticality.

Effects from accidents at ECF involving toxic chemicals were evaluated in Attachment F. Due to the amount and types of chemicals stored at ECF, toxic chemicals do not pose a risk to the public or the maximally exposed off-site individual following any of the postulated accidents. However, following the maximum foreseeable accident analyzed (a fire transient), a number of toxic chemicals would exceed Emergency Response Planning Guideline (ERPG) values for workers at ECF.

For maximum off-site individuals at INEL, ERPG-1 values for the toxic chemicals are not exceeded under 50% or 95% meteorology conditions. The concentrations of toxic chemicals following the fire transient as well as a summary of the analysis methods are provided in Attachment F.

5.2.14.2 Transportation Accidents. The health effects associated with accidents during

shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and the hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any health effects as a result of naval spent nuclear fuel and test specimen shipments since the risk estimates are much less than one fatal cancer or detrimental health effect for each alternative. However, the most severe accident, with a likelihood of occurrence greater than 1 x 10-7 events per year, is estimated to result in a maximum of approximately 2 fatalities. The details of the transportation analysis are provided in Attachment A.

5.2.14.3 Other Impacts of Accidents. In addition to the possible human health effects

associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives.
The analyses described in Attachment F showed that for the most severe hypothetical accidents, an area of approximately 8 to 11 acres, extending about 1/4 to 1/3 mile downwind, might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond this distance, exposures would be below 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who work at the federal facilities within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure.

The area affected by the hypothetical accidents would not extend beyond the boundaries of the INEL and, in fact, would not come close to approaching the boundaries. An accident might result in short-term restrictions on access to a relatively small area of the federally owned site, but it would not be expected to produce enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner and in full compliance with applicable laws and regulations. The area would vary only slightly among the alternatives considered.
Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with any of the alternatives would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for all alternatives considered. Similarly, since the areas which might be contaminated by chemicals or radioactive material to measurable levels during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. As previously stated, there are no endangered or threatened species unique to the area surrounding the Expended Core Facility at INEL, so an accident would not be expected to result in destruction of any species for any of the alternatives considered. The effects of accidents associated with any of the alternatives and any cleanup which might be performed would be localized within a small area extending only a short distance from the Expended Core Facility and thus would not be expected to appreciably affect the potential for survival of any species. Consequently, consideration of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.2.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear Fuel

Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the INEL would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

To place the impacts on environmental justice in perspective, the risk from hypothetical accidents associated with naval spent nuclear fuel examination under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.2.15 Waste Management

All non-hazardous solid wastes that cannot be recycled or used by other government agencies are transported to the INEL landfills at the Central Facilities Area. Operation of ECF makes little contribution to these wastes other than the trash associated with the approximately 500 persons who work at that facility. Therefore, the impact in this area at the INEL is little affected by the alternative selected.

The use of hazardous materials in essential applications at ECF results in the generation of some hazardous wastes, including photographic solutions, solutions containing heavy metals, organic solvents, paint-related wastes, and laboratory wastes. All hazardous wastes are transported by vendors to treatment, storage, and disposal facilities approved by the Environmental Protection Agency and operating under approvals or permits granted by state and federal regulatory agencies, and none are disposed of at INEL. When appropriate, wastes are recycled or provided to other federal agencies for use. The small amount of hazardous waste produced from ECF operation would be produced and managed in the same manner if the facility were constructed and operated at an alternate site, so the overall effect on the environment, including that in the vicinity of INEL, is essentially unchanged by the alternative selected.

Operations at ECF contribute approximately 425 cubic meters (15,000 cubic feet) of radioactive solid waste each year and this amount of solid radioactive waste would be reduced by approximately 75% after about three years if an alternative which stopped naval spent nuclear fuel examinations at INEL were selected. No high-level waste and almost no transuranic waste (less than 0.0001 cubic meter per year) are generated from current operations at ECF. None of the alternatives considered would increase the amount of radioactive waste at INEL resulting from naval spent nuclear fuel examinations. The radioactive waste from ECF examinations and related operations would be generated and managed in a similar manner if the facility were constructed and operated at an alternative site. Consequently, the overall effect on the environment is essentially unchanged by the alternative selected.

5.2.16 Cumulative Impacts

Up to this point, Section 5.2 has discussed the potential environmental consequences of operation of the ECF Project at INEL in terms of annual impacts (i.e., radiological exposures and health effects, accident risks, and quantities of wastes that would be generated during operation) based on the maximum annual capacity of the ECF Project. To determine the upper limit for the potential consequences of up to 40 years of future ECF operation (from 1995 to 2035), an evaluation of the accumulated environmental consequences and risks of operating ECF was performed.

5.2.16.1 Radiological Cumulative Impacts. Operation of the INEL-ECF does not result in

discharges of radioactive liquids; therefore, there would be no changes to the surface or ground water as a result of normal operations for any alternative. There are small quantities of radioactivity in the air released from ECF which would contribute to the cumulative air quality impacts. For those alternatives where the ECF is shut down, the cumulative impacts would decrease by the amount of ECF radioactivity releases.

The radiation exposure to the general population since the beginning of operations associated with naval spent nuclear fuel is less than 2 rem, which corresponds to approximately 0.001 cancer fatality. An overview of the historical radiological impacts from naval nuclear operations at the INEL and from transportation of naval spent nuclear fuel is provided in Section 4.2.12 and detailed analyses are provided in Attachments F and A. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The annual radiological impacts associated with the alternatives where naval spent nuclear fuel would be inspected or stored at the ECF at INEL are very small and are described in Section 5.2.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the general public from transportation and from the alternatives considered involving continued operation of the ECF at INEL would be less than 3.5 person-rem. This means that there would be less than 0.0017 fatal cancers from these operations over the entire 40-year period evaluated. The exposure to the maximally exposed off-site individual is calculated to be approximately 0.01 millirem from 40 years of ECF operation. The corresponding risk of a cancer fatality to the maximally exposed off-site individual is 5.2 x 10-9 during his or her lifetime. A worker at the ECF site located 100 meters from the facility would receive less than 3 millirem over 40 years of ECF operation, which corresponds to a 1.1 x 10-6 risk of fatal cancer during the worker's lifetime. Analyses of hypothetical accidents which might occur as a result of these alternatives show that the risk of cancer fatalities is small. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

Cumulative impacts due to radioactive waste generation are expected to be minimal.

Approximately 425 cubic meters of low-level waste are expected to be generated annually by ECF over the next 40 years. This is not expected to affect the INEL waste management program. Very little transuranic and mixed wastes and no high-level waste are generated from ECF operations.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

5.2.16.2 Non-radiological Cumulative Impacts. Cumulative socioeconomic impacts associated

with continued operation of the ECF Project at the INEL are expected to be minor. The INEL currently employs approximately 11,000 people. The ECF operations work force of 500 people would continue to be employed over the long term at INEL if an alternative is selected which would continue naval spent nuclear fuel examination at INEL. If an alternative were selected which resulted in naval fuel no longer being examined at INEL, the reduction in ECF work force would increase the predicted future reductions in work force at INEL by 500 jobs. Considering that the labor force in the region of influence consists of almost 105,000 people, the 500 ECF jobs would be expected to have only a minor impact in the INEL area.

Continued operation of the ECF Project at INEL is not expected to result in any appreciable impacts relative to cumulative non-radiological emissions. Current operations at INEL are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

As discussed in Section 5.2.8, the withdrawal of groundwater for continued ECF operation would be a small percentage of existing water withdrawals at INEL and well within the cumulative capabilities of the local water resources. ECF discharges of non-radioactive and non-hazardous liquid effluents at INEL would not affect water quality. The volume of ECF routine liquid effluents discharged at INEL would also not discernibly increase the impact to the local ecology.

Operation of the ECF has no effect on cumulative land use impacts. NRF occupies less than 0.02% of the approximately 571,000-acre INEL site and no additional land would be disturbed. Even for the options in which ECF is shut down, there would be no cumulative land use impacts since the site would need to be decommissioned and decontaminated before releasing it for other uses and this work would extend beyond the time frame of this study.

The cumulative impacts associated with non-radiological waste management are also small. The volume of hazardous, municipal, and sanitary wastes produced by ECF has not been calculated; however, considering the nature of the work associated with ECF and the number of workers, the amount of hazardous, municipal, and sanitary waste produced has a small effect on the cumulative impacts associated with this waste. For those options in which ECF is shut down, the effect of these wastes on the cumulative impacts is even smaller.

5.2.17 Unavoidable Adverse Effects

Small amounts of radioactivity, described in Section 5.2.12, would be released as a result of spent fuel operations at ECF, resulting in less than one health effect in the entire population surrounding INEL. The effects of these small releases, combined with the other factors described in Section 5.2.16, would produce no discernible cumulative effects. Similarly, continued operation of the facility would produce limited amounts of liquid sanitary waste and solid municipal waste and solid low-level radioactive waste. These amounts of waste would not differ from those produced in the past by operation of ECF and would not produce any major impacts in the vicinity of INEL.

The most important adverse effect in the vicinity of INEL would be the loss of jobs which would occur if an alternative which shut down the Expended Core Facility were chosen. As discussed in Section 5.2.3 above, approximately 500 people at INEL would lose their jobs if such an alternative were selected.

5.2.18 Irreversible and Irretrievable Commitments of Resources

There are few irreversible or irretrievable commitments of resources, other than costs, at INEL associated with the selection of any of the alternatives considered for naval spent nuclear fuel. The total cost of operating the INEL-ECF is approximately $2.6 billion. This cost represents the total cumulative cost over the 40-year period and includes the operations costs for ECF as well as the construction costs for completing the Dry Cell Facility. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

In the event an alternative which resulted in ceasing operations at the Expended Core Facility were selected, decommissioning and decontamination of ECF would not occur immediately. Instead, the facility would be placed in a safe storage condition while the federal government decided on the proper disposition of the facility, planned the disposition, and programmed funds to carry out the disposition. Any disposition of the facility would be conducted in accordance with applicable federal and state regulations.

5.3 SAVANNAH RIVER SITE

5.3.1 Overview of Environmental Impacts

The following sections discuss the potential environmental consequences that would occur if a replacement for the Expended Core Facility (ECF) were constructed and operated at the Department of Energy's Savannah River Site (SRS) or if the Barnwell Nuclear Fuel Plant (hereafter referred to as the Barnwell Plant) that is adjacent to and contiguous with the SRS were operated for this purpose. Both of these subalternatives will be referred to as the Savannah River ECF. The two proposed sites are depicted as Site A and Site B in Figure 4.3-1. Details of receipt, handling, and examination of naval spent nuclear fuel at the SRS and the modifications to the Barnwell Plant are described in Attachment E.

The environmental consequences of locating the ECF at the SRS are based on the same radiological source terms for normal and accidental releases and the estimated ECF atmospheric emissions, liquid effluents, and solid wastes discussed in Section 5.2. Consistent with the scope of a programmatic Environmental Impact Statement, the environmental effects due to normal and accidental releases were evaluated primarily for Site A. Some variations in the exposure to off-site individuals and workers at other SRS facilities would occur for the Barnwell Plant site. The environmental consequences of locating and operating the ECF at SRS would be similar to those for the ECF at the Idaho National Engineering Laboratory (INEL), and none would be large.

5.3.2 Land Use

Construction of a Savannah River ECF Project at Site A would directly affect about 30 acres of land. The Savannah River ECF site considered and its adjacent environs are relatively diverse and contain both pine stands and mixtures of hardwoods. Construction would not disturb any critical or sensitive ecological habitats, nor would it impact wetland areas. Compared to the INEL-ECF site, however, the Savannah River ECF site is considered more ecologically diverse.

The alternative location at the Barnwell Plant is approximately 6 miles from the Site A location. Forest removal at this site has already been completed, and any additional construction is not expected to have any effect on land use.

Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.3.3 Socioeconomics

The potential socioeconomic impacts associated with construction of the Savannah River ECF are expected to be equal to or less than those associated with the original ECF construction at the INEL because (1) a large movement of construction workers from other areas would not be expected for the Savannah River ECF construction due to the availability of construction craft workers within 70 miles of the SRS (Halliburton 1992); and (2) the six counties surrounding the SRS have a population much larger than the INEL area, which would provide a greater capability to absorb any temporary relocation of construction personnel.

Table 5.3-1 provides a summary of the direct jobs which would be required for the construction and operation of the Savannah River ECF during the 10-year period immediately after the Record of Decision. The greatest number of direct jobs would occur in 1999 during the peak of the construction phase. Estimates of the indirect jobs created as well as the effect on area population are included in Section 5.5.3 of Volume 1 as part of either the Regionalization or Centralization at the SRS alternatives.

Table 5.3-1. Summary of direct jobs due to the Savannah River ECF.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct Jobs	20	20	476	825	1033	894	850	500	500	500

During the Savannah River ECF construction period, operations personnel would be hired so that at the end of the construction period, most of the operations workers would be employed. When fully staffed, ECF operation at the SRS would require approximately 500 people, the same number of operating and support personnel as at the INEL-ECF. This would represent less than 3 percent of the total SRS work force. The six-county region of influence around the SRS had a 1990 population of 425,607 persons, or about twice that of the INEL. The larger population base associated with the SRS region would also provide a greater capability to absorb any personnel moving into the area during the construction period; however, the larger economic base of the SRS region (DOE 1988) would also have a greater tendency to diffuse potential economic benefits compared to the ECF Project at the INEL.

Given the small percentage increase in the number of jobs at the SRS attributable to Savannah River ECF operation, the impacts to local government services and community infrastructures are expected to be small. Volume 1 quantifies these effects. The economic benefits to the SRS region are expected to be similar to or less than those for the INEL region as the existing economic base of the SRS region is much greater and more diverse than the INEL region (DOE 1988).

5.3.4 Cultural Resources

None of the alternatives considered would impact known historical, archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.3.5 Aesthetic and Scenic Resources

The construction of the Savannah River ECF at Site A would directly affect 30 acres of land. As a result of its location and industrial characteristics, there is essentially no aesthetic or scenic impact, since the site would not be visible to the public.

No additional land would need to be cleared if the Barnwell Plant were used for an ECF. The building containing the existing water pool would need to be enlarged as part of the modifications discussed in Attachment E; however, the effect on the scenic resources would be minimal.

5.3.6 Geology

5.3.6.1 General Geology. The local geology of the SRS region determines the locations of the

surface waters and groundwaters at the site described in "Reactor Operation Environmental Information Document, Volume I, Geology, Seismology and Subsurface Hydrology" (WSRC 1989). The geology of the SRS region has not been affected by operations conducted at SRS and is not expected to be affected by Savannah River ECF operations.

5.3.6.2 Geologic Resources. The geology of both sites considered has sufficient strength to

support construction of the ECF structures, and operation of the Savannah River ECF is not expected to affect any geologic resources.

5.3.7 Air Resources

Toxic chemicals are used in the normal operations of an ECF. The use of these chemicals is controlled to limit the exposure of workers and the public. Airborne emissions from normal operations include the combustion gases from the boiler house, where fuel oil is burned to make steam from space heating. Emergency diesel generators, which are provided for safety, are operated periodically for test purposes and release exhaust fumes to the atmosphere. These emissions would not have any detectable environmental consequence.

The airborne releases of radioactivity for the Savannah River ECF would be the same as the INEL-ECF described in Section 5.2. The airborne release would result in no measurable exposure to on-site personnel or the general population. Details are provided in Attachment F.

5.3.8 Water Resources

5.3.8.1 Surface Water. Water required for construction of the facility would be withdrawn from

the Savannah River. The small amount of water withdrawn from the Savannah River would be negligible in comparison to the approximately 4.5 million gallons-per-minute flow near the SRS. No new water intake structure would be required.

Expected surface water withdrawals of 2.5 million gallons per year from the Savannah River during Savannah River ECF operations represent small incremental increases in the amount of water currently being withdrawn by on-going SRS operations (23.2 billion gallons annually) and represent a negligible withdrawal in comparison to the average flow of the Savannah River. There would be no discharge of Savannah River ECF liquids to the Savannah River.

5.3.8.2 Groundwater. Sanitary effluents generated during construction would be treated through

either the use of chemical toilets or a wastewater treatment facility. Solid waste generated during construction would be disposed of in the SRS sanitary landfill, which is operated in accordance with State of South Carolina guidelines. Mitigation and control measures for potential spills, fugitive dust, and erosion would be undertaken as part of construction activities.

Sanitary effluents generated as a result of Savannah River ECF operations would be discharged to a wastewater treatment plant. There would be no discharge of radioactive or hazardous liquid effluents to the ground at the Savannah River ECF site. Construction and operation of the Savannah River ECF is not expected to have an effect on the groundwater.

5.3.9 Ecological Resources

5.3.9.1 Terrestrial Ecology. During construction, plant and animal habitats associated with pine

and hardwood vegetation communities would be lost or displaced from the construction site. Additionally, construction may have short-term impacts on wildlife beyond the immediate construction site (i.e., impact on area animals due to construction and traffic noise). However, because the affected land area is small compared to the entire SRS, the impacts on wildlife from construction are expected to be minor.

During construction and operation of the Savannah River ECF, all effluents and emissions would comply with regulatory standards. Due to the level of the emissions described in Attachment F, they are not expected to have an impact on the area wildlife. Operation of the Savannah River ECF should result in less noise and traffic than the construction phase, and no effects on terrestrial ecology are expected from Savannah River ECF operation.

5.3.9.2 Wetlands. The only wetlands located on the proposed Savannah River ECF sites are the

Carolina Bays located at Site A. Because the Carolina Bays are located on the edge of the proposed site, they can be avoided during construction. Construction and operation of the Savannah River ECF would have no discernible impacts on other wetland areas and habitats at the SRS.

5.3.9.3 Aquatic Ecology. Experience has shown that SRS operations (e.g., reactor operation) can

have an adverse effect on the receiving aquatic ecosystems (e.g., L-Lake, Steel Creek, Pen Branch, etc.). However, because there would be no discharge of radioactive or hazardous liquid effluents from Savannah River ECF operation, Savannah River ECF operation is expected to have no effect on the aquatic ecology.

5.3.9.4 Endangered and Threatened Species. The endangered and threatened species are

described in Volume 1, Appendix C. The construction and operation of the Savannah River ECF are not expected to have any environmental impact on the endangered and threatened species found at the SRS.

5.3.10 Noise

The SRS is a large area of about 800 square kilometers (310 square miles). If the alternative involving construction of a new facility were selected, the construction of the Savannah River ECF would cause typical construction noises. There would be little or no noise accompanying normal operations of the Savannah River ECF.

5.3.11 Traffic and Transportation

Traffic and transportation would increase slightly in the SRS area if an ECF is constructed and operated at the SRS. The additional traffic would mainly be due to increased commuter traffic from construction workers and 500 operations workers as well as traffic from material shipments during the Savannah River ECF construction.

If the ECF Project were located at the SRS, routine shipments of naval spent nuclear fuel would be transported to the site in certified shipping containers. Low-level waste generated at the facility and transuranic waste would be moved from the facility to an SRS storage facility.

5.3.12 Occupational and Public Health and Safety

The health and safety assessment of normal operations at the Savannah River ECF was based on managing spent nuclear fuel for examination and storage by either of two approaches (i.e., handling in a water pool or in a dry cell). These are the same methods of spent nuclear fuel handling that have been employed or seriously considered for use at the INEL-ECF. The normal operational impacts associated with the Savannah River ECF would be similar to those for the INEL-ECF. The following sections describe the non-radiological and radiological impacts associated with the Savannah River ECF (refer to Section 5.2 for the INEL-ECF impacts).

5.3.12.1 Occupational Health and Safety. Projections of the number of occupational accidents

that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

During Savannah River ECF construction, workers are not expected to experience elevated background levels of radiation resulting from on-going SRS operations. The gamma radiation measured near the proposed Savannah River ECF site is similar to the radiation levels measured off-site in the SRS area (WSRC 1992). The potential exposure to a construction worker from inhalation of radionuclides released to the atmosphere from existing SRS operations is estimated to be less than 1 millirem per year, which is small compared to the external exposure. The very small exposure received by a construction worker would be well below the naval and Department of Energy (DOE) standard of 5000 millirem per year for occupationally related whole-body and internal exposures.

During operation of the Savannah River ECF, SRS personnel would be exposed to routine atmospheric emissions of radioactivity and might be exposed to potential emissions from accidents. Site A is located approximately 1 mile from the nearest SRS facility, while the Barnwell Plant is located approximately 5 miles from the nearest facility. As shown in Attachment F, no measurable exposure would be received by these collocated workers from normal Savannah River ECF operations. Exposures received by Savannah River ECF radiation workers from normal operations are expected to be similar to the exposures currently received by workers from ECF operation at the INEL, discussed in Section 5.2.12.

5.3.12.2 Public Health and Safety. The impacts of normal operation of the Savannah River ECF

would be similar to those for the INEL-ECF. Normal radiological releases to the atmosphere and the quantities of radioactive and hazardous wastes that would be generated would not differ from those previously discussed for the INEL. However, the location of the project relative to the surrounding SRS population and the distances to facilities that would be involved in routine shipments of material would result in differences in potential environmental consequences. Described below are the impacts to the public associated with operation of the Savannah River ECF (refer to Section 5.2.12 for the INEL-ECF impacts).

Assessment of the normal operations of the Savannah River ECF involved two options: fuel handling in a water pool and dry cell handling of fuel for examination and storage. For both options considered, the potential annual exposures were estimated for five different types of people: a worker at the Savannah River ECF site located 100 meters from the release point, the hypothetical maximally exposed collocated worker on the SRS site, the hypothetical maximally exposed off-site individual (MOI), an individual at the nearest public access (NPA), and the population within 80 kilometers (50 miles) of the Savannah River ECF site. Three pathways were included in the analysis: airborne, waterborne, and direct radiation, as applicable.

The results indicate that either the water pool or the dry cell option would be satisfactory for normal operations since the exposure is so low. The analysis shows that the exposure to all the individuals considered (workers, collocated workers, MOI, and NPA) from Savannah River ECF operations would be much less than 1 millirem per year. For perspective, it could be stated that one member of the entire population might experience a fatal cancer due to Savannah River ECF operations if operations continued for over 50,000 years. A description of the analysis methods and more detailed results are provided in Attachment F. The impacts from normal operations for all alternatives are summarized in Section 3.7.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.3.12.3 Incident-free Occupational and Public Health and Safety Effects on Environ-

mental Justice Due to Naval Spent Nuclear Fuel Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the examination of naval spent nuclear fuel at the SRS would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of activities associated with naval spent nuclear fuel examination under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the SRS do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game because of the very small impacts associated with examination of naval spent nuclear fuel.

To place the impacts on environmental justice in perspective, the risk associated with routine operations for naval spent nuclear fuel examination under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.3.13 Utilities and Energy

Heating, ventilation, and electrical systems appropriate to the needs of the Savannah River ECF for suitable working environments and to properly filter and exhaust the airborne discharges to the atmosphere are estimated to require approximately 10,000 MWh per year for normal operations. Emergency diesel electrical generators would provide 350 kw for life support and crucial facility services during power outages. The amount of energy consumed would be a small fraction of the total energy used at SRS, and no discernible environmental consequence is expected.

5.3.14 Facility and Transportation Accidents

The differences in the potential consequences and risks of accidents of a Savannah River ECF compared to the INEL-ECF are related to the meteorological transport of released material, the population exposure, and the distance of transport. The following sections address the potential accident consequences and risks associated with locating an ECF at the SRS.

5.3.14.1 Facility Accidents. The accident scenarios for the Savannah River ECF are the same as

those considered for the existing ECF at the INEL. These include radiological accidents which could occur during water pool and dry handling of spent nuclear fuel as well as accidents involving toxic chemicals used at ECF. The general types of radiological accidents analyzed included: (1) accidental criticality, (2) water pool drainage, (3) severe mechanical damage of spent fuel, (4) partial loss of shielding, and (5) an airplane crash into the ECF. Calculations of the cancer fatalities which might occur as a result of all the postulated accidents are provided in Attachment F. A comparison of the accident consequences for all alternatives is provided in Section 3.7.

The difference in the calculated consequences for accidents at the Savannah River ECF compared to the INEL-ECF is that the exposure received by the entire population would be greater at the Savannah River ECF due to the larger population within an 80-kilometer (50-mile) radius of the Savannah River ECF project site. Although the exposure received would be greater at the Savannah River ECF, the number of health effects which would result from any of the accidents considered would be small. The most limiting of the postulated accidents for the Savannah River ECF was an airplane crash into a dry cell facility. If this accident were to occur, the exposure to the entire population from this accident is calculated to cause 4.8 cancer fatalities over 50 years, as described in Attachment F. The risk associated with the airplane crash is 0.0000096 fatal cancers per year.

The exposures to collocated workers following all accidents are below the naval and DOE 5-rem standard for occupational exposure under 50% meteorology conditions. However, exposures to the worker located at the Savannah River ECF site 100 meters from the radiation release point would exceed this standard following an accident resulting in an inadvertent criticality and following an airplane crash.

Effects from accidents at the Savannah River ECF involving toxic chemicals are similar to those described in Section 5.2.14 for the existing INEL-ECF. Due to the amount and types of chemicals stored at the ECF site, toxic chemicals do not pose a risk to the public following any of the postulated accidents. However, following the maximum foreseeable accident analyzed (a fire transient), a number of toxic chemicals would exceed Emergency Response Planning Guideline (ERPG) values for workers on the Savannah River ECF site as well as for collocated workers. For the MOI under either 50% or 95% meteorology conditions, toxic chemical levels do not exceed ERPG-2 values with the ECF at Site A and ERPG-3 values if the ECF is at the Barnwell Plant Site. The concentrations of toxic chemicals as well as a summary of the analysis methods are provided in Attachment F.

5.3.14.2 Transportation Accidents. The health effects associated with accidents during

shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any health effects as a result of naval spent nuclear fuel and test specimen shipments since the risk estimates are much less than one fatal cancer or health effect for each alternative. However, the most severe accident, with a likelihood of occurrence greater than 1 x 10-7 events per year, is estimated to result in a maximum of approximately 2 fatalities. The details of the transportation analysis are provided in Attachment A.

5.3.14.3 Other Impacts of Accidents. In addition to the possible human health effects

associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives. The analyses described in Attachment F showed that for the most severe hypothetical accidents, an area of between about 8 acres extending about 1/4 mile downwind (for an accidental criticality) and approximately 210 acres extending about 1 1/4 mile downwind (for a large airplane crash into the fuel examination facility) might be contaminated to the point where exposure could approach 100 millirem per year. Beyond these distances, exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. The area affected by the hypothetical facility accidents would not extend beyond the boundaries of the Savannah River Site. However, if the currently inactive Barnwell Nuclear Fuel Plant were the site of such an accident, the affected area could extend beyond the boundaries of federally owned property. Persons who live in this area might be evacuated or otherwise experience restrictions in their daily activities for a brief period, and those who work at locations within this area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure.

An accident might result in short-term restrictions on access to a relatively small area, but there would be no enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area impacted would vary only slightly among the alternatives. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with an Expended Core Facility at the Savannah River Site would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for an alternative which would relocate the Expended Core Facility to the Savannah River Site. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. As previously stated, there are no endangered or threatened species unique to the area surrounding the location considered for a replacement Expended Core Facility at the Savannah River Site, so an accident would not be expected to result in destruction of any species. The effects of accidents associated with these alternatives or any cleanup which might be performed would be localized in a small area extending only a relatively short distance from the Expended Core Facility and thus would not be expected to appreciably affect the potential for survival of any endangered or threatened species in the Savannah River area. Consequently, consideration of impacts of accidents does not help to distinguish among alternatives.

5.3.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear Fuel

Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the SRS would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

To place the impacts on environmental justice in perspective, the risk from hypothetical accidents associated with naval spent nuclear fuel examination under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.3.15 Waste Management

During Savannah River ECF operation, non-radioactive and non-hazardous solid waste and hazardous solid waste would be generated in quantities similar to those for the INEL-ECF. Non-radioactive, non-hazardous wastes would be managed in a manner identical to that for the INEL-ECF (i.e., non-hazardous, non-radioactive solid wastes would be disposed of at a sanitary landfill). Hazardous wastes would be contained at their point of generation and stored at the SRS. Waste management practices for these wastes would produce no identifiable impact on public health and safety of the environment.

Operation of the ECF at the SRS would generate the same quantities of low-level waste, transuranic waste, and mixed wastes as the INEL-ECF. Low-level waste generated by the Savannah River ECF would be stored at the SRS. The 425 cubic meters of low-level waste generated annually by the ECF Project represents a small quantity when compared to the quantity of low-level waste disposed of at the SRS and would not impact planned disposal operations. No high-level waste would be generated.

Less than 0.0001 cubic meter of transuranic waste per year is generated by current ECF operations at the INEL. Any transuranic waste generated by the Savannah River ECF would be in addition to approximately 10,000 cubic meters currently held in storage at the SRS. Transuranic wastes generated at the Savannah River ECF would be a very small fraction of the SRS transuranic waste generated and would not impact planned SRS waste-handling operations.

Mixed wastes generated by Savannah River ECF operation would be stored at the SRS until treatment and disposal facilities are available. The amount of mixed waste generated would represent a small quantity in relation to the quantities requiring storage or disposal from past and ongoing SRS operations.

5.3.16 Cumulative Impacts

Up to this point, Section 5.3 has discussed the potential environmental consequences of constructing and operating the ECF Project at the SRS in terms of annual impacts (i.e., radiological doses and health effects, accident risks, and quantities of wastes that would be generated during operation) based on the maximum expected annual throughput of the ECF Project. To determine the potential consequences for 40 years of ECF operation (from 1995 to 2035), an evaluation of the accumulated environmental consequences and risks of constructing and operating the Savannah River ECF was performed.

5.3.16.1 Radiological Cumulative Impacts. The Savannah River Site has not been used for

naval spent nuclear fuel operations in the past. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

Operation of the Savannah River ECF will not result in discharges of radioactive liquids;

therefore, there would be no changes to the surface or ground water as a result of normal operations for any alternative. There will be small quantities of radioactivity in the air released from ECF which would contribute to the cumulative air quality impacts.

The annual radiological impacts associated with the alternatives where naval spent nuclear fuel would be inspected or stored at SRS are very small and are described in Section 5.3.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section

3.7.4.

The total exposure to the general public from transportation and from Savannah River ECF operations would be less than 14 person-rem. This means that there would be less than 0.0067 fatal cancers from these operations over the entire 40-year period evaluated. The exposure to the maximally exposed off-site individual would be less than 0.2 millirem from 40 years of Savannah River ECF operation at either Site A or the Barnwell Plant. The corresponding risk of a cancer fatality to the maximally exposed off-site individual is 9.6 x 10-9 at Site A and 7.6 x 10-8 at the Barnwell Plant during his or her lifetime. A worker at the Savannah River ECF site located 100 meters from the facility would receive less than 4 millirem over 40 years of Savannah River ECF operation, which corresponds to a 1.4 x 10-6 risk of fatal cancer during the worker's lifetime. These exposures and cancer risks are as a result of ECF operations only. The exposures and risks corresponding to site-wide operations (including ECF) are discussed in Volume 1, Chapter 5. Analyses of hypothetical accidents which might occur as a result of these alternatives show that the risk of cancer fatalities is small. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

Cumulative impacts due to radioactive waste generation are expected to be minimal. Approximately 425 cubic meters of low-level waste are expected to be generated annually by the Savannah River ECF over the next 40 years. This is not expected to affect the SRS waste management program. Very little transuranic waste or mixed waste and no high-level waste will be generated from Savannah River ECF operations.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

5.3.16.2 Non-radiological Cumulative Impacts. Cumulative socioeconomic impacts associated

with constructing and operating the ECF Project at the SRS are expected to be minor. The SRS currently employs over 20,000 people. In the past, no employment at the SRS has been associated with naval spent nuclear fuel operations. Savannah River ECF operations would provide long-term employment for 500 people at the SRS and would help offset predicted future reductions in the SRS work force (Halliburton 1992). The peak number of additional jobs created at the SRS in any given year would be approximately 1050, which includes both construction and operations workers during the peak of the Savannah River ECF construction effort. Considering that the labor force in the region of influence consists of 209,000 people, the additional number of jobs added from the construction and operation of the Savannah River ECF would be expected to have only a minor socioeconomic impact in the SRS area.

Construction and operation of the ECF Project at the SRS are not expected to result in any discernible impacts relative to cumulative non-radiological emissions. Construction of the ECF Project at either Site A or Site B is sufficiently remote and removed from the nearest SRS boundaries such that concentrations of fugitive emissions from construction would be well below applicable standards, as discussed in Section F.4 of Attachment F. Current operations at the SRS are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

As discussed in Section 5.3.8, the withdrawal of surface water for ECF construction and operation at the SRS would be a small percentage of existing withdrawals and well within the cumulative capabilities of the respective water resources. ECF discharges of non-radioactive and non-hazardous liquid effluents at the SRS would not affect water quality. The volume of ECF routine liquid effluents discharged at SRS would also have no measurable impact on aquatic biota or the wetland habitat.

Minimal cumulative land use impacts would be expected to occur as a result of the construction of a new ECF. The land that would be dedicated for this purpose is on existing federal property. The use of this land would not result in the need for additional land to be added to the federally owned property in the foreseeable future. The SRS occupies an area of approximately 800 square kilometers (310 square miles) with only about 5% of the land occupied by constructed facilities. No land area at the Savannah River Site has been affected by past operations involving naval spent nuclear fuel. Construction of the Savannah River ECF would affect 30 acres of land. This is less than 0.02% of the total Savannah River Site land area.

The cumulative impacts associated with non-radiological waste management are also expected to be small. The volume of hazardous waste produced by ECF has not been calculated; however, considering the nature of the work associated with ECF, the amount of hazardous waste produced would have a small effect on the cumulative impacts associated with this waste. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of wastes.

5.3.17 Unavoidable Adverse Effects

The construction of the ECF Project at the SRS would directly impact about 30 acres of land area. An estimated 30 acres of stands of loblolly pine and mixtures of hardwoods would be cleared as part of construction activities for Site A. For the Barnwell Plant, no land would need to be cleared due to the limited amount of construction required for this site. During construction at Site A, plant and animal habitats associated with pine and hardwood vegetation communities would be lost or displaced.

Construction of the Savannah River ECF would also generate liquid effluents, atmospheric emissions, and solid wastes typical of those for construction of a major industrial facility. All effluents and emissions would be below applicable environmental requirements and would not be expected to result in any major adverse impacts.

During Savannah River ECF operation, non-radioactive and non-hazardous solid waste and hazardous solid waste would be generated in quantities similar to those discussed for the INEL. Non-radioactive and non-hazardous solid waste would be disposed of in the SRS sanitary landfill and off-site in a commercial landfill. Hazardous wastes would be stored at the SRS in storage buildings or on storage pads. The Resource Conservation and Recovery Act regulates these wastes. The amount of hazardous waste generated by Savannah River ECF operation would be small in comparison to the amount of hazardous waste that is generated and currently in interim storage at the SRS. No discernible differences from normal hazardous waste management at the SRS would result from this strategy.

During Savannah River ECF operation, unavoidable radiation exposures would include occupational exposures and exposures to the public from normal atmospheric emissions of radioactive materials that would be minimal compared to criteria contained in the Environmental Protection Agency's 40CFR61 and DOE Order 5480.1B. Sanitary waste and service waste liquid discharges would be below applicable environmental standards. Solid wastes generated during operation, including transuranic, low-level, hazardous, and mixed wastes, would result in small increases in potential exposures to radioactive and hazardous materials. Freon emissions would result in a negligible increase in the risk of skin cancer; substitutes will be used when available.

In general, the unavoidable adverse impacts would be few and limited, and none have been identified that would have a detectable effect on public health and safety. The difference in the impacts between the ECF alternative at SRS and the other DOE sites (INEL, Hanford, Oak Ridge, Nevada Test Site) is not discernible.

5.3.18 Irreversible and Irretrievable Commitments of Resources

During operation of the Savannah River ECF, additional fuel oil would be burned to supply steam for heat. The fuel is not in short supply. The water to be used for the Savannah River ECF would be withdrawn from the Savannah River and would be a negligible amount. No new water intake structure would be required, and no observed impacts have resulted from previous withdrawals. Total consumption of water attributable to water pool operations and consumption of potable water by operating personnel represent less than one-thousandth of a percent of the Savannah River average annual flow.

The total cost of locating a new ECF at Savannah River is approximately $3.5 billion. This cost represents the total cumulative costs over the 40-year period and includes construction and operations costs of the new ECF as well as the costs associated with shutting down the INEL-ECF. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives. This cost would be reduced if the Barnwell Plant were selected.

As is the case with the INEL-ECF, construction and operation of the Savannah River ECF would not require the use or consumption of scarce resources.

5.4 HANFORD SITE

5.4.1 Overview of Environmental Impacts

The following sections discuss the potential environmental consequences that would arise if a facility to replace the Idaho National Engineering Laboratory Expended Core Facility (INEL-ECF) were to be constructed and operated at the Department of Energy (DOE) Hanford Site (Hanford ECF). Two options exist at Hanford: build a new ECF between the 200 West and the 200 East Areas, or modify the existing Fuels and Materials Examination Facility (FMEF) in the 400 Area (see Figure 4.4-1). Details of the receipt, handling, and examination of naval spent nuclear fuel at Hanford and the modifications to the FMEF are described in Attachment E. A detailed discussion of the potential environmental consequences of other actions and alternatives at Hanford is contained in Volume 1, Appendix A.

The environmental consequences of constructing and operating the Hanford ECF are based on the same radiological source terms for normal and accidental releases and the estimated atmospheric emissions, liquid effluents, and solid wastes for the INEL-ECF discussed in Section 4.2.

The environmental consequences for the Hanford ECF would be similar to those for the INEL-ECF (see Section 5.2), and none would be large.

5.4.2 Land Use

The Hanford ECF would use essentially the same land area as that which was affected by construction of the INEL-ECF. The structure itself would occupy approximately 5 acres, and the total affected land area would be approximately 30 acres. The higher elevation of the Hanford ECF location relative to a Probable Maximum Flood would reduce the amount of grading and the resulting atmospheric emissions from construction activities.

The land area that would be affected at the Hanford Site has been dedicated through previous operations as a nuclear materials handling area. The land area affected by construction is of the sagebrush vegetation community typical of the arid Hanford Site region. Land areas disturbed by construction but not affected during operation would revert to the natural sagebrush community.

Native American rights and interests may be affected by construction or operations associated with alternatives that involve construction or modification of facilities at the Hanford Site. DOE is assisting Native Americans who have expressed an interest in renewing their use of some Hanford land-use resources, in accordance with the Treaty of 1855. Details are provided in Volume 1, Appendix A.

5.4.3 Socioeconomics

If the Hanford ECF were to be constructed, the potential socioeconomic impacts associated with construction of the facility are expected to be equal to or less than those that were associated with constructing the existing INEL-ECF because: (1) as at the INEL, a large migration of construction workers into the area would not be expected for constructing the project at the Hanford Site due to the availability of construction craft workers who were formerly involved in construction work at the Hanford Site; and (2) the existing population base within 80 kilometers (50 miles) of the Hanford Site is larger than that surrounding the INEL and would provide a larger capability to absorb the incoming construction workers. The estimates of the social and economic requirements of the operational work force expected to be employed during the construction period are small and similar to those estimated for the INEL. Details are available in Volume 1, Appendix A.

Table 5.4-1 provides a summary of the direct jobs which would be required for the construction and operation of the Hanford ECF during the 10-year period immediately after the Record of Decision. The greatest number of direct jobs would occur in 1999 during the peak of the construction phase. Estimates of the indirect jobs created as well as the effect on area population are included in Section 5.5.1 of Volume 1 as part of either the Regionalization or Centralization at Hanford alternatives.

Table 5.4-1. Summary of direct jobs due to the Hanford ECF.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct Jobs	20	20	476	825	1033	894	850	500	500	500

During the construction period, operations personnel would be hired so that at the end of the construction period, most of the workers required for operation and support would be employed. When fully staffed, operation of the Hanford ECF would require approximately 500 people, the same number of operating and support personnel as operation of the INEL-ECF. The total operating work force would represent about 3 percent of the Hanford Site employment. The potential economic benefits to the area are expected to be similar to those for the INEL area. The benefits would result from the new jobs that would be created and the associated jobs that would become reinforced (DOE 1986a).

With the small percentage increase in the number of jobs at the Hanford Site attributable to Hanford ECF operations, the impacts to local government services and community infrastructures are expected to be small. Volume 1 quantifies these effects. The beneficial economic impacts to the region are expected to be similar to the economic benefits for the INEL region.

5.4.4 Cultural Resources

Construction at this site would neither impact any known archaeological and historic sites nor disturb any known habitats for rare or endangered species. None of the alternatives considered would impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.4.5 Aesthetic and Scenic Resources

The Hanford Site is in a semi-arid region of southeastern Washington. Since 1943, when the site was selected to become the facility for the production of plutonium for the Manhattan Project, the site has been devoted to research, development, and production activities. As a result of its isolated location, its industrial characteristics are not readily visible to the public. The architecture is compatible with the current industrial setting.

5.4.6 Geology

5.4.6.1 General Geology. The local geology of the Hanford region determines the locations of

the surface waters and groundwaters at the site. The geology of the Hanford region is not expected to be affected by the Hanford ECF construction or operations.

5.4.6.2 Geologic Resources. Two geological resources are of particular relevance to the Hanford

Site and to its utility as a location for the Hanford ECF. The water table is located several hundred feet beneath the site. The region between the surface and the water table is an unsaturated zone; it provides an effective barrier between the large aquifer in the groundwater below and the radiological work conducted above. No radiological or hazardous liquid effluent from the Hanford ECF would be discharged to the ground. The operation of the Hanford ECF is not expected to alter the character of the unsaturated zone or the aquifer under the Hanford Site.

5.4.7 Air Resources

The meteorology of the Hanford region is described in Section 4.4.7. There is no potential for the construction and operation of the Hanford ECF to have any impacts on the meteorology of the region.

Consideration of general weather parameters in the Hanford region indicates a high potential for air pollution due to frequent low rates of turbulence or mixing in the atmosphere. The lowest rates of mixing in an atmospheric layer are found in thermally stable layers. Thermally stable conditions occur at Hanford about 44 percent of the time, on the average. Neutral conditions (moderate mixing) occur about 31 percent of the time. The highest rates of mixing (thermally unstable) occur only about 25 percent of the time.

The stagnation that results from low mixing permits an abnormally high concentration of pollutants to accumulate from sources within the region. This applies to ordinary pollutants, such as smoke and other exhaust fumes from regional sources, as well as to airborne emissions from Hanford and a Hanford ECF. The normal emissions from a Hanford ECF would be low enough that the increase that might be accumulated during an inversion would not have any discernible environmental consequence. Less than 1 percent of the total calculated number of fatal cancers in the 80-kilometer (50-mile) population would be due to the normal operations of a Hanford ECF.

Some of the chemicals that are used in the normal operations of an ECF are classified as toxic chemicals. The use of these chemicals is controlled to limit the exposure of workers and the public. Airborne emissions from normal operations include the combustion gases from the boiler house, where fuel is burned to make steam for space heating. Emergency diesel generators are provided for safety, are operated periodically for test purposes, and release exhaust fumes to the atmosphere.

The airborne release of radioactivity for the Hanford ECF would be the same as the INEL-ECF described in Section 5.2. The airborne releases would result in no measurable exposure to on-site personnel or the general public. Details are provided in Attachment F.

Experience with construction activities at Hanford indicates that fugitive dust concentrations at the nearest point of public access and at the site boundaries would be less than the Washington State limits. Standard control techniques such as applying water to the disturbed ground could be used to limit the dust emissions at the construction site.

5.4.8 Water Resources

5.4.8.1 Surface Water. Water required for construction would be withdrawn from the Columbia

River. The amount of water withdrawn from the Columbia River would be negligible in comparison with the 3400 cubic meters per second (120,000 cubic feet per second) annual average flow rate of the river at the Hanford Site. No new water withdrawal intake structure would be required.

Expected surface water withdrawals from the Columbia River during Hanford ECF operations represent small incremental increases in the amount of water currently being withdrawn by ongoing Hanford operations and represent a negligible withdrawal in comparison to the average flow of the Columbia River. There would be no discharge of liquids from the Hanford ECF to either the Columbia or Yakima River.

5.4.8.2 Groundwater. The groundwater at the potential Hanford ECF site is several hundred feet

beneath the surface. This distance provides an ample buffer between the surface operations and the aquifer.

There would be no discharge of radioactive or hazardous liquid effluents from the Hanford ECF to the ground. The existence of contamination in the groundwater due to previous operations at the Hanford Site is discussed in Section 4.4.8.

Sanitary effluents generated during construction would be treated through the use of a septic tank and drain field. Solid non-radioactive and non-hazardous waste resulting from construction would be disposed of on-site at a sanitary landfill. Mitigative and control measures for potential spills and fugitive dust emissions would be undertaken as required.

Sanitary effluents generated as a result of Hanford ECF operations would be discharged to a septic tank located outside of the protected-area fence. Effluent from the septic tank would then be discharged to a sanitary tile field. Other liquid effluents, such as process steam condensate that would be within the limits of DOE and federal standards (DOE 1986b; CFR 1991; CFR 1992a), would be monitored and discharged to a tile field. Liquid effluents meeting these standards and requirements would not result in contamination of groundwater resources.

5.4.9 Ecological Resources

The largest impacts would result from the Centralization alternative. It requires the construction and operation of the Hanford ECF. It is expected that these impacts would be small and similar to those already experienced at Hanford from the construction and operation of other facilities of similar size and scope of operations. The expected impacts are discussed in the following subsections.

5.4.9.1 Terrestrial Ecology. Construction of the Hanford ECF would disturb approximately 30

acres of land, and would permanently occupy 5 acres of land. The remaining land would be revegetated with native grasses. There would be some adverse effect on animal populations, especially the less-mobile animals that might be destroyed during land clearing, but the larger ones would move to another location. The small quantities of radioactivity that would be released are expected to have no effect on man, and are expected to have no effect on the terrestrial organisms. Further discussion is provided in Volume 1, Appendix A.

5.4.9.2 Wetlands. Due to the semi-arid nature of the Hanford environment, there are few affected

wetland areas. They are found along the Columbia River and in local areas at the edges of ponds where the growth of various plants is enhanced. Hanford ECF operations would not have any adverse impact on these areas. Additional information is provided in Volume 1, Appendix A.

5.4.9.3 Aquatic Ecology. There are no aquatic habitats at the potential site for the Hanford ECF.

Hence, there would be no impact on aquatic resources due to construction or operation of the Hanford ECF. Aquatic resources are discussed further in Volume 1, Appendix A. Experience has shown that Hanford operations have not adversely affected its aquatic ecology. The Hanford ECF alternatives are expected to have no adverse impact.

5.4.9.4 Endangered and Threatened Species. Construction and operation of the Hanford ECF

would remove approximately 30 acres of sagebrush habitat until it was revegetated and reestablished after construction. This would impact some members of the species that nest and breed there. Similarly, there would be some impact on vegetation and less-mobile animals, but in general the impacts would be local and the affected animals would be expected to relocate to another suitable habitat on the site. Further discussion and mitigation measures are provided in Volume 1, Appendix A.

5.4.10 Noise

The Hanford Site is a very large area, about 1450 square kilometers (560 square miles), but only about 6 percent of the area is occupied by constructed facilities. Other than the normal noises associated with sparsely spaced industrial facilities and air, rail and road traffic, there is essentially no detectable noise on the site. Construction of the Hanford ECF would cause typical construction noises during the construction period. There would be little or no noise accompanying the normal operations of the Hanford ECF.

5.4.11 Traffic and Transportation

Traffic and transportation would increase slightly in the Hanford area if an ECF is constructed and operated at Hanford. The increased traffic would be mainly due to material shipments during Hanford ECF construction and additional commuter traffic from the construction workers and the operations workers.

The Hanford ECF site would be served by railway and roads. Naval spent nuclear fuel and any irradiated test specimens would be shipped by railway in shielded shipping containers from the shipyard, prototype, or test reactor to the Hanford ECF. There they would be examined and prepared for storage at a DOE facility. Stored fuel and scrap specimens would be stored until they would be shipped to a designated site for disposition. Solid, low-level waste from Hanford ECF handling would be transported by roadway to a Hanford shallow land burial site.

5.4.12 Occupational and Public Health and Safety

The health and safety assessment of normal operations at the Hanford ECF is based on handling spent nuclear fuel for examination and storage by either of two approaches: handling in a water pool or handling in a shielded dry cell. These are the same methods of spent nuclear fuel handling that have been used or were seriously considered for use at the INEL-ECF.

The normal operational impacts associated with the Hanford ECF would be similar to those for the INEL-ECF. The following sections describe the non-radiological and radiological impacts associated with the Hanford ECF (refer to Section 5.2 for the INEL-ECF impacts).

5.4.12.1 Occupational Health and Safety. Projections of the number of occupational accidents

that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

During construction of the Hanford ECF at the Hanford Site, construction personnel would be exposed to a slightly elevated background level of radioactivity resulting from ongoing Hanford Site operations. The maximum additional annual exposure from ongoing operations at the Hanford Site for a construction worker in the vicinity of the 200-East Area would be approximately 2 to 3 millirem if he or she spent 2000 hours per year (40 hours per week for 50 weeks per year) at the Site. This annual exposure of approximately 2 to 3 millirem to a construction worker at the Hanford Site would be well below the DOE standard of 5000 millirem per year for occupational exposure.

During operation of the Hanford ECF, other Hanford personnel would be exposed to routine atmospheric emissions of radioactivity and to potential emissions from accidents. The radiological exposure received by on-site personnel would be below the DOE standard for occupationally related external and internal exposure. Approximately 3000 workers are employed in the 200-East Area within a 1.6-kilometer (l-mile) radius of the Hanford ECF site. Fewer workers are employed near the 400 Area (alternative FMEF site for the Hanford ECF). As shown in Attachment F, the health effects due to exposures received by the collocated worker from normal Hanford ECF operation would be small. Exposures received by Hanford ECF workers are expected to be similar to the exposures that have been received by workers from recent ECF operations at the INEL, discussed in Section 5.2.12.

5.4.12.2 Public Health and Safety. Radiological releases to the atmosphere during normal

operations and the quantities of radioactive and mixed wastes normally generated would be approximately the same as those previously discussed for the INEL. However, the location of the Hanford ECF relative to the surrounding Hanford Site population and the distances to other facilities that would be involved in routine shipments of material would result in small differences in potential environmental consequences.

Assessment of the normal operations of the Hanford ECF involved two options: fuel handling in a water pool or dry cell for examination and storage. For both options considered, the potential annual exposures were estimated for five different types of people: a worker at the Hanford ECF site located 100 meters from the release point, the hypothetical maximally exposed collocated worker on the Hanford Site, the hypothetical maximally exposed off-site individual (MOI), an individual at the nearest public access (NPA), and the population within 80 kilometers (50 miles) of the Hanford ECF site. Three pathways were included in the analysis: airborne, waterborne, and direct radiation, as applicable.

The results indicate that either the water pool or the dry cell option would be satisfactory for normal operations since the exposure is so low. The analysis shows that the exposure to all the individuals considered (workers, collocated workers, MOI, and NPA) from Hanford ECF operations would be much less than 1 millirem per year. For perspective, it could be stated that one member of the entire population might experience a fatal cancer due to Hanford ECF operations if operations continued for over 200,000 years. A description of the analysis methods and more detailed results are provided in Attachment F. The impacts from normal operations for all alternatives are summarized in Section 3.7.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.4.12.3 Incident-free Occupational and Public Health and Safety Effects on Environ-

mental Justice Due to Naval Spent Nuclear Fuel Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the examination of naval spent nuclear fuel at the Hanford Site would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of activities associated with naval spent nuclear fuel examination under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the Hanford Site do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game because of the very small impacts associated with examination of naval spent nuclear fuel.

To place the impacts on environmental justice in perspective, the risk associated with routine operations for naval spent nuclear fuel examination under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.4.13 Utilities and Energy

Heating, ventilation, and electrical systems appropriate to the needs of the Hanford ECF for suitable working environments and to properly filter and exhaust the airborne discharges to the atmosphere are estimated to require approximately 10,000 MWh per year for normal operations. Emergency diesel electrical generators would provide 350 kw for life support and crucial facility services during power outages. The increase in electrical power needs might create the demand for additional capacity. The amount of energy consumed would be a small fraction of the total energy used at the Hanford Site, and no discernible environmental consequence is expected.

5.4.14 Facility and Transportation Accidents

The potential consequences and risks of accidents for the Hanford ECF compared to the INEL-ECF are related to the meteorological transport of released material, the population exposed, and (for the transport of naval spent nuclear fuel and any test specimens) the distance of transport.

The following sections address the major potential accident consequences and risks associated with the Hanford ECF compared to the INEL-ECF.

5.4.14.1 Facility Accidents. The accident scenarios for the Hanford ECF are the same as those

considered for the existing ECF at the INEL. These include radiological accidents which could occur during water pool and dry handling of spent nuclear fuel as well as accidents involving toxic chemicals used at ECF. The radiological accidents analyzed included: (1) an inadvertent criticality caused by an earthquake or similar catastrophic event, (2) accidental loss of large amounts of water containing radioactive material from a water pool into the ground and then into water sources, and (3) severe damage of spent fuel if it were dropped from a crane during handing or had a heavy object dropped on it. The probability of an accident caused by an airplane crash was calculated for the Hanford ECF and was determined to be less than 10-7. Due to the low probability, no consequences were calculated for this accident. Calculations of the cancer fatalities which might occur as a result of all the postulated accidents are provided in Attachment F. A comparison of the accident consequences for all alternatives is provided in Section 3.7.

The difference in the calculated consequences for accidents at the Hanford ECF compared to the INEL-ECF is that the exposure received by the entire population tended to be greater at the Hanford ECF due to the larger population within an 80-kilometer (50-mile) radius of the Hanford ECF project site. Although the exposure received was greater at the Hanford ECF, it is unlikely that any health effects would result from any of the accidents considered. As was the case with the INEL-ECF, the most limiting of the postulated accidents for the Hanford ECF was water pool drainage, ultimately resulting in fuel overheating. The exposure to the entire population from this accident is calculated to cause 0.047 cancer fatalities over 50 years, as described in Attachment F. This amounts to an approximately 5-percent chance of one cancer fatality in 50 years from this potential accident.

The exposures to collocated workers following any accident are well below the naval and DOE 5-rem standard for occupational exposure. However, exposures to the worker located at the Hanford ECF site 100 meters from the radiation release point would exceed this standard following an accident resulting in an inadvertent criticality.

The effects from accidents involving the use of toxic chemicals at the Hanford ECF are similar to those described in Section 5.2.14 for the INEL-ECF. The same amount and types of chemicals stored and used at the INEL-ECF would be used at the Hanford ECF, so toxic chemicals would not pose a risk to the public following any of the postulated accidents. However, following the maximum foreseeable accident analyzed (a fire transient), a number of toxic chemicals would exceed the Emergency Response Planning Guideline (ERPG) values for workers on the Hanford ECF site as well as collocated workers. For the maximum off-site individual (MOI), EPRG-1 values for the toxic chemicals are not exceeded under 50-percent or 95-percent meteorology conditions. The concentrations of toxic chemicals following the fire transient and a summary of the analysis methods are provided in Attachment F.

5.4.14.2 Transportation Accidents. The health effects associated with accidents during

shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancer as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. However, the most severe accident with a likelihood of occurrence greater than 1 x 10-7 events per year is estimated to result in a maximum of approximately 2 cancer fatalities. The details of the transportation analysis are provided in Attachment A.

5.4.14.3 Other Impacts of Accidents. In addition to the possible human health effects

associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives.

The analyses described in Attachment F showed that for the most severe hypothetical accidents, an area of between about 8 acres extending about 1/4 mile downwind (for an accidental criticality) and approximately 210 acres extending about 1 1/4 mile downwind (for a large airplane crash into the fuel examination facility) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. Persons who work at locations within this area might be prevented from going to their jobs at the federally owned facilities until measures had been taken to reduce the potential for exposure.

The area affected by the hypothetical accidents would not extend beyond the boundaries of the federally owned Hanford Site. An accident might result in short-term restrictions on access to a relatively small area, but it would not be expected to produce any enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area would vary only slightly among alternatives. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with an Expended Core Facility at the Hanford Site would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for an alternative which would relocate the Expended Core Facility to the Hanford Site. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, any effects on the ecology would be limited to small areas. As previously stated, there are no endangered or threatened species unique to the area surrounding the location considered for a replacement Expended Core Facility at the Hanford Site, so an accident would not be expected to result in destruction of any species. The effects of accidents related to any of the alternatives and any cleanup which might be performed would be localized in a small area which would not extend beyond a relatively short distance from the Expended Core Facility and thus would not be expected to appreciably affect the potential for survival of endangered or threatened species in the Hanford area. Based on these considerations, evaluation of impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.4.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear Fuel

Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the Hanford Site would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

To place the impacts on environmental justice in perspective, the risk from hypothetical accidents associated with naval spent nuclear fuel examination under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.4.15 Waste Management

During Hanford ECF operations, non-radioactive and non-hazardous solid waste and hazardous solid waste would be generated in quantities similar to those for the INEL-ECF. These wastes would be managed in a manner identical to that for the INEL-ECF (that is, non-hazardous, non-radioactive solid wastes would be disposed of at a sanitary landfill, and hazardous wastes would be contained at their point of generation and transported off-site to an approved treatment, storage, and disposal facility). During normal waste management practices for these wastes, no identifiable impact on public health and safety or the environment would occur.

Operation of the Hanford ECF would generate essentially the same quantities of low-level waste, transuranic waste, and mixed wastes as discussed for the INEL. Additional information on materials and waste management at Hanford is provided in Volume 1, Appendix A.

5.4.16 Cumulative Impacts

The potential environmental consequences of constructing and operating the Hanford ECF are discussed above in terms of annual impacts (that is, radiological exposures and health effects, accident risks, and quantities of wastes that would be generated during operation) based on the evaluation of operating experiences at the INEL-ECF. This section provides a discussion of the potential consequences of up to 40 years of operation of the Hanford ECF (from 1995 to 2035).

5.4.16.1 Radiological Cumulative Impacts. Operation of the Hanford ECF would not result in

discharges of radioactive liquids; therefore, there would be no changes to the surface or ground water as a result of normal operations for any alternative. There would be small quantities of radioactivity in the air released from the Hanford ECF which would contribute to the cumulative air quality impacts. The Hanford Site has not been used for naval spent nuclear fuel operations in the past. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The annual radiological impacts associated with the alternatives where naval spent nuclear fuel would be inspected or stored at Hanford Site are very small and are described in Section 5.4.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the general public from transportation and from Hanford ECF operations would be about 5 person-rem. This means that there would be about 0.0025 fatal cancers from these operations over the entire 40-year period evaluated. The exposure to the maximally exposed off-site individual would be less than 0.02 millirem from 40 years of Hanford ECF operation at either the 200 Area or the FMEF. The corresponding risk of a cancer fatality to the maximally exposed off-site individual is 4.8 x 10-9 at the 200 Area and 8.8 x 10-9 at the FMEF during his or her lifetime. A worker at the Hanford ECF site located 100 meters from the facility would receive less than 4 millirem over 40 years of Hanford ECF operation, which corresponds to a 1.4 x 10-6 risk of fatal cancer during the worker's lifetime. These exposures and cancer risks are as a result of ECF operations only. The exposures and risks corresponding to site-wide operations (including ECF) are discussed in Volume 1, Chapter 5. Analyses of hypothetical accidents which might occur as a result of these alternatives show that the risk of cancer fatalities is small. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

Cumulative impacts due to radioactive waste generation are expected to be minimal. Approximately 425 cubic meters of low-level waste are expected to be generated annually by the Hanford ECF over the next 40 years. This is not expected to affect the Hanford waste management program. Very little transuranic waste or mixed waste and no high-level waste will be generated from Hanford ECF operations.

5.4.16.2 Non-radiological Cumulative Impacts. The cumulative socioeconomic impacts

associated with constructing and operating the Hanford ECF are expected to be small. The Hanford Site currently employs over 18,000 people. In the past, no employment at the Hanford Site has been associated with naval spent nuclear fuel operations. Hanford ECF operations would provide long-term employment for 500 people at the Hanford Site. The peak number of additional jobs created at the Hanford Site in any given year would be approximately 1050, which includes both construction and operations workers during the peak of the Hanford ECF construction effort. Considering that the labor force in the region of influence consists of approximately 88,000 people, the additional number of jobs added from the construction and operation of the Hanford ECF would be expected to have only a minor socioeconomic impact in the Hanford area.

Construction and operation of the Hanford ECF are not expected to result in any impacts from cumulative hazardous or toxic emissions. Construction would be sufficiently remote from the nearest site boundaries such that concentrations of any fugitive construction emissions would be well below applicable standards, as discussed in Section F.4 of Attachment F. Current operations at the Hanford Site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

As discussed in Section 5.4.8, the withdrawal of surface water for construction and operation of the Hanford ECF would be a small percentage of existing withdrawals and well within the cumulative capabilities of the respective water resources. Discharges of ECF non-radioactive and non-hazardous liquid effluents to tile fields at the Hanford Site are not expected to impact groundwater quality (that is, either of itself or on a cumulative basis).

Minimal cumulative land use impacts would be expected to occur as a result of the construction of a new ECF at Hanford. The land that would be dedicated for this purpose is on existing federal property. The use of this land would not result in the need for additional land to be added to the federally owned property in the foreseeable future. The Hanford Site occupies an area of approximately 1450 square kilometers (560 square miles) with only about 6% of the land occupied by constructed facilities. No land area at the Hanford Site has been affected by past operations involving naval spent nuclear fuel. Construction of the Hanford ECF would affect 30 acres of land. This is less than 0.01% of the total Hanford Site land area.

The cumulative impacts associated with non-radiological waste management are expected to be small. The volume of hazardous waste produced by ECF has not been calculated; however, considering the nature of the work associated with ECF, the amount of hazardous waste produced would have a small effect on the cumulative impacts associated with this waste. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of wastes.

5.4.17 Unavoidable Adverse Effects

Construction of the Hanford ECF would directly impact a total of about 120,000 square meters (30 acres) of land area previously dedicated to the handling of nuclear materials, and approximately 400,000 square meters (100 acres) outside the protected site area for the construction of a transmission line and tile field. During construction, plant and animal habitats associated with a sagebrush vegetation community would be lost or displaced from areas not previously disturbed. None of the land area outside the protected site area associated with the construction of the transmission line and less than half of the land area within the protected site area would be affected by operation; the rest would revert to a sagebrush vegetation community through natural plant succession. Modification of the FMEF would have lesser impacts because the construction work would be less extensive. Refer to Attachment E for details.

Construction of the Hanford ECF would also generate liquid effluents, atmospheric emissions, and solid wastes typical of those for construction of a major industrial facility. All effluents and emissions would be below applicable environmental requirements and would not be expected to result in any adverse impact.

During operation of the Hanford ECF, unavoidable radiation exposures would include occupational exposures and exposures to the public from normal atmospheric emissions of radioactive materials that would be minimal compared to the criteria imposed by the "Environment, Safety, and Health Program for Department of Energy Operations" (DOE 1986b) and the "National Emission Standard for Hazardous Air Pollutants" (CFR 1992b). Sanitary and service waste liquid discharges that would eventually be discharged to the soil column through tile fields would all be below applicable environmental standards, including radioactivity standards for drinking water. Solid wastes generated during operation, including transuranic, low-level, hazardous, and mixed wastes, would result in small increases in potential exposures to radioactive and hazardous materials. Freon emissions would be controlled, but might result in a negligible increase in the risk of skin cancer; substitutes would be used when available.

In general, the unavoidable adverse impacts would be few and limited, and none have been identified that would affect public health and safety.

5.4.18 Irreversible and Irretrievable Commitments of Resources

During operation of the Hanford ECF, additional fuel would be burned to supply steam, similar to the levels experienced at the INEL-ECF. The water to be used for the Hanford ECF would be withdrawn from the Columbia River. The amount of water that would be withdrawn from the Columbia River would be negligible. No new water withdrawal intake structure would be required and no observed impacts have resulted from previous withdrawals. Total consumption of water attributable to water pool operations and consumption of potable water by operating personnel represent less than one-thousandth of a percent of the Columbia River average flow rate.

The total cost of locating a new ECF at Hanford would be approximately $3.4 billion. This cost represents the total cumulative cost over the 40-year period and includes construction and operations costs of the new ECF as well as the cost associated with shutting down the INEL-ECF. If the FMEF were to be modified for use as the Hanford ECF, the cost would be less. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

Construction and operation of the Hanford ECF would not require the use or consumption of scarce resources. Expected withdrawals of surface water and groundwater during construction and operation would represent small incremental increases in the amounts of water being withdrawn by ongoing Hanford operations.

5.5 OAK RIDGE RESERVATION

5.5.1 Overview of Environmental Impacts

The following sections discuss the potential environmental consequences that would occur if a replacement for the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) were constructed and operated at the Department of Energy's Oak Ridge Reservation (ORR). This replacement will be referred to as Oak Ridge ECF. The new ECF would be sited near the K-25 Site which is located on the western portion of the ORR (see Figure 4.5-1 of Section 4.5).

The environmental consequences of locating and operating the ECF at ORR are based on the same radiological source terms for normal and accidental releases and the estimated atmospheric emissions, liquid effluents, and solid wastes discussed in Section 5.2 for the ECF at INEL. The environmental consequences of locating and operating the ECF at ORR would be similar to those for the ECF at INEL, and none would be large.

5.5.2 Land Use

Construction of an ECF at ORR would directly affect about 30 acres of land near the already highly developed K-25 Site area. Site preparation for construction would disturb areas of natural vegetation cover which primarily include oak/hickory forest land. The direct loss of terrestrial habitat would be minimized to the extent practical. Following completion of construction, the grounds around the ECF would be landscaped with trees and shrubbery in a manner consistent with other facilities in the K-25 Site area. The affected land area is very small compared to the entire ORR.
Native American rights and interests would not be modified by construction or operation of the Oak Ridge ECF.

5.5.3 Socioeconomics

The potential socioeconomic impacts associated with construction of the ECF at ORR are expected to be equal to or less than those associated with the original ECF construction at INEL because (1) a large movement of construction workers from other areas would not be expected for the Oak Ridge ECF construction due to the availability of construction craft workers in the ORR region and (2) the existing population base within 80 kilometers (50 miles) of the ORR is larger than that surrounding the INEL area and would provide a greater capability to absorb the incoming construction personnel.

Table 5.5-1 provides a summary of the direct jobs which would be associated with construction and operation of the Oak Ridge ECF during the 10-year period immediately following the Record of Decision. The greatest number of direct jobs would occur in 1999 during the peak of the construction phase. Estimates of the indirect jobs created as well as the effect on area population are included in Chapter 5 of Volume 1 for Regionalization at the ORR and for Centralization at the ORR.

Table 5.5-1. Summary of direct jobs due to Oak Ridge ECF construction and operation.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct Jobs	20	20	476	825	1033	894	850	500	500	500

During the Oak Ridge ECF construction period, operations workers would be hired so that at the end of the construction period, most of the 500 operations personnel would be employed. The percentage of operations workers expected to move into the area from other areas varies based on skill requirements. Overall, approximately 20 percent are estimated to move into the ORR area. The four-county region of influence around the ORR had a 1990 population of 489,230 persons, or more than twice that of the INEL.

ECF operations at the ORR would require essentially the same number of operations personnel as at the INEL. This would represent less than 3 percent of the total ORR work force. Given an average family size of 2.6 persons per household for operations personnel moving into the area, the expected population increase attributable to operations personnel would represent about 14 percent of the average annual growth rate from 1980 to 1990 in the ORR's four-county region of influence. This percentage of population increase attributable to Oak Ridge ECF operations in relation to normal population increases in the ORR region might have a short-term, minor impact on local government services and community infrastructures. The economic benefits to the ORR region are expected to be similar to or less than those for the INEL region since the existing economic base of the ORR region is greater and more diverse than that of the INEL region.

5.5.4 Cultural Resources

Construction or operation of the Oak Ridge ECF would not impact known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.5.5 Aesthetic and Scenic Resources

Construction of the Oak Ridge ECF would directly affect 30 acres of land. The proposed facility would be seen from Bear Creek Road as being completely surrounded by undeveloped areas. The forested ridges to the northwest and southeast of this area reduce its visibility from privately owned lands, so that impacts to aesthetic and scenic resources would be minor.

5.5.6 Geology

5.5.6.1 General Geology. Although some ripping or blasting of limestone, dolomite, or quartz

layers could be necessary to construct the ECF, no unique geological features would be affected. There are no mining activities in this vicinity that could be impacted by ECF construction or operation. Previously disturbed areas would be regraded to accommodate the new ECF. Sediment runoff from such land disturbances would be minimized by implementation of soil erosion and sediment control measures.

5.5.6.2 Geologic Resources. Since no extensive or unique geologic or mineral resources are

known to occur near the K-25 Site, impacts to such resources from ECF construction or operation would not be expected.

5.5.7 Air Resources

Minor short-term emissions of fugitive dust and exhaust from heavy equipment would be possible during Oak Ridge ECF construction. The use of toxic chemicals during ECF normal operations is controlled to limit the exposure of workers and the public. Airborne emissions from normal operations would include the combustion gases from the boiler house, where fuel would be burned to make steam for space heating. Emergency diesel generators, which would be provided for safety, would be operated periodically for test purposes and release exhaust fumes to the atmosphere. The environmental impacts of these emissions would be negligible.

The airborne releases of radioactivity for the ECF at ORR would be the same as for the ECF at INEL described in Section 5.2. The airborne release would result in no measurable exposure to on-site personnel or the general population. Details are provided in Attachment F.

5.5.8 Water Resources

5.5.8.1 Surface Water. Water required for construction of the Oak Ridge ECF would be withdrawn from the Clinch River. The small amount of water withdrawn would be negligible in comparison to the approximately 1.29 x 1010 liters (3.40 x 109 gallons) per day flow at the Melton Hill Dam. No new water intake structure would be required.

The 2.5 million gallons per year additional surface water withdrawal from the Clinch River during Oak Ridge ECF operations would represent a very small increase in the 6.93 x 107 liters (1.83 x 107 gallons) per day currently being withdrawn by ongoing ORR operations and represent a negligible withdrawal in comparison to the average flow of the Clinch River.

Liquid discharges from the Oak Ridge ECF would be treated by a wastewater treatment plant which would be built to service the new DOE spent nuclear fuel facilities. Discharges of treated wastewater to area receiving waters would be in accordance with applicable National Pollutant Discharge Elimination System effluent limits. These discharges would have a negligible impact on the receiving water system. Design controls would render spills and leaks that could contaminate surface or groundwater unlikely.

The Oak Ridge ECF would not be located within the 500-year floodplain.

5.5.8.2 Groundwater. No groundwater would be used for construction and operation of the Oak Ridge ECF, given the plentiful surface water supplies. Therefore, no impact on groundwater levels or quantity is expected. Because there would be no direct discharge of process water to groundwater, and because wastewater would be treated prior to a National Pollutant Discharge Elimination System-permitted discharge to surface waters, no impacts on groundwater are expected.

5.5.9 Ecological Resources

5.5.9.1 Terrestrial Ecology. Areas of natural vegetation cover which primarily include oak/hickory forest land would be disturbed for the Oak Ridge ECF. The loss of terrestrial habitats would be minimized to the extent practical. Construction and traffic noise might have a short-term, minor impact on wildlife beyond the immediate construction site.

During construction and operation of the Oak Ridge ECF, all effluents and emissions would comply with regulatory standards and are not expected to have an impact on the area wildlife. Operation of the Oak Ridge ECF should result in less noise and traffic than the construction phase, and no effects on terrestrial ecology are expected from Oak Ridge ECF operations.

5.5.9.2 Wetlands. Construction of the Oak Ridge ECF may displace forested wetlands adjacent to tributaries of Grassy Creek flowing near the proposed site. This displacement of wetlands would be accomplished in accordance with Corps of Engineers and Tennessee Water Quality Control Administration requirements.

5.5.9.3 Aquatic Ecology. Aquatic habitat would be affected by the rechanneling of tributaries to Grassy Creek during construction of the Oak Ridge ECF. Minor increases in water withdrawal from the Clinch River and water discharged to its tributaries would not greatly affect the aquatic ecology of these water bodies. All wastewater would be discharged in compliance with National Pollutant Discharge Elimination System permit limitations.

5.5.9.4 Endangered and Threatened Species. No known terrestrial or aquatic areas potentially

providing habitat to federally listed or state listed threatened or endangered species are found in the construction area; consequently, impacts to threatened and endangered species are not expected to be a concern.

5.5.10 Noise

Noises generated on the ORR do not propagate off-site at levels that impact the general population. Noise increases outside the ORR due to the Oak Ridge ECF would be limited to those produced by truck, car, and train traffic on roads and railroads approaching the ORR. These increases would not be large enough to be objectionable to the communities bordering the roads and railroads.

5.5.11 Traffic and Transportation

Traffic and transportation would increase slightly in the ORR area if an ECF were constructed and operated at ORR. The additional traffic would mainly be due to increased commuter traffic from construction workers and 500 operations workers as well as traffic from material shipments during Oak Ridge ECF construction and operation.

If the Oak Ridge ECF were established, naval spent nuclear fuel would be routinely transported to the ORR in certified shipping containers. Various types of wastes generated at the ECF would be dispositioned on-site and off-site. Following examination, most of the spent nuclear fuel would be transferred to the spent fuel storage location at ORR until the time that permanent geologic storage becomes available.

5.5.12 Occupational and Public Health and Safety

The health and safety assessment of normal operations at the Oak Ridge ECF was based on handling and examination of naval spent nuclear fuel either in a water pool or in a dry cell. These are the same methods of spent nuclear fuel handling that have been employed or seriously considered for use at the ECF at INEL. The normal operational impacts associated with the ECF at ORR would be similar to those for the ECF at INEL. The following sections describe the non-radiological and radiological impacts associated with the ECF at ORR (refer to Section 5.2 for the ECF at INEL impacts).

5.5.12.1 Occupational Health and Safety. Projections of the number of occupational accidents

that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

During Oak Ridge ECF construction, workers are not expected to experience elevated background levels of radiation resulting from ongoing ORR operations. The potential exposure to a construction worker from inhalation of radionuclides released to the atmosphere from existing ORR operations is expected to be small compared to the external exposure. The exposure received by a construction worker would be well below the naval and Department of Energy (DOE) standard of 5000 millirem per year for occupationally related whole-body and internal exposures.

During operation of the Oak Ridge ECF, ORR personnel would be exposed to routine atmospheric emissions of radioactivity and might be exposed to potential emissions from accidents. The Oak Ridge ECF site is located approximately 1 mile from the nearest ORR facility. As shown in Attachment F, no measurable exposure would be received by these collocated workers from normal Oak Ridge ECF operations. Exposures received by radiation workers from normal operation of the ECF at ORR are expected to be similar to the exposures currently received by workers from normal operation of the ECF at INEL, discussed in Section 5.2.12.

Exposures, injuries, and potential fatalities to workers at the Oak Ridge ECF could also occur as a result of accidents during ECF operations. However, the safety record of the ECF at INEL is very good, and similar safe working conditions could be established at the new facility.

5.5.12.2 Public Health and Safety. The impacts of normal operation of the ECF at ORR would

be similar to those for the ECF at INEL. Normal radiological releases to the atmosphere and the quantities of radioactive and hazardous wastes that would be generated would not differ from those previously discussed for the INEL. However, location of the ECF relative to the surrounding ORR population and the distances to facilities that would be involved in routine shipments of material would result in differences in potential environmental consequences. Described below are the impacts to the public associated with operation of the ECF at ORR (refer to Section 5.2.12 for the ECF at INEL impacts).

Assessment of normal operation of the Oak Ridge ECF involved handling and examination of spent fuel either in a water pool or in a dry cell. For both cases, the potential annual exposures were estimated for five different types of people: a worker at the Oak Ridge ECF site located 100 meters from the release point, the hypothetical maximally exposed collocated worker on the ORR site, the hypothetical maximally exposed off-site individual, an individual at the nearest public access, and the population within 80 kilometers (50 miles) of the Oak Ridge ECF site. Three pathways were included in the analysis: airborne, waterborne, and direct radiation, as applicable.

The results indicate that handling and examination of spent fuel either in a water pool or in a dry cell would be satisfactory for normal operations since the exposure is so low. The analysis shows that the exposure to all the individuals considered (workers, collocated workers, and off-site individuals) from Oak Ridge ECF operations would be much less than 1 millirem per year. For perspective, it could be stated that one member of the entire population might experience a fatal cancer due to Oak Ridge ECF operations if operations continued for 20,000 years. A description of the analysis methods and more detailed results are provided in Attachment F. The impacts from normal operations for all alternatives are summarized in Section 3.7.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.5.12.3 Incident-free Occupational and Public Health and Safety Effects on Environ-

mental Justice Due to Naval Spent Nuclear Fuel Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the examination of naval spent nuclear fuel at the ORR would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of activities associated with naval spent nuclear fuel examination under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the ORR do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game because of the very small impacts associated with examination of naval spent nuclear fuel.

To place the impacts on environmental justice in perspective, the risk associated with routine operations for naval spent nuclear fuel examination under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.5.13 Utilities and Energy

Heating, ventilation, and electrical systems appropriate to the needs of the Oak Ridge ECF for suitable working environments and to properly filter and exhaust the airborne discharges to the atmosphere are estimated to require approximately 10,000 MWh per year for normal operations. Emergency diesel electrical generators would provide 350 kw for life support and crucial facility services during power outages. The amount of energy consumed would be a small fraction of the total energy used at ORR and no discernible environmental consequence is expected.

5.5.14 Facility and Transportation Accidents

The differences in the potential consequences and risks of accidents at the ECF at Oak Ridge compared to the ECF at INEL are related to the meteorological transport of released material, the population exposure, and the distance of transport. The following sections address the potential accident consequences and risks associated with locating an ECF at the ORR.

5.5.14.1 Facility Accidents. A number of hypothetical accidents were evaluated for the Oak

Ridge ECF. These included radiological accidents involving naval spent nuclear fuel during water pool storage, dry storage, and dry cell operations as well as accidents involving toxic chemicals used at ECF. Calculations of the cancer fatalities which might occur as a result of all the postulated accidents are provided in Attachment F. A comparison of the accident consequences for all alternatives is provided in Section 3.7.

The difference in the calculated consequences for accidents at the ECF at ORR compared to the ECF at INEL is that the exposure received by the entire population would be greater at the Oak Ridge ECF due to the larger population within an 80-kilometer (50-mile) radius of the Oak Ridge ECF site. Although the exposure received was greater at the Oak Ridge ECF, the number of health effects which would result from any of the accidents considered would be small. The most limiting of the postulated accidents for the ECF at Oak Ridge would be an airplane crash into a dry cell facility. The exposure to the entire population from this accident is calculated to cause 8.4 cancer fatalities over 50 years, as described in Attachment F. The risk associated with the airplane crash would be approximately 0.000008 fatal cancers per year.

Effects from two accidents at the ECF at Oak Ridge involving toxic chemicals were evaluated in Attachment F. The first accident was a chemical spill and fire; the second was a fire involving diesel fuel. Both accidents could expose the public to various toxic chemicals at concentrations which exceed Emergency Response Planning Guidelines (ERPG) level 3 limits. Both accidents could also expose workers at the Oak Ridge ECF to various toxic chemicals at concentrations which exceed ERPG-3 limits. In both cases, however, it is expected that actual toxic chemical exposures would be much less due to the mitigative measures that would be implemented. A summary of the analysis methods, the toxic chemical concentrations, and a discussion of the mitigative measures for toxic chemicals are provided in Attachment F.

5.5.14.2 Transportation Accidents. The health effects associated with accidents during

shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any health effects as a result of naval spent nuclear fuel and test specimen shipments since the risk estimates are much less than one fatal cancer or health detriment for each alternative. However, the most severe accident, with a likelihood of occurrence greater than 1 x 10-7 events per year, is estimated to result in a maximum of 2.1 fatalities. The details of the transportation analysis are provided in Attachment A.

5.5.14.3 Other Impacts of Accidents. In addition to the possible human health effects

associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives.
The analyses described in Attachment F showed that for the most severe hypothetical accidents, an area of between about 8 acres extending about 1/4 mile downwind (for an accidental criticality) and approximately 210 acres extending about 1 1/4 mile downwind (for a large airplane crash into the fuel examination facility) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem per year, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. The area which might be affected by one of these hypothetical accidents could extend slightly beyond the boundaries of the Oak Ridge Reservation, so some people who live in the affected area might be evacuated or otherwise experience restrictions in their daily activities, and those who work at locations within the affected area might be prevented from going to their jobs until measures had been taken to reduce the potential for exposure.

An accident might result in short-term restrictions on access to a relatively small area, but it would not be expected to produce any enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area would vary only slightly among the alternatives. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with an Expended Core Facility at the Oak Ridge Reservation would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for an alternative which would relocate the Expended Core Facility to the Oak Ridge Reservation. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, effects on the ecology should be limited to small areas. As previously stated, there are no endangered or threatened species unique to the area surrounding the location considered for an Expended Core Facility at the Oak Ridge Reservation, so an accident would not be expected to result in destruction of any species. The effects of accidents related to any of the alternatives and any cleanup which might be performed would be localized within a small area which would extend only a relatively short distance from the Expended Core Facility and thus would not be expected to appreciably affect the potential for survival of endangered or threatened species in the vicinity. Based on these considerations, evaluation of the impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.5.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear Fuel

Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the ORR would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

To place the impacts on environmental justice in perspective, the risk from hypothetical accidents associated with naval spent nuclear fuel examination under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.5.15 Waste Management

During Oak Ridge ECF operations, non-radioactive and non-hazardous waste and hazardous waste would be generated in quantities similar to those for the ECF at INEL. Solid sanitary and industrial wastes would be disposed of at an on-site landfill. Hazardous solid wastes would be contained at their point of generation and transported off-site to an approved disposal facility. Waste management practices for these wastes would produce no identifiable impact on public health or safety of the environment.

Operation of the ECF at ORR would generate the same quantities of radioactive low-level waste, transuranic waste, and mixed wastes as the ECF at INEL. Low-level waste generated by the Oak Ridge ECF would be stored on-site pending a future disposal action. The 425 cubic meters (556 cubic yards) of low-level waste generated annually by the ECF at INEL represents a small fraction of the low-level waste managed at ORR. No high-level waste would be generated.

Less than 0.0001 cubic meter of transuranic waste per year is generated by current ECF operations at the INEL. Any transuranic waste generated by the Oak Ridge ECF would be a very small fraction of the transuranic waste at ORR and would not impact planned waste handling operations.
Much of the newly generated and retrievably stored transuranic waste at ORR will be treated and certified for eventual disposal at the DOE Waste Isolation Pilot Project.

Any mixed waste generated by Oak Ridge ECF operations would be stored on-site pending a future disposal action. This would represent a very small fraction of the mixed waste at ORR from past and ongoing operations requiring disposition.

5.5.16 Cumulative Impacts

Up to this point, Section 5.5 has discussed the potential environmental consequences of constructing and operating the ECF at the ORR in terms of annual impacts (i.e., radiological doses and health effects, accident risks, and quantities of wastes that would be generated during operations) based on the maximum expected annual workload of the ECF. To determine the potential consequences for 40 years of ECF operation (from 1995 to 2035), an evaluation of the accumulated environmental consequences and risks of constructing and operating the Oak Ridge ECF was performed.

5.5.16.1 Radiological Cumulative Impacts. Operation of the Oak Ridge ECF would not result

in discharges of radioactive liquids; therefore, there would be no changes to the surface or ground water as a result of normal ECF operations. There would be small quantities of radioactivity in the air released from ECF which would contribute to the cumulative air quality impacts.

The Oak Ridge Reservation has not been used for naval spent nuclear fuel operations in the past. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

The annual radiological impacts associated with the alternatives where naval spent nuclear fuel would be inspected or stored at ORR are very small and are described in Section 5.5.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure to the general public from transportation and from Oak Ridge ECF operations would be approximately 15 person-rem. This means that there might be 0.0075 fatal cancers from these operations over the entire 40-year period evaluated. The exposure to the maximally exposed off-site individual would be 4 millirem from 40 years of Oak Ridge ECF operation. The corresponding risk of a cancer fatality to the maximally exposed off-site individual is 2.0 x 10-6 during his or her lifetime. A worker at the Oak Ridge ECF site located 100 meters from the facility would receive less than 5 millirem over 40 years of Oak Ridge ECF operation, which corresponds to a 1.9 x 10-6 risk of fatal cancer during the worker's lifetime. These exposures and cancer risks are as a result of ECF operations only. The exposures and risks corresponding to site-wide operations (including ECF) are discussed in Volume 1, Chapter 5. Analyses of hypothetical accidents which might occur as a result of these alternatives show that the risk of cancer fatalities is small. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

Cumulative impacts due to radioactive waste generation are expected to be minimal. Approximately 425 cubic meters (556 cubic yards) of low-level waste are expected to be generated annually by the Oak Ridge ECF over the next 40 years. This is not expected to affect the ORR waste management program. Very little transuranic waste or mixed waste and no high-level waste will be generated from Oak Ridge ECF operations.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

5.5.16.2 Non-radiological Cumulative Impacts. The cumulative socioeconomic impacts

associated with constructing and operating the Oak Ridge ECF are expected to be minor. The Oak Ridge Reservation employs over 17,000 people. In the past, no employment at the ORR has been associated with naval spent nuclear fuel operations. Oak Ridge ECF operations would provide long-term employment for 500 people at the ORR. The peak number of additional jobs created at the ORR in any given year would be approximately 1050, which includes both construction and operations workers during the peak of the Oak Ridge ECF construction effort. Considering that the labor force in the region of influence consists of over 292,000 people, the additional number of jobs added from the construction and operation of the Oak Ridge ECF would be expected to have only a minor socioeconomic impact in the Oak Ridge area.

Construction and operation of the Oak Ridge ECF are not expected to result in any discernible impacts relative to cumulative non-radiological emissions. Construction of the ECF is sufficiently remote and removed from the nearest ORR boundaries such that concentrations of fugitive emissions from construction would be well below applicable standards, as discussed in Section F.4 of Attachment F. Current operations at the Oak Ridge Reservation are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

The withdrawal of surface water for ECF construction and operation at the ORR would be a small percentage of existing withdrawals and well within the cumulative capabilities of the respective water resources. Discharges of ECF non-radioactive and non-hazardous liquid effluents at the ORR would have no measurable impact on water quality or aquatic ecology.

Minimal cumulative land use impacts would be expected to occur as a result of the construction of a new ECF. The land that would be dedicated for this purpose is on existing federal property. The use of this land would not result in the need for additional land to be added to the federally owned property in the foreseeable future. The Oak Ridge Reservation occupies an area of approximately 140 square kilometers (54 square miles) with only about 8% of the land occupied by the Y-12 Plant, K-25 Site, and Oak Ridge National Laboratory. No land area at the Oak Ridge Reservation has been affected by past operations involving naval spent nuclear fuel. Construction of the Oak Ridge ECF would affect 30 acres of land. This is less than 0.09% of the total Oak Ridge Reservation land area.

The cumulative impacts associated with non-radiological waste management are also expected to be small. The volume of hazardous waste produced by ECF has not been calculated; however, considering the nature of the work associated with ECF, the amount of hazardous waste produced would have a small effect on the cumulative impacts associated with this waste. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of wastes.

5.5.17 Unavoidable Adverse Effects

Construction of an ECF at ORR would directly affect about 30 acres of land area. Site preparation for construction would disturb areas of natural vegetation cover which primarily include oak/hickory forest land. The direct loss of terrestrial habitat would be minimized to the extent practical.

Construction of the Oak Ridge ECF would also generate liquid effluents, atmospheric emissions, and solid wastes typical of those for construction of a major industrial facility. All effluents and emissions would be below applicable environmental requirements and would not be expected to result in any major adverse impacts.

During Oak Ridge ECF operations, non-radioactive and non-hazardous waste and hazardous waste would be generated in quantities similar to those discussed for the INEL. Solid sanitary and industrial wastes would be disposed of in an ORR landfill. Hazardous wastes would be contained at their point of generation and transported off-site to an approved disposal facility. The amount of hazardous waste generated by Oak Ridge ECF operations would be small in comparison to the amount of hazardous waste that is generated at the ORR. No discernible differences from normal hazardous waste management at the ORR would result from this strategy.

During Oak Ridge ECF operations, unavoidable radiation exposures would include occupational exposures and exposures to the public from normal atmospheric emissions of radioactive materials that would be small compared to criteria contained in 40CFR Part 61.92 and DOE Order 5480.1B. Sanitary waste and service waste liquid discharges would be below applicable environmental standards. Solid wastes generated during operations, including transuranic, low-level, hazardous, and mixed wastes, would result in small increases in potential exposures to radioactive and hazardous materials.

Construction and operation of the Oak Ridge ECF would not require the use or consumption of scarce resources. Expected surface water withdrawals during construction and operation would represent small incremental increases in the amount of water being withdrawn by ongoing ORR operations. In general, the unavoidable adverse impacts would be few and limited, and none have been identified that would have a detectable effect on public health and safety. The difference in the impacts between the ECF alternative at ORR and the other DOE sites (INEL, Savannah River, Hanford, Nevada Test Site) is not discernible.

5.5.18 Irreversible and Irretrievable Commitments of Resources

During operation of the Oak Ridge ECF, additional fuel would be burned to supply steam for heat. The fuel is not in short supply. The water to be used for the Oak Ridge ECF would be withdrawn from the Clinch River and would be a small amount. No new water intake structure would be required, and no observed impacts have resulted from previous withdrawals. Total consumption of water attributable to water pool operations and consumption of potable water by operations personnel represent less than one-thousandth of a percent of the Clinch River average annual flow.

The total cost of locating a new ECF at Oak Ridge is approximately $3.5 billion. This cost represents the total cumulative cost over the 40-year period and includes construction and operation costs of the new ECF as well as the cost associated with shutting down the ECF at INEL. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

As is the case with the ECF at INEL, construction and operation of the ECF at ORR would not require the use or consumption of scarce resources.

5.6 NEVADA TEST SITE

5.6.1 Overview of Environmental Impacts

The following sections discuss the potential environmental consequences that would occur if a replacement for the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) were constructed and operated at the Department of Energy's Nevada Test Site (NTS). This facility will be referred to as the Nevada ECF. The affected environment for the proposed site, depicted on Figure 4.6-1, is discussed briefly in Section 4.6 and in greater detail in Volume 1, Appendix F.

The environmental consequences of locating and operating the ECF at NTS are based on the same radiological source terms for normal and accidental releases and the estimated atmospheric emissions, liquid effluent, and solid wastes discussed in Section 5.2 for the ECF at INEL. The environmental consequences of locating and operating the Nevada ECF would be similar to those for the ECF at INEL, and none would be large.

5.6.2 Land Use

Over 40.5 square kilometers (10,000 acres) of land exists in the area being considered as a location for the proposed Nevada ECF. This is in the same general area being considered for the proposed spent nuclear fuel storage facility discussed in Volume 1, Appendix F. Construction of an ECF at NTS would directly affect about 30 acres of land. This would result in only a minimal reduction in the available land base of the NTS. Located next to Mercury Highway, the proposed area would support construction and maintenance of an ECF, railcar holding facilities, and necessary support facilities. The ECF facilities would be compatible with all existing and presently foreseeable NTS facilities. The affected land area is small compared to the entire NTS. Native American rights and interests would not be modified by construction or operations associated with any of the alternatives considered.

5.6.3 Socioeconomics

The potential socioeconomic impacts associated with construction of the Nevada ECF are expected to be equal to or less than those associated with the original ECF construction at the INEL because (1) a large movement of construction workers from other areas would not be expected for the Nevada ECF construction due to the availability of construction craft workers in the Las Vegas area; and (2) the counties surrounding the NTS have a population adequate to absorb any temporary relocation of construction personnel.

Table 5.6-1 provides a summary of the direct jobs which would be required for the construction and operation of the Nevada ECF during the 10-year period immediately after the Record of Decision. The greatest number of direct jobs would occur in 1999 during the peak of the construction phase. Estimates of the indirect jobs created as well as the effect on area population are included in Section 5.5.6 of Volume 1 as part of either the Regionalization or Centralization at the Nevada Test Site alternatives.

Table 5.6-1. Summary of direct jobs due to the Nevada ECF.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct Jobs	20	20	476	825	1033	894	850	500	500	500

During the Nevada ECF construction period, operations personnel would be hired so that at the end of the construction period, most of the operations workers would be employed. The percentage of operations workers expected to move into the area from other areas varies based on skill requirements. Overall, approximately 20 percent are estimated to move into the NTS area. The Las Vegas Metropolitan Service Area, which constitutes the major portion of the population in the region of influence, had a 1990 population of 735,000 and an estimated population of 900,000 as of August 1993.

The Nevada ECF operation would require essentially the same number of operations personnel (500) as at the INEL. This would represent a relatively small percentage of the total NTS work force. Given the 20-percent estimate for immigration and an average family size of 2.6 persons per household for operations personnel moving into the area, the expected population increase attributable to the operating personnel would be 260 persons.

Given the small percentage of population increase attributable to Nevada ECF operations in relation to normal population increases in the NTS region, no major adverse impacts to local government services and community infrastructures are expected. The economic benefits to the NTS region are expected to be similar to those for the INEL region.

5.6.4 Cultural Resources

Construction at the site considered for the Nevada ECF would not impact any known archaeological or Native American sites. Procedures which comply with all applicable laws and regulations would be implemented to protect previously undetected archaeological and cultural sites.

5.6.5 Aesthetic and Scenic Resources

The construction of the Nevada ECF would directly affect approximately 30 acres of land. As a result of its location and industrial characteristics, there is essentially no aesthetic or scenic impact since the site would not be visible to the public.

5.6.6 Geology

5.6.6.1 General Geology. The local geology of the NTS region has been impacted as a result of

past nuclear testing. This impact has been in the form of surface faulting. Because construction and operation of the Nevada ECF would not produce forces near the magnitude of those produced from past nuclear tests, it is highly unlikely that this activity would cause additional faulting.

5.6.6.2 Geologic Resources. Precious metals may exist in certain carbonate rocks and volcanic

or sedimentary rocks at the NTS. The Nevada ECF would not be located within a mining district and the site will likely remain closed to mining operations so the impact to any precious metal deposits that may exist at the NTS will not change if the proposed facility is sited there.

5.6.7 Air Resources

Minor short-term emissions of fugitive dust and exhaust from heavy equipment would be possible during Nevada ECF construction. The use of toxic chemicals during ECF normal operations would be controlled such that the exposure levels of workers and the public would be negligible. Airborne emissions from normal operations would include the combustion gases from the boiler house, where fuel would be burned to make steam for space heating. Emergency diesel generators, which would be provided for safety, would be operated periodically for test purposes and release exhaust fumes to the atmosphere. These emissions would not have any detectable environmental consequence.

The airborne releases of radioactivity for the ECF at NTS would be the same as for the ECF at INEL described in Section 5.2. The airborne release would result in no measurable exposure to on-site personnel or the general population. Details of the analyses supporting this conclusion are provided in Attachment F.

5.6.8 Water Resources

5.6.8.1 Surface Water. As stated in Section 4.6.8, with the exception of short periods of runoff

from spring discharges, there is no perennial surface water at the NTS. As such, the daily water supply required to operate the Nevada ECF could not be obtained from local surface waters. In fact, the NTS currently derives its complete water supply from the groundwater aquifers. Therefore, the construction and operation of the Nevada ECF would have no impact on the quantity and quality of surface water in the area.

There are no National Pollutant Discharge Elimination System permits for the NTS, as there are no wastewater discharges to on-site and off-site surface waters. NTS wastewaters are discharged to sewage lagoons. Therefore, all wastewaters associated with the construction and operation of the Nevada ECF would likely be discharged into the on-site lagoon system along with the other wastewaters generated at the NTS. Thus, surface water quantity and quality in the NTS area would not be expected to be impacted.

5.6.8.2 Groundwater. The NTS currently extracts groundwater from aquifers within two

hydrographic subbasins: Alkali Flat-Furnace Creek Ranch and Ash Meadows. These subbasins, along with their specific hydrographic areas and NTS well locations, are described in Section 5.8 of Volume 1, Appendix F. The 2.5 million gallons per year additional withdrawal of water from these aquifers required for operation of an ECF represents less than a 3-percent increase over the present rate at which water is withdrawn for use in Area 6 and less than 0.5 percent of the total NTS usage rate.

5.6.9 Ecological Resources

5.6.9.1 Terrestrial Ecology. During construction and operation of the Nevada ECF, all effluent

and emissions would comply with regulatory standards and are not expected to have an impact on the area wildlife. Operation of the Nevada ECF should result in less noise and traffic than the construction phase, and no effects on terrestrial ecology are expected from Nevada ECF operations.

5.6.9.2 Wetlands. National Wetland Inventory maps of the NTS have not been prepared, nor

have wetlands been delineated on the site. However, available information indicates that wetlands on the NTS are limited in distribution and extent. Small areas of wetlands could be present in or on the margins of the surface drainages, playas, and reservoirs on the NTS. It is expected that construction and operation of the Nevada ECF would have negligible impact on any wetlands.

5.6.9.3 Aquatic Ecology. Because there would be no discharge of radioactive or hazardous liquid

effluent from Nevada ECF operation, these operations are expected to have no effect on the aquatic ecology.

5.6.9.4 Endangered and Threatened Species. The endangered and threatened species are

described in Section 4.6.9. The desert tortoise is the only federally listed species that could be affected by the construction of an ECF facility. Forty-five percent of the total known desert tortoise habitat is located in the Yucca Mountains. The area that could be affected directly by the proposed ECF are Frenchman Flat and the southern bajada of Control Point Hills.

Construction and maintenance of roads, utility and communication lines, buildings, water pipelines, sewage lagoons, and other facilities could result in harm or harassment of desert tortoises and loss of habitat. Tortoises could become injured by falling into open trenches or other temporary construction excavations and might not be able to escape. They could become submerged in water storage ponds, wastewater lagoons, and other impoundments not fenced to exclude them.

5.6.10 Noise

Noises generated on the NTS do not propagate off-site at levels that impact the general population. Noise increases outside the NTS due to the Nevada ECF would be limited to those produced by truck, car, and train traffic on roads and railroads approaching the NTS. These increases would not be large enough to be objectionable to the areas bordering the roads and railroads.

5.6.11 Traffic and Transportation

Traffic and transportation would increase in the area if an ECF is constructed and operated at the NTS. The additional traffic would mainly be due to increased commuter traffic from construction workers and 500 operations workers as well as traffic from material shipments during the Nevada ECF construction.

If the Nevada ECF were established, naval spent nuclear fuel would be routinely transported to the site in certified shipping containers. Various types of wastes generated at the facility would be dispositioned on-site and off-site. Following examination, most of the naval spent nuclear fuel would be transferred to the spent fuel storage location on the NTS until the time that permanent geologic storage becomes available.

5.6.12 Occupational and Public Health and Safety

The health and safety assessment of normal operations at the Nevada ECF was based on handling and examination of spent nuclear fuel either in a water pool or in a dry cell. These are the same methods of spent nuclear fuel handling that have been employed or seriously considered for use at the ECF at INEL. The normal operational impacts associated with the Nevada ECF would be similar to those for the ECF at INEL. The following sections describe the non-radiological and radiological impacts associated with the ECF at NTS (refer to Section 5.2 for the ECF at INEL impacts).

5.6.12.1 Occupational Health and Safety. Projections of the number of occupational accidents

that might occur during construction and operation of naval spent nuclear fuel storage and examination facilities have been made for each alternative. These projections are presented in Attachment F. Based on the results of these projections, it is concluded that the number of occupational fatalities and injuries or illnesses for construction activities and storage and examination operations would be very small for any alternative.

During Nevada ECF construction, workers are not expected to experience elevated background levels of radiation resulting from on-going NTS operations. The gamma radiation measured near the proposed Nevada ECF site is similar to the radiation levels measured off-site in the NTS area. The potential exposure to a construction worker from inhalation of radionuclides released to the atmosphere from previous and current NTS operations is expected to be small compared to the external exposure. The exposure received by a construction worker would be well below the naval and Department of Energy (DOE) standard of 5000 millirem per year for occupationally related whole-body and internal exposures.

During operation of the Nevada ECF, NTS personnel would be exposed to routine atmospheric emissions of radioactivity and might be exposed to potential emissions from accidents. The Nevada ECF site is located approximately 3 miles from the Radioactive Waste Management Facility, which is the nearest existing NTS facility. As shown in Attachment F, no measurable exposure would be received by these collocated workers from normal Nevada ECF operations. Exposures received by radiation workers from normal operation of the ECF at NTS are expected to be similar to the exposures currently received by workers from normal operation of the ECF at INEL, discussed in Section 5.2.12.

Exposures, injuries, and potential fatalities to workers at the Nevada ECF could also occur as a result of accidents during ECF operations. However, the safety record of the ECF at INEL is very good, and similar safe working conditions could be established at the new facility.

5.6.12.2 Public Health and Safety. The impacts of normal operation of the Nevada ECF would

be similar to those for the ECF at INEL. Normal radiological releases to the atmosphere and the quantities of radioactive and hazardous wastes that would be generated would not differ from those previously discussed for the INEL. However, the location of the project relative to the surrounding NTS population and the distances to facilities that would be involved in routine shipments of material would result in differences in potential environmental consequences. Described below are the impacts to the public associated with operation of the ECF at NTS (refer to Section 5.2.12 for the ECF at INEL impacts).

Assessment of the normal operations of the Nevada ECF involved handling and examination of spent fuel either in a water pool or in a dry cell. For both cases, the potential annual exposures were estimated for five different types of people: a worker at the Nevada ECF site located 100 meters from the release point, the hypothetical maximally exposed collocated worker on the NTS site, the hypothetical maximally exposed off-site individual, an individual at the nearest public access, and the population within 80 kilometers (50 miles) of the Nevada ECF site. Three pathways were included in the analysis: airborne, waterborne, and direct radiation, as applicable.

The results indicate that handling and examination of spent fuel either in a water pool or in a dry cell would be satisfactory for normal operations since the exposure is so low. The analysis shows that the exposure to all the individuals considered (workers, collocated workers, and off-site individuals) from Nevada ECF operations would be much less than one millirem per year. For perspective, it could be stated that one member of the entire population might experience a fatal cancer due to Nevada ECF operations if operations continued for over 11 million years. A description of the analysis methods and more detailed results are provided in Attachment F. The impacts from normal operations for all alternatives are summarized in Section 3.7.

The radiological and non-radiological health effects associated with the incident-free transportation of naval spent nuclear fuel and test specimens have been assessed for the general population, transportation workers, and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any fatal cancers as a result of naval spent nuclear fuel and test specimen shipments since the estimates are much less than one fatal cancer for each alternative. The details of the transportation analysis are provided in Attachment A.

5.6.12.3 Incident-free Occupational and Public Health and Safety Effects on Environ-

mental Justice Due to Naval Spent Nuclear Fuel Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from normal operations associated with the examination of naval spent nuclear fuel at the NTS would be small under any of the alternatives considered. For example, it is unlikely that a single fatal cancer would occur as a result of activities associated with naval spent nuclear fuel examination under any alternative. Since the potential impacts due to normal operations or accident conditions for any of the alternatives considered present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects would be expected for any particular segment of the population, minorities and low-income groups included.

The conclusion that there would be no disproportionately high and adverse impacts on human health or the environment is not affected by the prevailing winds or direction of surface or subsurface water flow. This is true for normal operations because the effects of routine operations are so small. It is also true for accident conditions because the consequences of any accident would depend on the random conditions at the time it occurred, and the wind directions at the NTS do not display any strongly dominant direction. Similarly, the conclusion is not affected by concerns related to subsistence consumption of fish or game because of the very small impacts associated with examination of naval spent nuclear fuel.

To place the impacts on environmental justice in perspective, the risk associated with routine operations for naval spent nuclear fuel examination under any of the alternatives considered would be less than one fatality per year for the entire population. For comparison, in 1990 there were approximately 510,000 cancer deaths in the United States population and there were about 64,000 cancer deaths among people of color in the U. S. Even if all of the impacts associated with one of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would be unlikely to experience a single additional cancer fatality in any year. Therefore, the cancer risk for that population from naval spent nuclear fuel management would not constitute a disproportionately high and adverse impact on human health or the environment. The same conclusion can be drawn for low-income groups.

5.6.13 Utilities and Energy

Heating, ventilation, and electrical systems appropriate to the needs of the Nevada ECF for suitable working environments and to properly filter and exhaust the airborne discharges to the atmosphere are estimated to require approximately 10,000 MWh per year for normal operations. This would represent about a 4-percent increase in NTS electrical consumption and may require transmission line upgrades. Emergency diesel electrical generators would provide 350 kW for crucial facility services during power outages.

5.6.14 Facility and Transportation Accidents

The differences in the potential consequences and risks of accidents at the ECF at NTS compared to the ECF at INEL are related to the meteorological transport of released material, the population exposure, and the distance of transport. The following sections address the potential accident consequences and risks associated with locating an ECF at the NTS.

5.6.14.1 Facility Accidents. A number of hypothetical accidents were evaluated for the Nevada

ECF. These included radiological accidents involving naval spent nuclear fuel during water pool storage, dry storage, and dry cell operations, as well as accidents involving toxic chemicals used at ECF. Calculations of the cancer fatalities which might occur as a result of all the postulated accidents are provided in Attachment F. A comparison of the accident consequences for all alternatives is provided in Section 3.7.

The difference in the calculated consequences for accidents at the Nevada ECF compared to the ECF at INEL is that the exposure received by the entire population would be less at the Nevada ECF due to a different population distribution within an 80-kilometer (50-mile) radius of the site. The most limiting of the postulated accidents for the Nevada ECF would be an airplane crash into a dry cell facility. The exposure to the entire population from this accident is calculated to cause 0.18 cancer fatalities over 50 years, as described in Attachment F.

The exposures to collocated workers following all accidents are well below the naval and DOE standard of 5 rem per year for occupational exposure. However, exposures to the worker located at a Nevada ECF site 100 meters from the radiation release point could exceed this standard following an accident resulting in an inadvertent criticality or an airplane crash into a dry cell.

Effects from accidents at the Nevada ECF involving toxic chemicals are similar to those described in Section 5.2.14 for the existing ECF at INEL. Due to the amount and types of chemicals stored at the ECF site, toxic chemicals do not pose a risk to the public following any of the postulated accidents. However, following the maximum foreseeable accident analyzed (a fire transient), a number of toxic chemicals would exceed Emergency Response Planning Guideline (ERPG) values for workers on the Nevada ECF site. For the maximum off-site individual, ERPG-2 values for the toxic chemicals are not exceeded under either 50% meteorology or 95% meteorology conditions. The concentrations of toxic chemicals as well as a summary of the analysis methods are provided in Attachment F.

5.6.14.2 Transportation Accidents. The health effects associated with accidents during

shipments of naval spent nuclear fuel and test specimens have been assessed for the general population and hypothetical maximum exposed individual for each alternative. As summarized in Section 3.7, it is unlikely that there will be any health effects as a result of naval spent nuclear fuel and test specimen shipments since the risk estimates are much less than one fatal cancer or detrimental health effect for each alternative. However, the most severe accident, with a likelihood of occurrence greater than 1 x 10-7 events per year, is estimated to result in a maximum of 2.1 fatalities. The details of the transportation analysis are provided in Attachment A.

5.6.14.3 Other Impacts of Accidents. In addition to the possible human health effects

associated with facility or transportation accidents described in the preceding sections, other effects such as the impacts on socioeconomics and land use in the area and the costs of cleanup have been estimated in order to develop a perspective and to evaluate potential differences among alternatives.
The analyses described in Attachment F showed that for the most severe hypothetical accidents, an area of between about 8 acres extending about 1/4 mile downwind (for an accidental criticality) and approximately 210 acres extending about 1 1/4 mile downwind (for a large airplane crash into the fuel examination facility) might be contaminated to the point where exposure could exceed 100 millirem per year. Beyond these distances, the exposure would be less than 100 millirem, the Nuclear Regulatory Commission's standard for protection of the general population from radiation. The area affected by the hypothetical accidents would not extend beyond the boundaries of the Nevada Test Site. Persons who work at locations within this area might be prevented from going to their jobs at the federally owned facilities until measures had been taken to reduce the potential for exposure.

An accident might result in short-term restrictions on access to a relatively small area, but it would not be expected to produce any enduring impacts on cultural or similar resources or concerns such as Native American rights or interests, partially because the area involved would be small and partly because all remedial actions would be conducted in a careful, controlled manner in full compliance with applicable laws and regulations. The area would vary only slightly among the alternatives. Overall, the risks are small so these considerations do not assist in distinguishing among alternatives.

Facility or transportation accidents associated with an Expended Core Facility at the Nevada Test Site would not have an appreciable effect on the ecology of the area, considering the potential for human health effects and the amount of land which might be affected, as described in earlier parts of this section. There is little consensus among scientists on methods for estimating the effects of radiation on ecological resources such as plant or animal life, but since human health effects for all the accidents analyzed are small and most plants and animals are not thought to be more sensitive to radiation than human beings, the small impacts on human health provide an indication that the impacts on animal and plant species in the area would also be small for an alternative which would relocate the Expended Core Facility to the Nevada Test Site. Similarly, since the areas which might be contaminated to measurable levels by chemicals or radioactive material during the hypothetical accidents would be relatively small, effects on the ecology should be limited to small areas. As previously stated, there are no endangered or threatened species unique to the area surrounding the location considered for an Expended Core Facility at the Nevada Test Site, so an accident would not be expected to result in destruction of any species. The effects of accidents related to any of the alternatives and any cleanup which might be performed would be localized within a small area which would extend only a relatively short distance from the relocated Expended Core Facility and thus would not be expected to appreciably affect the survival potential of endangered or threatened species in the vicinity. Based on these considerations, evaluation of the impacts of accidents on ecological resources does not help to distinguish among alternatives.

5.6.14.4 Effects of Accidents on Environmental Justice Due to Naval Spent Nuclear Fuel

Storage and Handling. As discussed in the preceding paragraphs, the impacts on human health or the environment resulting from facility or transportation accidents associated with the management of naval spent nuclear fuel at the NTS would be small under any of the alternatives considered. For example, it is unlikely that a single additional fatal cancer would occur as a result of naval spent nuclear fuel management activities under any alternative. Since the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the surrounding population, no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any particular segment of the population, minorities and low-income groups included.

To place the impacts on environmental justice in perspective, the risk from hypothetical accidents associated with naval spent nuclear fuel examination under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident involving any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience less than one additional fatal cancer per year. The same conclusion can be drawn for low-income groups.

5.6.15 Waste Management

During Nevada ECF operation, non-radioactive and non-hazardous solid waste and hazardous solid waste would be generated in quantities similar to those for the ECF at INEL. These wastes would be managed in a manner identical to that for the ECF at INEL (i.e., non-hazardous, non-radioactive solid wastes would be disposed of at a sanitary landfill and hazardous solid wastes would be contained at their point of generation and transported off-site to an approved disposal facility). Waste management practices for these wastes would produce no identifiable impact on public health and safety of the environment.

Operation of the ECF at NTS would generate the same quantities of low-level waste, transuranic waste, and mixed wastes as the ECF at INEL. Low-level waste generated by Nevada ECF would be disposed of at the NTS. The 425 cubic meters (556 cubic yards) of low-level waste generated annually by the ECF at INEL represents a small fraction of the low-level waste managed at the NTS and would not impact planned disposal operations. No high-level waste would be generated.

Less than 0.0001 cubic meter of transuranic waste per year is generated by current ECF operations at the INEL. Any transuranic waste generated by the Nevada ECF would be added to the Nevada Test Site's transuranic waste storage cell, and would not impact planned waste handling operations. Any mixed wastes generated by Nevada ECF operation would be stored on-site pending a future disposal action.

5.6.16 Cumulative Impacts

Up to this point, Section 5.6 has discussed the potential environmental consequences of constructing and operating the ECF Project at the NTS in terms of annual impacts (i.e., radiological doses and health effects, accident risks, and quantities of wastes that would be generated during operations) based on the maximum expected annual workload of the ECF. To determine the potential consequences for 40 years of ECF operation (from 1995 to 2035), an evaluation of the accumulated environmental consequences and risks of constructing and operating the Nevada ECF was performed.

5.6.16.1 Radiological Cumulative Impacts. The Nevada Test Site has not been used for naval

spent nuclear fuel operations in the past. Prior to this time, naval spent nuclear fuel inspections and storage operations have been conducted only at INEL. Therefore, no cumulative impacts have resulted from previous naval spent nuclear fuel inspection and storage operations at any alternate site except for INEL.

Operation of the Nevada ECF will not result in discharges of radioactive liquids; therefore, there would be no changes to the surface or ground water as a result of normal operations for any alternative. There will be small quantities of radioactivity in the air released from ECF which would contribute to the cumulative air quality impacts.

The annual radiological impacts associated with the alternatives where naval spent nuclear fuel would be inspected or stored at the NTS are very small and are described in Section 5.6.12, with the detailed results of analyses provided in Attachment F. In order to calculate cumulative impacts for the period between 1995 and 2035, the annual radiological impacts associated with each location and alternative were summed over 40 years. The results of this summation are tabulated in Tables 3-5 and 3-6 of Section 3.

The cumulative transportation impacts for the population groups from naval spent nuclear fuel transportation activities since the beginning of the Naval Nuclear Propulsion Program also have been calculated and are very small. In addition, the cumulative impacts from transportation of naval spent nuclear fuel over the 40-year period between 1995 and 2035 for each alternative have been assessed. The detailed results of these calculations are presented in Attachment A and summarized in Section 3.7.4.

The total exposure (from operations and transportation) to the general public from Nevada ECF operation would be approximately 6 person-rem. This means that there would be less than 3 x 10-3 fatal cancers from these operations over the entire 40-year period evaluated. The exposure to the maximally exposed off-site individual would be less than 1 millirem from 40 years of Nevada Test Site ECF operation. The corresponding risk of a cancer fatality to the maximally exposed off-site individual is 6.8 x 10-9 during his or her lifetime. A worker at the Nevada Test Site ECF located 100 meters from the facility would receive less than 2 millirem over 40 years of Nevada Test Site ECF operation, which corresponds to a 7.2 x 10-7 risk of fatal cancer during the worker's lifetime. These exposures and cancer risks are as a result of ECF operations only. The exposures and risks corresponding to site-wide operations (including ECF) are discussed in Volume 1, Chapter 5. Analyses of hypothetical accidents which might occur as a result of these alternatives show that the risk of cancer fatalities is small. The impacts associated with transportation of naval spent nuclear fuel for all of the alternatives considered would be similarly low.

Cumulative impacts due to radioactive waste generation are expected to be minimal. Approximately 425 cubic meters of low-level waste are expected to be generated annually by the Nevada ECF over the subject 40-year period. This is not expected to affect the NTS waste management program. Very little transuranic waste or mixed waste and no high-level waste will be generated from Nevada ECF operations.

No contribution to cumulative impacts from accidents involving naval spent nuclear fuel has been included in the analyses presented in this Environmental Impact Statement because there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity which had a significant effect on the environment.

5.6.16.2 Non-radiological Cumulative Impacts. The cumulative socioeconomic impacts

associated with constructing and operating the Nevada ECF are expected to be minor. The Nevada Test Site currently employs over 8,500 people. In the past, no employment at the NTS has been associated with naval spent nuclear fuel operations. Nevada Test Site ECF operations would provide long-term employment for 500 people at the NTS. The peak number of additional jobs created at the NTS in any given year would be approximately 1050, which includes both construction and operations workers during the peak of the Nevada Test Site ECF construction effort. Considering that the labor force in the region of influence is expected to reach 792,309 people by 2004, the additional number of jobs added from the construction and operation of the Nevada Test Site ECF would be expected to have only a minor socioeconomic impact in the NTS area.

Construction and operation of the Nevada ECF are not expected to result in any discernible impacts relative to cumulative non-radiological emissions. Construction of the ECF is sufficiently remote and removed from the nearest NTS boundaries such that concentrations of fugitive emissions from construction would be well below applicable standards, as discussed in Section F.4 of Attachment F. Current operations at the Nevada Test Site are in compliance with Title 40, Code of Federal Regulations, Part 61, "National Emission Standards for Hazardous Air Pollutants." Cumulative air emissions would not threaten to exceed any applicable air quality requirement or regulation, either federal, state, or local in radiological and non-radiological categories.

Minimal cumulative land use impacts would be expected to occur as a result of the construction of a new ECF. The land that would be dedicated for this purpose is on existing federal property. The use of this land would not result in the need for additional land to be added to the federally owned property in the foreseeable future. The Nevada Test Site occupies an area of approximately 3,500 square kilometers (1,350 square miles) of which only about 0.55% is developed. No land area at the Nevada Test Site has been affected by past operations involving naval spent nuclear fuel. Construction of the Nevada Test Site ECF would affect 30 acres of land. This is less than 0.004% of the total Nevada Test Site land area.

The cumulative impacts associated with non-radiological waste management are also expected to be small. The volume of hazardous waste produced by ECF has not been calculated; however, considering the nature of the work associated with ECF, the amount of hazardous waste produced would have a small effect on the cumulative impacts associated with this waste. The volume of municipal solid wastes and sanitary wastes which would be generated is expected to be proportional to the number of additional workers added, and this small incremental increase would not be discernible. The amount of non-radiological wastes generated would not introduce any changes to the site's waste management practices and would not impose any additional stress on the capacity of on-site or off-site waste disposal or treatment facilities. Therefore, any cumulative impacts associated with the generation and disposal of additional wastes would be very small. There are no current environmental problems associated with these types of wastes.

5.6.17 Unavoidable Adverse Effects

Construction of an ECF at NTS would directly affect about 30 acres of land area. The direct loss of terrestrial habitat would be minimal.

Construction of the Nevada ECF would also generate liquid effluents, atmospheric emissions, and solid wastes typical of those for construction of a major industrial facility. All effluents and emissions would be below applicable environmental requirements and would not be expected to result in any major adverse impacts.

During Nevada ECF operations, non-radioactive and non-hazardous solid waste and hazardous solid waste would be generated in quantities similar to those discussed for the INEL. Non-radioactive and non-hazardous solid waste would be disposed of in the NTS sanitary landfill. Hazardous wastes would be contained at their point of generation and transported off-site to an approved disposal facility. The amount of hazardous waste generated by Nevada ECF operation would be small in comparison to the amount of hazardous waste that is generated and currently in interim storage at the NTS. No discernible differences from normal hazardous waste management at the NTS would result from this strategy.

During Nevada ECF operations, unavoidable radiation exposures would include occupational exposures and exposures to the public from normal atmospheric emissions of radioactive materials that would be minimal compared to criteria contained in 40CFR Part 61.92 and DOE Order 5480.1B. Sanitary waste and service waste liquid discharges would be below applicable environmental standards. Solid wastes generated during operations, including transuranic, low-level, hazardous, and mixed wastes, would result in small increases in potential exposures to radioactive and hazardous materials. Freon emissions would result in a negligible increase in the risk of skin cancer; substitutes will be used when available.

Construction and operation of the Nevada ECF would not require the use or consumption of scarce resources. Expected groundwater withdrawals during construction and operation would represent small incremental increases in the amount of water being withdrawn by ongoing NTS operations. In general, the unavoidable adverse impacts would be few and limited, and none have been identified that would have a detectable effect on public health and safety. The difference in the impacts between the ECF alternative at the NTS and the other DOE sites (INEL, Savannah River, Hanford, Oak Ridge) is not discernible.

5.6.18 Irreversible and Irretrievable Commitments of Resources

During operation of the Nevada ECF, additional fuel would be burned to supply steam for heat. The fuel is not in short supply. The water to be used for the Nevada ECF would be withdrawn from the groundwater aquifers. No new water wells are expected to be required, and no observed impacts have resulted from previous withdrawals. Total consumption of water attributable to water pool operations and consumption of potable water by operating personnel would represent only a small percentage of the supply available by aquifer recharge.

The total cost of locating a new ECF at the Nevada Test Site is approximately $3.5 billion. This cost represents the total cumulative cost over the 40-year period and includes construction and operation costs of the new ECF as well as the cost associated with shutting down the ECF at INEL. Refer to Section 3.7 for a comparison of the total cumulative costs among alternatives.

As is the case with the ECF at INEL, construction and operation of the Nevada ECF would not require the use or consumption of scarce resources.

5.7 RELATIONSHIP BETWEEN SHORT-TERM USE OF THE ENVIRONMENT AND THE MAINTENANCE AND ENHANCEMENT OF LONG-TERM PRODUCTIVITY

Implementation of any of the alternatives for the Navy will commit and utilize some environmental resources shortly after the implementation date. In general, up to an additional 30 acres of land could be committed to support naval spent nuclear fuel management activities; it should be noted however that the land at the Naval Reactors Facility at the Idaho National Engineering Laboratory is already committed to this purpose and implementation of the Preferred Alternative would not require the commitment of any additional land. The spent nuclear fuel management activities are expected to require up to 2.5 million gallons of water per year and up to 10,000 megawatt-hours of electrical energy per year depending on the alternative selected. As discussed throughout this Appendix, the normal operations associated with naval spent nuclear fuel management will result in some radioactive releases and releases of some toxic chemicals and other pollutants; however, due to the types of operations involved and the stringent controls that would be in place, these releases would be extremely small and would not affect long-term productivity of any site.

Commitment of these resources is necessary to support long-term safe handling, storage, and examination of naval spent nuclear fuel.

5.8 POTENTIAL MITIGATION MEASURES

As stated earlier, all of the environmental impacts associated with implementation of any of the alternatives would be small. However, measures will be taken to reduce these small effects to the lowest possible levels. Consistent with existing Naval Nuclear Propulsion Program policies and historical practices, actions would be taken to prevent pollution, and to mitigate the impacts of naval spent nuclear fuel management facility construction, operations and potential accidents. These measures are summarized below; additional discussion is provided in Attachment F.

5.8.1 Pollution Prevention

Extensive environmental control programs and procedures are in place at all naval sites in order to minimize any environmental and public safety and health impacts that might result from radiological and non-radiological operations. A summary of some of these controls is provided in the following sections.

5.8.1.1 Radiological Pollution Prevention Actions.

The policy of the U.S. Navy is to reduce to the minimum practicable the amounts of radioactivity released to the environment. This policy is implemented at shipyards and prototype sites through procedures that are consistent with the recommendations of the National Council on Radiation Protection and Measurements and the standards issued by the U.S. Environmental Protection Agency, International Commission on Radiation Protection, International Atomic Energy Agency, National Academy of Science - National Research Council, U.S. Nuclear Regulatory Commission, and U.S. Department of Energy.

The principal source of radioactivity in liquid effluents is trace amounts of corrosion and wear products from reactor plant metal surfaces in contact with reactor cooling water. Concentrations of radioactive fission products are normally not a consideration for waste disposal because these fission products remain within spent nuclear fuel elements, which are not handled as waste. Radioactive liquids that are generated at shipyard and prototype sites are collected in containers, processed to remove most of the radioactivity, and reused rather than intentionally discharged to the environment.

Radiological work facilities are designed to ensure that there are no appreciable discharges of radioactivity in airborne exhausts. Radiological controls are exercised in radiological work facilities to preclude exposure of workers to airborne radioactivity exceeding limits specified in Title 10, Code of Federal Regulations, Chapter 20. These controls include performing work involving radioactive materials inside plastic bags or glove boxes which are completely sealed off from the environment. Air exhausted from radiological work facilities is passed through high efficiency particulate air filters which remove more than 99.9 percent of all particles from air, and is monitored during discharge to verify the effectiveness of the control measures.

Sources of radiation are controlled at shipyards and prototypes. Radiological work facilities are designed to minimize radiation exposure to personnel who perform work in the facility and to ensure that exposure to personnel outside the facility is negligible. Ambient radiation is measured with sensitive devices outside the boundaries of areas where radiological work is performed in order to confirm that radiological operations result in no measurable increase in exposure to the general public.

Shipyards and prototypes are not permitted to dispose of radioactive waste on their sites. All solid radioactive wastes are packaged in strong, tight containers, shielded as necessary, and shipped to burial sites that are either licensed by the U.S. Nuclear Regulatory Commission or a state under agreement with the U.S. Nuclear Regulatory Commission or are authorized for radioactive waste disposal by the U.S. Department of Energy. The volume of waste that is generated and shipped is minimized through use of work procedures that limit the amount of material that becomes contaminated during work on radioactive systems and reactor components. Workers periodically receive training specifically intended to help them minimize the production of radioactive waste.

Personnel who work with radioactive materials receive specific training regarding the potential hazards associated with radioactive materials, the general and specific radiological aspects which he or she might encounter, and his or her responsibility to the Navy and the public for safe handling of radioactive materials. More details regarding the scope of this training are provided in Naval Nuclear Propulsion Program Reports NT-94-2 and NT-94-3 (NNPP 1994b and NNPP 1994c).

5.8.1.2 Non-radiological Pollution Prevention Actions. Naval shipyards and prototype sites

follow applicable federal, state, and local requirements for the prevention of release of non-radiological pollutants to the environment. Procedures are in place at each location that ensure that operations at the shipyard or prototype comply with environmental requirements and that the operations do not have an adverse effect on the workers, the public, and the environment.

Shipyards and prototype sites are subject to regulation under the Clean Air Act. All sites follow Environmental Protection Agency, state, and local regulations regarding air pollution prevention. Permits are secured as required for operation of facilities which might emit criteria, toxic, or hazardous air pollutants. Equipment is designed and operated in order to comply with the National Emission Standards for Hazardous Air Pollutants and National Ambient Air Quality Standards for the region. Procedures are also in place at shipyard and prototype sites to ensure that the facilities comply with federal, state, and local requirements regarding asbestos emissions, open burning, vehicle emissions, and use of ozone depleting substances. When appropriate, air emissions are treated in order to achieve compliance with requirements and to ensure that the emissions will not degrade ambient air quality.

Shipyard and prototype sites also must comply with the requirements of the Clean Water Act. The Navy policy is to reduce or eliminate the need for wastewater treatment by minimizing or eliminating pollutants at the source. Permits are secured as required for all point source discharges to navigable waters and corrective measures are taken to comply with the terms of these permits. For cases where Publicly Owned Treatment Works are used for industrial wastewater discharges, measures are taken by the site to ensure that the discharges are in accordance with federal, state, and local requirements.

Each site has an active program for evaluating equipment and chemicals proposed for purchase to minimize or eliminate environmental, safety, and health hazards. These evaluations also help to minimize the amount of hazardous waste that is generated by ensuring that the types and quantities of hazardous materials procured are kept to a minimum. Each site has an active program to investigate the replacement of toxic or hazardous materials with other materials and, when possible, substitutions are made in order to avoid the use of chemicals that would result in the generation of hazardous waste. The procurement program includes approval by appropriate safety and health organizations at the site. Hazardous wastes and other toxic substances, such as polychlorinated biphenyls, are handled and disposed of in accordance with applicable Environmental Protection Agency, state, and local requirements. Personnel who handle hazardous materials, hazardous wastes, and other potentially hazardous substances receive training regarding the specific hazards of the materials that they are expected to handle and the methods for safely handling those materials. This training is conducted in accordance with applicable requirements such as those mandated by the Occupational Safety and Health Administration, the Department of Transportation, and the Environmental Protection Agency. Non-hazardous solid wastes are handled and disposed of in accordance with applicable federal, state, and local requirements. When practicable and economically feasible, materials are recycled or recovered.

Naval designs also consider the effects of the life-cycle of components, including the ultimate disposal. For example, stainless steel fittings are frequently used in equipment in place of brass or bronze fittings, which contain lead, and which can allow lead to leach out of the metal alloys. Similarly, solvents chosen for naval work in recent years have been selected to avoid volatile substances and complex organic chemicals.

Contingency plans exist at shipyard and prototype sites to respond to all accidental discharges and hazardous substance (radiological and non-radiological) releases. These plans have been developed in accordance with the applicable federal, state, and local requirements and are intended to ensure that workers, the public, and the environment would be protected in the event of an accidental release.

5.8.1.3 Prevention of Mixed Wastes. Mixing of radioactive and chemically hazardous materials

is avoided; compounding the intrinsic hazards of radioactivity with the chemical hazards of other materials creates a complex regulatory and occupational safety and health situation that impairs the execution of the work. For example, hazardous materials which could give rise to hazardous wastes listed under the Resource Conservation and Recovery Act (such as acetone) are precluded from use in radiological work. Other materials such as alcohol are used instead. The success of Program efforts in avoiding the creation of mixed radioactive and hazardous waste is reflected by the fact that in 1993, Program sites, naval shipyards, and Program DOE laboratories and prototypes produced less than 30 m3 of mixed waste and hold a current inventory of less than 100 m3.

5.8.2 Construction

In the event that implementation of an alternative requires construction of a new facility, the location will be selected to avoid impacts on the cultural, archaeological, aesthetic, or scenic resources of the area and to ensure that the rights and interests of Native American or Native Hawaiian groups are not infringed. Ecologically sensitive areas such as those in the vicinity of threatened or endangered species, and sites listed in the National Register of Historical Places would be avoided.

If upon implementation of an alternative, it is determined that construction of a naval spent nuclear fuel management facility would appreciably impact some resources, then actions to minimize those impacts would be taken. These actions could include, but would not be necessarily limited to, items such as: archaeological data collection prior to construction, education of workers about cultural resources and unauthorized artifact collection, involvement of Native Americans or Native Hawaiians in the selection of a mitigation strategy, and memorandums of agreement between the DOE and concerned parties. Preactivity surveys would be conducted to identify any plant or animal species that could be affected. As needed, mitigation measures and recovery plans would be developed; agencies such as the U.S. Fish and Wildlife Services and the Corps of Engineers would be consulted.
The potential for soil erosion could be reduced through methods such as control of storm water runoff, including sediment catch basins. Fugitive dust emissions would be minimized by periodically wetting exposed soils. Traffic concerns could be controlled by widening of roads and traffic demand management. Workers in the construction environment would be protected by the use of hard hats and ear plugs and other safety equipment as needed.

5.8.3 Normal Operations

As has been the policy of the Naval Nuclear Propulsion Program, normal work practices at any naval spent nuclear fuel management facility would be designed to minimize releases and therefore mitigate the impacts on the environment. Releases as a result of normal operations would be minimized through a variety of measures, including: closely controlling the generation of contaminated waste, using total containment devices for certain work that could result in a radioactive release, filtering the ventilation exhaust from radiological facilities, and recycling and treating water used in contaminated systems. All radiological workers at naval facilities are trained in these mitigation principles and in other methods of minimizing radiation exposure. Mitigative measures for the use of toxic or hazardous materials make use of administrative controls, training, and safety equipment to provide personnel protection and emergency response. For personnel protection, controls involve safety review committees for planned activities that establish requirements, safe work permits and procedures, and the use of required clothing such as rubber boots, gloves, face shields, and eye protection that mitigate the effects associated with use of toxic or hazardous materials. Procedures may also require provisions for positioning mitigative devices such as eyewash stations and emergency showers before work is allowed to commence. All of the facilities being evaluated would employ emergency response programs to mitigate impacts of potential toxic chemical accidents to workers and the public.

5.8.4 Accidents

Although a serious accident involving naval spent nuclear fuel is highly unlikely, emergency plans are in place at all nuclear naval facilities to mitigate the impacts of a facility or transportation accident. These plans include activation of emergency control organizations throughout the Naval Nuclear Propulsion Program to provide on-scene response as well as support for the on-scene response team. Realistic training exercises are conducted periodically to ensure that the response organizations maintain a high level of readiness, and to ensure that coordination and communication lines with local authorities and other federal and state agencies are effective. In addition, naval fuel is designed to resist corrosion and damage due to accident conditions; this rugged construction would also have an important mitigative effect on the impacts of an accident involving naval spent nuclear fuel.

Emergency response measures include provisions for immediate response to any emergency at any naval site, identification of the accident conditions, and communications with civil authorities providing radiological data and recommendations for any appropriate protective actions. In the event of an accident involving radioactive or toxic materials, workers in the vicinity of the accident would promptly evacuate the immediate area. This evacuation can typically be accomplished within minutes of the accident and would reduce the hazard to workers.

For members of the general public residing at the site boundary and beyond, action would be taken to prevent the public from exceeding certain limits on exposure to radiation or other hazards if needed. Individuals that reside or work on site, or those that may be traversing the site in a vehicle would be evacuated from the affected area within 2 hours. Security personnel and appropriate local officials at all locations would oversee the removal of residents, workers, and travelers in a safe and efficient manner. Periodic training and evaluation of the emergency response personnel is conducted to ensure that correct actions are taken during an actual casualty. Therefore, exposure of residents, workers, and travelers to any hazard, including the potential for ingestion and inhalation of contamination, would be limited, as much as possible. Upon stabilization of the situation, recovery and remediation actions would be implemented as soon as practicable.

LIST OF TABLES

ATTACHMENT A

TRANSPORTATION OF
NAVAL SPENT NUCLEAR FUEL

A.1 PURPOSE AND SCOPE

This attachment provides an evaluation of the radiological and non-radiological risks associated with the transportation of naval spent nuclear fuel and test specimens that originate from Navy and commercial shipyards, prototypes, and related Department of Energy laboratories. This evaluation covers all past shipments through May 1995 and shipments planned in the 40-year period from June 1995 through the end of 2035. This attachment evaluates the radiological risks associated with the five alternatives described in Section 3.

A.2 BACKGROUND

The transportation of naval spent nuclear fuel and test specimens covered in this attachment falls into the following four categories:

- Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes
- Transfers of Naval Spent Nuclear Fuel to Storage Following Examination
- Transfers of Naval Test Specimen Assemblies Between the Examination Facility and the Test Reactor Area
- Shipments of Naval Test Specimens to Examination and Testing Facilities.

Each category is described in more detail below.

A.2.1 Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes

Since 1956, spent nuclear fuel has been removed from Navy nuclear-powered ships and prototypes as a routine part of their operational cycle. The spent nuclear fuel has been transported to the Expended Core Facility (ECF) for examination and evaluation. ECF is part of the Naval Reactors Facility (NRF) within the Idaho National Engineering Laboratory (INEL). The examinations of the spent nuclear fuel and irradiated test specimens have provided and will continue to provide engineering data for materials and designs used in technology development for naval nuclear reactors.

In the past, shipments have originated from two prototype sites, nine shipyard locations, and the Shippingport Atomic Power Station (SAPS), located in Shippingport, Pennsylvania. The two prototype locations are the Kenneth A. Kesselring Site (KSO), located in West Milton, New York and the Windsor Site Operation (WSO), located in Windsor, Connecticut. The nine shipyard locations are Newport News Shipbuilding (NNS), located in Newport News, Virginia; the Norfolk Naval Shipyard (NOR), located in Portsmouth, Virginia; the Pearl Harbor Naval Shipyard (PHNS), located in Pearl Harbor, Hawaii; the Portsmouth Naval Shipyard (PNS), located in Kittery, Maine; the Puget Sound Naval Shipyard (PSNS), located in Bremerton, Washington; the Charleston Naval Shipyard (CNS), located in Charleston, South Carolina; the Mare Island Naval Shipyard (MINS), located in Vallejo, California; the Electric Boat Division of General Dynamics (EB), located in Groton, Connecticut, and Ingalls Shipbuilding (INGL), located in Pascagoula, Mississippi. Figure A-1 provides a map of the United States showing the transportation origins for naval spent nuclear fuel. No future shipments from the Electric Boat Division, Ingalls Shipbuilding, and Shippingport Atomic Power Station facilities are planned. The Mare Island Naval Shipyard, Charleston Naval Shipyard, and Windsor Site Operations facilities are being phased out.

The naval spent nuclear fuel has been shipped in M-130, M-140, M-160, and S2W/S2Wa shipping containers. Only the M-130, M-140, and M-160 shipping containers will be used in the future. A detailed description of the shipping containers to be used for naval spent nuclear fuel shipments from shipyards and prototype sites is provided in Section A.4.1.

Figure A-1. Transportation origins for naval spent nuclear fuel.

The naval spent nuclear fuel is primarily shipped by rail. However, for the two prototype sites, rail spurs to the sites are not available. Therefore, the shipping containers are transported by heavy-lift transporter to a nearby commercial rail line where the containers are then transported by rail. For the Pearl Harbor Naval Shipyard, the containers are transported by ship to the Puget Sound Naval Shipyard where the containers are then transported to ECF by rail. Since 1956, 599 containers of naval spent nuclear fuel have been shipped to ECF. An additional 16 containers of spent nuclear fuel were shipped (12 from Shippingport Atomic Power Station to Hanford and 4 from ECF to Hanford); however, these shipments are covered by the DOE historic shipment calculations in Appendix I, Volume 1 of this Environmental Impact Statement. Table A-1 provides a list of these shipments made by year and originating facility.

A.2.2 Transfers of Naval Spent Nuclear Fuel to Storage Following Examination

In the past, following examinations at ECF, the spent nuclear fuel has been prepared and transferred to the Idaho Chemical Processing Plant (ICPP), also located on the INEL. A detailed description of the operations performed in the Expended Core Facility is provided in Attachment B. Naval spent nuclear fuel is currently being held at ICPP until permanent disposition becomes possible.

Since 1956, approximately 5400 transfers of naval spent nuclear fuel have been made from ECF to ICPP in shipping casks transported by truck dedicated to performing only such shipments (exclusive-use). For alternatives involving continued transfers to storage, the transfers would be made in the NFS-100, Peach Bottom, and Large Cell casks, in exclusive-use trucks. A detailed description of the

shipping casks
used for naval spent nuclear fuel transfers to storage is provided in Section A.4.2.

A.2.3 Transfers of Naval Test Specimen Assemblies Between the

Examination Facility and the Test Reactor Area

In addition to naval spent nuclear fuel from ships and prototypes, irradiated test specimen assemblies (fuel and non-fuel) have also been transported to ECF for examination. Test specimens, which
are constructed of plant materials, reactor structural materials, and fuels used in naval reactor

Table A-1. Number of past naval spent nuclear fuel containers shipped to ECF by origin.

(1) Shipments in these years cover those authorized by the court injunction.

plants are tested and qualified to characterize their performance for the lifetime of the plant. Part of this qualification program is to perform various irradiation tests of the materials for lifetime effects prior to certification. Along with those tests are pre- and post-examinations that provide the necessary data for subsequent analysis of the material in question. This work is considered a fundamental requirement for the design and safe operation of naval reactor plants. Therefore, the transfers of test specimen assemblies to the examination facility and shipments of the test specimens to the test facilities are included in the transportation evaluation. The test specimens have been assembled into test specimen assemblies and irradiated at the Test Reactor Area (TRA) on the INEL. The irradiated test specimen assemblies are returned to ECF for disassembly and examination.

Since 1956, approximately 3600 transfers of naval test specimen assemblies have been made between ECF and TRA in shipping casks transported by exclusive-use truck. For alternatives involving future transfers of this type, the transfers would be made in the NR-1, ATR-2, NR-3, NR-4, and Test Train casks. A detailed description of the shipping casks used to transfer irradiated test specimen assemblies is provided in Section A.4.3.

A.2.4 Shipments of Naval Irradiated Test Specimens to Examination

and Testing Facilities

Following disassembly and examination of the test specimen assemblies at ECF, some specimens are shipped to off-site facilities for further testing or examination. These tests and examinations are generally very specialized and ECF does not have the capability to perform them or cannot perform them in a timely manner due to other examination priorities. Specimens are also shipped back to ECF for examination or further irradiation at TRA.

Test specimen shipments have been shipped to or from several laboratories and test facilities. They are the Bettis Atomic Power Laboratory (Bettis), located in West Mifflin, Pennsylvania; the

Knolls Atomic Power Laboratory (KAPL), located in Niskayuna, New York; the Oak Ridge National Laboratory (ORNL), located in Oak Ridge, Tennessee; the Argonne National Laboratory (ANL)-East, located in Argonne, Illinois; the Battelle Memorial Institute, located in Columbus, Ohio; the Chalk River Nuclear Laboratories, located in Chalk River, Ontario, Canada (1 shipment only); the Hanford Site, located in Richland, Washington; and the ANL-West, Central Facilities Area (CFA), TRA, and ICPP facilities, all located on the INEL. Based on current schedules, Bettis and KAPL will be the only origins for future shipments. Figure A-2 provides a map of the United States showing the transportation origins and destinations for the test specimen shipments.

Since 1956, approximately 850 shipments of naval test specimens have been made between ECF and on- and off-site testing and examination facilities, in shipping containers transported by exclusive-use truck. The shipments have been made in NRBK-41, -42, -43, and -44 shipping containers and the WAPD-39 and -40 shipping containers. For alternatives involving future shipments of this type, the shipments would be made in the NRBK-41 and WAPD-40 shipping containers. A detailed description of the shipping containers used to ship irradiated test specimens between off-site facilities and the examination facility is provided in Section A.4.4.

A.3 ALTERNATIVES TO BE EVALUATED

A detailed description of the alternatives is provided in Section 3. The specific impacts on each of the four types of naval shipments (described in Section A.2) are described below for each alternative.

A.3.1 Alternative 1 - No Action

Under this alternative, after implementation, there would be no further shipments of naval spent nuclear fuel from the shipyards and prototypes. The Expended Core Facility would be shut down. Naval spent nuclear fuel would be stored at a facility at the site where it was removed during reactor servicing, with the exception of naval spent nuclear fuel removed at Newport News Shipbuilding, a commercial shipyard, which would be transported to Norfolk Naval Shipyard for storage. All naval spent nuclear fuel currently at ECF would be transferred to ICPP prior to the start of the 40-year period with the exception of the fuel saved for future examinations, referred to as reference specimens. The reference specimens and the naval spent nuclear fuel which originated at the prototype sites at NRF would be shipped from ECF to ICPP sometime during the 40-year period. The TRA facility would perform any work associated with the assembly, disassembly, and routine examination of the test train assemblies; therefore, no transfers would be required. Specimens shipped off-site would remain at the destination following examination. Table A-2 summarizes the shipments for the No Action alternative.

Figure A-2. Transportation origins and destinations for test specimen shipments.

Table A-2. Summary of shipments for the No Action alternative.

Type of Shipment	
Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes	
- Shipyards and Prototypes to ECF	None
- Newport News to Norfolk	Yes
Transfers of Naval Spent Nuclear Fuel from ECF to ICPP	Reference Specimens and Prototype Only
Transfers of Naval Test Specimen Assemblies Between ECF and TRA	None
Shipments of Irradiated Test Specimens Between Off-Site Facilities and ECF	
- Shipments from ECF	Yes
- Shipments back to ECF	None

A.3.2 Alternative 2 - Decentralization

As described in Section 3.4, this alternative also involves storage of the naval spent nuclear fuel near the point of origin. An evaluation of each of the three subalternatives defined in Section 3 was performed. The impact of the transportation related to each subalternative is briefly described below.

A.3.2.1 Alternative 2a - Store Naval Spent Nuclear Fuel at or Close to Locations Where Removed Without

Examination. From the standpoint of transportation, this subalternative is equivalent to the No Action alternative.

A.3.2.2 Alternative 2b - Examine a Limited Amount of Naval Fuel in the Puget Sound Naval Shipyard Water

Pit Facility and Store All Naval Fuel at Navy Facilities. For this alternative, the Expended Core Facility at NRF would be shut down and only high priority spent nuclear fuel would be transported to the Puget Sound Naval Shipyard for examination. For the naval spent nuclear fuel, approximately 10 percent of the total spent nuclear fuel for the 40-year period would be shipped. Following examination, the fuel would remain at Puget Sound Naval Shipyard. As in the No Action alternative, only the reference specimens would remain at ECF after June 1995. Ten percent of the reference specimens would be transferred from ECF to Puget Sound Naval Shipyard. The remainder of the reference specimens and the naval spent nuclear fuel which originated at the prototype sites at NRF would be transferred to ICPP. The TRA facility would perform any work associated with the assembly, disassembly, and routine examination of the test specimen assemblies; therefore, no transfers would be required. Shipments of test specimens to off-site facilities for specialized examinations would continue. Test specimens shipped off-site would remain at the destination following examination. Table A-3 summarizes the shipments.

Table A-3. Summary of shipments for the Decentralization - Limited Inspection alternative.

Type of Shipment	
Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes	
- Shipyards and Prototypes to Puget Sound	Approximately 10% of spent fuel
- Newport News to Norfolk	Yes
Transfers of Naval Spent Nuclear Fuel from ECF to ICPP	Reference Specimens and Prototype Only
Transfers of Naval Test Specimen Assemblies Between Puget Sound and TRA	None
Shipments of Irradiated Test Specimens to Off-Site Facilities	
- Shipments from TRA	Yes
- Shipments back to TRA	None

A.3.2.3 Alternative 2c - Examine All Naval Spent Nuclear Fuel at the INEL and Return to Navy Facilities

for Storage. For this alternative, all naval spent nuclear fuel would be shipped to ECF and examined as it has been in the past. Only non-destructive examinations would be performed. The spent nuclear fuel would be returned in the same condition as originally shipped. Following examination, the fuel would be returned to the originating shipyard or prototype site for storage in the same type of container with the exception that naval spent nuclear fuel which originated at Newport News Shipbuilding would be shipped to Norfolk Naval Shipyard for storage. New equipment would have to be designed and procured to handle the spent nuclear fuel which returns to the shipyard. As in the No Action alternative, only reference specimens would remain at ECF after June 1995. The naval spent nuclear fuel which originated in the prototype sites at NRF (A1W and S5G) would be transferred to ICPP. Transfers of the irradiated test specimen assemblies would continue, along with the shipments of test specimens from ECF to off-site testing or examination facilities. Specimens shipped off-site would remain at the destination following examination. Table A-4 summarizes the planned shipments for this alternative.

Table A-4. Summary of shipments for the Decentralization - Full Examination alternative.

Type of Shipment	
Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes	
- Shipyards and Prototypes to ECF	Yes
- Newport News to Norfolk	To Norfolk from ECF
Transfers of Naval Spent Nuclear Fuel from ECF to ICPP	NRF Prototypes
Transfers of Naval Test Specimen Assemblies Between ECF and TRA	Yes
Shipments of Irradiated Test Specimens to Off-Site Facilities	
- Shipments from ECF	Yes
- Shipments back to ECF	None

A.3.3 Alternative 3 - 1992/1993 Planning Basis

This alternative plans on making the same types of shipments described in Section A.2 of this attachment. The only difference is that some of the historical origins of naval spent nuclear fuel and some destinations for the test specimen shipments will not be used. Table A-5 summarizes the planned shipments for this alternative.

Table A-5. Summary of shipments for the 1992/1993 Planning Basis alternative.

Type of Shipment	
Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes	
- Shipyards and Prototypes to ECF	Yes
- Newport News to Norfolk	No
Transfers of Naval Spent Nuclear Fuel from ECF to ICPP	Yes
Transfers of Naval Test Specimen Assemblies Between ECF and ATR	Yes
Shipments of Irradiated Test Specimens to Off-Site Facilities	
- Shipments from ECF	Yes
- Shipments back to ECF	Yes

A.3.4 Alternative 4 - Regionalization

As described in Section 3.4, this alternative would distribute existing and new spent nuclear fuel between various sites either on the basis of the fuel type or on the basis of dividing storage between the eastern and western parts of the United States. An evaluation of each of the options for this alternative described in Section 3.4 was performed. The impact of the transportation related to each option under this alternative is briefly described below.

A.3.4.1 Alternative 4a - Regionalization Using Storage at Three Sites.

From the standpoint of transportation of naval spent nuclear fuel and test specimens, this alternative is equivalent to the 1992/1993 Planning Basis alternative.

A.3.4.2 Alternative 4b - Regionalization Using Storage at Two Sites.

This alternative would utilize an existing DOE site in the eastern part of the United States and another existing DOE site in the western part of the country for storage of spent nuclear fuel. From the standpoint of transportation of naval spent nuclear fuel and test specimens, this alternative is equivalent to the Centralization alternative at each of the DOE sites because the Navy would operate a facility for examining naval spent nuclear fuel at only one of the DOE sites and the naval spent nuclear fuel would be stored at the same site where it was examined.

A.3.5 Alternative 5 - Centralization

This alternative considers consolidating all naval spent nuclear fuel and test specimens at the INEL, Hanford Site, Savannah River Site, Oak Ridge Reservation, or Nevada Test Site. Centralization at INEL is identical to the 1992/1993 Planning Basis alternative. For the other centralization sites, the type and number of shipments would be identical to the 1992/1993 Planning Basis alternative with the only difference being the destination. The naval spent nuclear fuel will be shipped to the centralization site for examination and subsequently transferred to a storage facility at the centralization site which would be equivalent to ICPP. Naval spent nuclear fuel shipments from Newport News Shipbuilding to Norfolk Naval Shipyard would not be necessary. As in the No Action alternative, only reference specimens would remain at ECF after June 1995. All reference specimens would be shipped to the centralization site. The naval spent nuclear fuel which originated in the prototype sites at NRF would also be transferred to the centralization site. The test specimen assembly shipments would be shipped between TRA and the alternate site. The test specimen shipments would originate at the centralization site and all specimens would ultimately return to that site for storage.

A.4 GENERAL DESCRIPTIONS

The following general information is common to all of the alternatives evaluated.

A.4.1 Spent Nuclear Fuel Shipping Containers

For naval spent nuclear fuel, the M-130, M-140, and M-160 shipping containers would be used for all alternatives. The shipping containers are primarily transported by railcars used only for this purpose as part of general-use freight trains. Section A.2.1 describes the special circumstances where the shipping containers are transported by ship or heavy-lift transporter. A brief description of each shipping container follows.

A.4.1.1 M-130 Shipping Container. The M-130 shipping container is a large, lead-lined, steel-shelled

shipping container that is transported in the vertical position on a depressed center railcar (Figure A-3). The major components of the M-130 shipping container include the shielded container, closure head, and dust cover. Module holders are installed inside the container to hold the irradiated fuel modules in place and can be modified to accept different sized fuel modules. The container is shipped dry with the exception of a small amount of residual water. Cooling fins on the outside of the container are designed to dissipate the heat generated by the spent nuclear fuel.

Figure A-3. M-130 shipping container mounted on railcar.

The M-130 shipping container weighs approximately 214,500 pounds in the standard loaded configuration. The container is approximately 13 feet tall and 7 feet in diameter. The container is a closed bottom cylindrical lead shell that is covered both on the inside and the outside with a 1-inch thick layer of steel. The lead on the cylindrical sides is about 10 inches thick and is a minimum of 9.5 inches thick on the bottom. In the standard configuration, the closure head at the top of the container is primarily constructed of 5.25 inches of lead and 7 inches of steel.

A.4.1.2 M-140 Shipping Container. The M-140 shipping container is a large, stainless steel shipping

container that is transported in the vertical position on a specially designed well-type railcar (Figure A-4). The major components of the M-140 shipping container include the shielded container, closure head, and protective dome. Module holders are installed inside the container to hold the irradiated fuel modules in place and can be modified to accept different sized fuel modules. The container is shipped dry with the exception of a small amount of residual water. Cooling fins on the outside of the container are designed to dissipate the heat generated by the fuel.

The M-140 shipping container weighs approximately 375,000 pounds in the loaded condition. The container is approximately 16 feet tall with a maximum diameter of 10.5 feet. The container body is made from stainless steel forgings with 14-inch thick walls and a 12-inch thick bottom. The closure head and protective dome have a total thickness of 17.5 inches of stainless steel.

A.4.1.3 M-160 Shipping Container. The M-160 shipping container is a large, lead-lined, steel-shelled

shipping container that is transported in a horizontal position on a support structure mounted on a modified flat bed railcar (Figure A-5). The major components of the M-160 shipping container include the shielded container, closure head, and dust cover. Module holders are installed inside the container to hold the irradiated fuel modules in place. The container is shipped dry with the exception of a small amount of residual water. Cooling fins on the outside of the container are designed to dissipate the heat generated by the fuel.

Figure A-4. M-140 shipping container mounted on railcar. Figure A-5. M-160 shipping container mounted on railcar.

The M-160 shipping container weighs approximately 235,500 pounds in the loaded condition. The container is approximately 16.5 feet long and 6.5 feet in diameter. The container consists of two concentric bottom closed steel cylinders with a 9.4-inch annulus between the cylinders that is filled with lead. The outer shell is made from 1.5-inch thick steel, and the inner shell is made from 1-inch thick steel. The bottom plate is approximately 7 inches thick, and the closure head is approximately 15 inches thick.

A.4.1.4 Government Escorts for Spent Nuclear Fuel. Commercial railroads, exclusive-use heavy-lift

transporters, or exclusive-use ships are used to transport the naval spent nuclear fuel from the prototypes and shipyards. The specific routes used to transport the spent nuclear fuel are selected by the rail or shipping companies. All naval spent nuclear fuel shipments are accompanied by government escorts. The escorts perform the duties necessary to ensure the safe, expeditious transportation of the naval spent nuclear fuel.

The government escorts receive specialized training in shipment safety procedures, radiological controls, security, and emergency response. Routine shipment escort procedures involve processing of authorization and shipping documentation, pre-shipment inspections, tracking shipment progress and schedules, enroute inspections, shipment observation and surveillance, and periodic communication checks. The government escorts have been trained to use and are equipped with the necessary radiological monitoring equipment to verify the shipping container integrity.

A large amount of the government escorts' training involves emergency response. This training involves emergency procedures for notification of technical and safeguards support personnel. The government escorts are equipped to immediately notify emergency assistance personnel, immediately assess the containment status of the shipping container, and communicate this information to emergency support personnel. Depending on the situation, the technical and support personnel may activate various emergency control centers that are prepared to provide the government escorts with the necessary support to quickly and safely bring an emergency situation under control. All railroads, which handle escorted shipments, also have specific emergency response procedures to safely expedite recovery for shipments that are involved in a rail line accident. Continually manned railroad operation centers maintain the capability to contact personnel from a combination of resources which provide appropriate equipment and manpower at the accident scene.

A.4.2 Spent Nuclear Fuel Shipping Casks for Transfers to Storage Following Examination

For naval spent nuclear fuel being transferred from the examination facility to storage (e.g., ECF to ICPP), the Nuclear Fuel Services Model 100 cask (NFS-100), Peach Bottom cask, and the Large Cell cask will be used for all alternatives. These shipping containers are transported by exclusive-use truck. A brief description of each cask follows.

A.4.2.1 NFS-100 Cask. The NFS-100 cask is a large, lead-lined, steel-shelled shipping cask that is transported in the horizontal position on a skid assembly attached to a tandem axle trailer (Figure A-6). The major components of the NFS-100 cask include the shielded cask and closure head. A fuel holding insert is installed inside the cask to hold the irradiated fuel modules in place. The container is shipped dry with the exception of a small amount of residual water. The cask is enclosed on the truck by a metal cover during shipment.

The NFS-100 cask weighs approximately 110,000 pounds in the loaded configuration. The cask is approximately 10.5 feet tall and 7 feet in diameter. The cask is a closed bottom cylinder of lead with a 0.375-inch thick steel inner shell and a 2-inch thick outer shell. The lead on the cylindrical sides is about 8.75 inches thick and the lead on the bottom is 8.8 inches thick. The closure head at the top of the cask is constructed of 9.75 inches of lead and 2 inches of steel.

A.4.2.2 Peach Bottom Cask. The Peach Bottom cask is a large, lead-lined, steel-shelled shipping cask that is transported in the horizontal position on a skid assembly attached to a tandem axle trailer (Figure A-7). The major components of the Peach Bottom cask include the shielded cask and closure heads. A fuel holding insert is installed inside the cask to hold the irradiated fuel modules in place. The cask is shipped dry with the exception of a small amount of residual water. The cask is enclosed on the truck by a metal cover during shipment.

Figure A-6. NFS-100 cask mounted on truck. Figure A-7. Peach Bottom cask mounted on truck.

The Peach Bottom cask weighs approximately 68,400 pounds in the loaded configuration. The cask is approximately 16 feet tall and 3.5 feet in diameter. The cask is a stepped cylinder of lead with a 0.25-inch thick steel inner shell and a 1.75-inch thick steel outer shell. The lead on the cylindrical sides ranges from 5.25 to 6.25 inches thick. The closure heads on each end of the cask are essentially identical and are constructed of 8.5 inches of steel.

A.4.2.3 Large Cell Cask. The Large Cell cask, currently being designed for larger fuel types, will be a

large, stainless steel shipping cask that is transported in the vertical position on a low-boy tractor trailer (Figure A-8). The major components of the Large Cell cask will include a shielded cask, closure head, shipping cask, and external impact limiters. Fuel-holding inserts will be installed inside the cask to hold the irradiated fuel modules in place. The cask will be shipped dry with the exception of a small amount of residual water. Cooling fins on the outside of the shipping cask are designed to dissipate the heat generated by the fuel.

The Large Cell cask will weigh approximately 220,000 pounds in the loaded condition. The shielded cask will be approximately 14 feet tall and 7 feet in diameter. The shielded cask body will be a closed bottom cylinder made from stainless steel forgings with 13.5-inch thick walls and a 13-inch thick bottom. The closure head will be a 14-inch thick stainless steel forging. The shielded cask will be assembled to the shipping cask during transport. The shipping cask will be a 2-inch thick aluminum closed bottom cylinder with fins extending to a total diameter of 93.6 inches. The external impact limiter assemblies, located on both ends of the cask, will be constructed of encased bi-directional aluminum honeycomb and are approximately 10 feet in diameter. The total Large Cell cask height will be approximately 17 feet.

A.4.2.4 Shipment Controls. All spent nuclear fuel transfers to a storage facility at the same site as the

examination facility will be accompanied by escorts. The escorts are personnel who are specially trained to perform the duties necessary to ensure the safe transportation of the spent nuclear fuel. The escorts are in vehicles located in front of and behind the truck carrying the shipping cask.

The escorts receive specialized training in shipment safety procedures, radiological controls, security, and emergency response. The escort vehicles are equipped with distinctive warning flashers, and the escorts are capable of radio contact with each other, the driver of the transport vehicle, and on-site emergency coordinating personnel.

Figure A-8. Large Cell cask.

A large amount of the escorts' training involves emergency response. This training involves emergency procedures for notification of site technical and safeguards support personnel. The escorts are equipped to immediately notify emergency assistance personnel, immediately assess the containment status of the shipping cask, and communicate this information to emergency support personnel. Depending on the situation, the technical and support personnel may activate various emergency control centers that are equipped with the equipment and manpower to provide the escorts with the necessary support to quickly and safely bring an emergency situation under control.

Additional administrative controls are imposed on the transfers to further minimize risks. For example, the transfers are not allowed to travel during heavy traffic periods such as shift changes, and the convoy travels at reduced speeds. The route itself also enhances safety, since the route is essentially flat and the highest possible drop distance in the event of an accident is approximately 5 meters (16.5 feet) at the location where the highway crosses a river bed.

A.4.3 Naval Test Specimen Assembly Casks for Transfers Between

TRA and the Examination Facility

For naval test specimen assemblies being transferred on-site between TRA and the examination facility, the NR-1, ATR-2, NR-3, NR-4, and Test Train casks will be used. These casks are transported by exclusive-use truck. For off-site shipments to the examination facility at the centralization sites, only the Test Train cask will be used. A brief description of each cask follows.

A.4.3.1 NR and ATR Casks. The NR and ATR casks are large, lead-lined, steel-shelled casks that are transported approximately 10y off horizontal in a cradle assembly attached to a tandem trailer (see Figure A-9). The major components of the casks include the shielded body, mast, and bottom closure/shield.

The shielded bodies of the casks are all approximately 32 inches in diameter. The outer steel shell thickness ranges from 0.5 inch to 1.0 inch. The thickness of the inner steel shell is approximately 0.4 inch for each cask. The lead ranges from approximately 10 inches to 11 inches for the various casks. The height of the shielded body ranges from approximately 6 feet to 12 feet. The mast is a tower section formed of reinforced aluminum and serves to support the structural end of the specimen assemblies which require very little shielding. A winch and platform are also attached to each cask. The bottom closure/shield is constructed of 1.0 to 1.75 inches of steel and 7.0 to 8.75 inches of lead.

Figure A-9. NR/ATR cask mounted on truck.

The NR and ATR casks range in weight from approximately 19,000 to 48,000 pounds. The overall cask height ranges from approximately 20 to 30 feet.

A.4.3.2 Test Train Casks. A new test specimen container would be required to transport irradiated test specimen assemblies between TRA and the examination facility located at the sites other than INEL for the Centralization alternative. A new cask is currently being designed to replace the current casks used to transport the test specimen assemblies between ECF and TRA, which are approaching the end of their design lifetime. The basic concept for this new cask is a thick-walled, stainless steel body with stainless steel closures on each end. Energy absorbers will be attached to the cask to prevent damage to the test specimens. The current estimated size of this cask is 34 feet long by 5 feet in diameter, weighing approximately 40 tons. This cask would be shipped by exclusive-use truck.

A.4.3.3 Shipment Controls. All spent nuclear fuel transfers to an examination facility at the same site as the irradiation facility will be accompanied by two escorts. The escorts are personnel who are specially trained to perform the duties necessary to ensure the safe transportation of the spent nuclear fuel. The escorts are in vehicles located in front of and behind the truck carrying the shipping cask.

The escorts receive specialized training in shipment safety procedures, radiological controls, security, and emergency response. A large amount of the escorts' training involves emergency response. This training involves emergency procedures for notification of site technical and safeguards support personnel. The escorts are equipped to immediately notify emergency assistance personnel, immediately assess the containment status of the shipping cask, and communicate this information to emergency support personnel. Depending on the situation, the technical and support personnel may activate various emergency control centers that are equipped with the equipment and manpower to provide the escorts with the necessary support to quickly and safely bring an emergency situation under control. The escort vehicles are equipped with distinctive warning flashers, and the escorts are capable of radio contact with each other, the driver of the transport vehicle, and emergency coordinating personnel.

Additional administrative controls are imposed on the shipments to further minimize risk. For example, the transfers are not allowed to travel during heavy traffic periods such as shift changes, and the convoy travels at reduced speeds. The route itself also enhances safety, since the route is essentially flat and the maximum possible drop in the event of an accident is from the bed of the truck to the road bed.

For the Centralization alternative, the casks would be shipped off-site. In this instance, only casks certified for over-the-road transportation in accordance with the Nuclear Regulatory Commission regulations would be used for shipments of the test trains. No escorts or additional administrative controls would be used.

A.4.4 Test Specimen Shipping Containers

For test specimens, the WAPD-40 and NRBK-41 shipping containers would be used to transport the specimens between ECF and the off-site laboratories and test facilities for all alternatives. These shipping containers are transported by an enclosed truck using a commercial carrier. A brief description of each container follows.

A.4.4.1 WAPD-40 Shipping Container. The WAPD-40 shipping container (Figure A-10) is a cylindrical,

lead-shielded, steel-clad container that is shipped in a horizontal position. The inner steel shell is 0.25-inch thick, and the outer steel shell is 0.5-inch thick with 9.875 inches of lead shielding in between. The container is approximately 13 feet long and 2 feet in diameter. Steel clad, lead-shielded end plugs bolt onto each end, and 0.5-inch thick plates are bolted over the end plugs. The specimens are placed into special sealed inner containers prior to placement into the WAPD-40 shipping container. The weight of the container and skid assembly is approximately 28,000 pounds. The container and skid assembly are mounted into a special holddown cradle on the truck. This holddown cradle weighs approximately 5,000 pounds.

A.4.4.2 NRBK-41 Shipping Container. The NRBK-41 shipping container (Figure A-11) is a cylindrical,

lead-shielded, steel-clad container that is shipped in the vertical position. The inner steel shell is 0.25-inch thick, and the outer steel shell is 0.5-inch thick with 10 inches of lead shielding in between. The container has a 1-inch thick steel plate welded to the bottom with a second 1-inch thick steel plate welded to the first plate with a 0.125-inch deep recess to provide a thermal break for the bottom of the container. The container also has a 0.25-inch thick steel outer thermal shield attached that provides a 0.125-inch air gap between the outer shell and the thermal shield. The container is approximately 4 feet tall and 2.25 feet in diameter. The container is bolted to a welded 48-inch square I-beam skid that is used to distribute the container load. The specimens are placed into a special sealed inner container prior to placement into the NRBK-41 shipping container. The weight of the loaded container is approximately 9,000 pounds.

Figure A-10. WAPD-40 shipping container. Figure A-11. NRBK-41 shipping container.

A.4.5 Shipping Container Design Requirements

The M-130, M-140, M-160, NRBK-41, and WAPD-40 shipping containers have been designed and built to meet the regulations specified in Title 49, Code of Federal Regulations, Part 173 (49CFR173), entitled " Shippers - General Requirements for Shipments and Packagings" (CFR 1991). Shipments of naval spent nuclear fuel and test specimens are further regulated by Title 10, Code of Federal Regulations, Part 71 (10CFR71), entitled "Packaging of Radioactive Material for Transportation and Transportation of

Radioactive Material Under Certain Conditions" (CFR 1993). These regulations require the shipping container to meet specific criteria under normal transport and accident conditions. The shipping container must be evaluated under free drop, puncture, heat, cold, pressure, water spray, and vibration for normal conditions and a series of severe hypothetical accident conditions with the results compared against the criteria provided in 10CFR71.

The M-130, M-140, M-160, WAPD-40, and NRBK-41 shipping containers have undergone rigorous engineering evaluations to assure compliance with 49CFR173 and 10CFR71 requirements. In addition, actual scale model or mock-up tests have been performed to verify selected engineering evaluations. This compliance has been certified by the U. S. Department of Energy and the Nuclear Regulatory Commission. The new Test Train and Large Cell casks will also be designed in accordance with the requirements of 49CFR173 and 10CFR71 and will undergo the same rigorous engineering evaluations and testing.

The safety analyses for the NFS-100, Peach Bottom, NR, and ATR casks demonstrate compliance with the requirements specified by the Department of Energy (DOE) in DOE Order 5480.3, entitled "Safety Requirements for the Packaging and Transportation of Hazardous Materials, Hazardous Substances, and Hazardous Wastes" (DOE 1985) and supplemented by DOE Idaho Operations Office Order ID 5480.3, entitled "Hazardous Materials Packaging and Transportation Safety Requirements" (DOE 1991). These requirements are similar to the requirements of 10CFR71 with the major difference being that a worst credible accident can be defined based on site-specific information.

The NFS-100, Peach Bottom, NR, and ATR casks have undergone rigorous engineering evaluations to assure compliance with the DOE requirements. In addition, actual scale model or mock-up tests have been performed to verify selected engineering evaluations. The shipping casks comply with the requirements of DOE 5480.3 and DOE ID 5480.3 and this compliance is demonstrated by approval from the Idaho Operations Office of the Department of Energy.

A.5 TECHNICAL APPROACH - GENERAL

Several computer codes were used to assess the radiological risks associated with the transportation of naval spent nuclear fuel and test specimens. Specifically, the RADTRAN 4 risk analysis model, developed by Sandia National Laboratories (Neuhauser and Kanipe 1992), was used to calculate the general population and transportation crew (occupational) radiological risks associated with the transportation of radioactive materials. This computer code was used extensively in the incident-free and accident risk assessments. In some cases, other methods were more appropriate than the RADTRAN 4 computer code for naval spent nuclear fuel. In these cases, other calculational models were used and are specifically identified.

The RISKIND computer code, developed by Argonne National Laboratory (Yuan et al. 1993), also specifically analyzes radiological consequences and health risks to individuals from exposure associated with transportation. For incident-free evaluations, RISKIND uses a generic truck cask and does not allow adjustments for different sized casks which is not appropriate for naval spent nuclear fuel and test specimen casks; therefore, this code was not used. RISKIND (a version which accepts fuel-specific isotopes) was found to be the best code for calculation of the maximum individual and general population consequences for the accident scenario and was used for that purpose.

Several other computer codes were used to provide input for the RADTRAN 4 and RISKIND computer codes. The codes include INTERLINE, HIGHWAY, SPAN4, and ORIGEN2. A description of each computer code and how the code was used is provided below.

The INTERLINE computer code, developed by Oak Ridge National Laboratory (Johnson et al. 1993a), was used to evaluate the rail routes used for the spent nuclear fuel shipments.

The HIGHWAY computer code, also developed by Oak Ridge National Laboratory (Johnson et al. 1993b), was used to evaluate the truck routes used for the test specimen shipments.

The SPAN4 computer code (Wallace 1972) was used to perform gamma exposure rate calculations for the various shipping containers to assess the effect of increased distance from the source on exposure. SPAN4 is a point kernel code where appropriate exponential kernels are integrated over a source distribution. SPAN4 was developed by the Bettis Atomic Power Laboratory specifically for naval spent nuclear fuel.

The ORIGEN2 is a computer code, developed by Oak Ridge National Laboratory (Croff 1980), that is used to simulate radiation and decay of materials that are irradiated in a nuclear reactor. The ORIGEN2 computer code is widely accepted in the public domain and was used to independently confirm the fission product inventory for naval fuel developed using the standard Bettis Atomic Power Laboratory method. In addition, the standard Bettis Atomic Power Laboratory method has been used in Safety Analysis Reports for Packaging, reviewed and accepted by the Nuclear Regulatory Commission.

The radiological risks associated with the transportation of spent nuclear fuel and irradiated test specimens have been assessed for the general population, transportation workers (occupational), and hypothetical maximum exposed individuals under incident-free and accident conditions for the alternatives presented in Section A.3. The maximum consequences for an accident are also provided for each alternative. The radiation exposure to the government escorts for shipments was considered occupational in nature and was included with the transportation worker results.

The radiological impacts are first expressed as the calculated total exposure for the exposed population, occupational workers, and the maximum exposed individuals. The calculated total exposures are then used to estimate the hypothetical health effects, expressed in terms of estimated cancer fatalities. The health risk conversion factors used in this evaluation are taken from the International Commission on Radiological Protection (ICRP Publication 60) which specifies 0.0005 fatal cancer cases per person-rem for members of the public, 0.0004 fatal cancer cases per person-rem for workers (ICRP 1991). To calculate the estimated health detriment, the calculated exposure would be multiplied by the conversion factors of 0.00073 health detriments per person-rem for members of the public, and 0.00056 health detriments per person-rem for workers (ICRP 1991).

The numerical estimates of cancer deaths and other health detriments presented were obtained by the practice of linear extrapolation from the nominal risk estimate for lifetime total cancer mortality at 10 rad. Other methods of extrapolation to the low-dose region could yield higher or lower numerical estimates of cancer deaths. Studies of human populations exposed at low doses are inadequate to demonstrate the actual level of risk. There is scientific uncertainty about cancer risk in the low-dose region below the range of epidemiologic observation, and the possibility of no risk cannot be excluded (CIRRPC 1992). In this appendix, the doses have been provided in all cases to allow independent evaluation using any relation between exposure and health effects.

Non-radiological risks related to the transportation of naval spent nuclear fuel are also estimated. The non-radiological risks are associated with vehicle exhaust emission for incident-free transportation and fatalities resulting from transportation accidents. The non-radiological risks associated with shipments that return empty containers to the origin are also included. Risk factors for vehicle exhaust emissions and state-level accident fatality rates were obtained from "Non-Radiological Impacts of Transporting Radioactive Material" (Rao et al. 1982), "Transportation Impacts of the Commercial Radioactive Waste Management Program" (Cashwell et al. 1986), and "Longitudinal Review of State-Level Accident Statistics for Carriers of Interstate Freight" (Saricks and Kvitek 1994), respectively.

The shipments of radioactive waste at shipyards are not addressed. The exposure related to incident-free transportation would be small and would be the same for all alternatives which would not affect the decision-making process. The consequences of an accident would also be insignificant compared to the accidents analyzed for spent nuclear fuel.

For the ocean-going portion of the shipments of naval spent nuclear fuel from shipyards and prototypes, there would be no exposure to the general population. The basis for this conclusion is that the ship's hull provides a considerable amount of additional shielding and that there would be no members of the general population close enough to the ship to receive appreciable exposure during these shipments. The consequences of an accident during the ocean-going portion have also not been evaluated because the forces on the container during an accident aboard the ship would not be large enough to cause damage to the container or fuel inside it since the ship itself would sustain the direct impact. This is substantiated by the fact that the impact forces to the container would be less than the regulatory criteria. Therefore, no release would occur.

A.5.1 Technical Approach for the Assessment of

Incident-free Transportation

For incident-free transportation of naval spent nuclear fuel, the RADTRAN 4 computer code was used to calculate the radiological exposure for the general population and a portion of the occupational exposure.

Included in the RADTRAN 4 computer code incident-free risk calculations for transport are models describing (1) exposures to persons (e.g., residents) adjacent to the transport route (off-link exposures), (2) exposures to persons (e.g., passengers on passing trains or vehicles) sharing the transport route (on-link doses), (3) exposures to persons at stops (e.g., residents or rail and truck crew not directly involved with the shipment), and (4) exposures to transportation crew members (occupational). The exposures calculated for the first three groups were added together to estimate the general population exposure estimates for rail and truck transport; the exposure calculated for the fourth group represents occupational exposure to the rail crew exposures during inspections and truck crew during transit and inspections. Table A-6 summarizes the calculational methods used for each group for the shipment of naval spent nuclear fuel and test specimens.

As shown in Table A-6, simple calculations were performed to account for situations where the RADTRAN 4 computer code was not the best calculational model with respect to the transportation of naval spent nuclear fuel. The information used in the simple calculations was based on historical information. The results obtained using these simple calculations are expected to be equal to or greater than any exposures which might actually occur.

The maximum possible radiological exposure to an individual for the routine transport of naval spent nuclear fuel and test specimens off-site was estimated for transportation workers, as well as members of the general population. For rail shipments, the three general population scenarios were: (1) a railyard worker who might be working at a distance of 10 meters (32.8 feet) from the shipping container for 2 hours, (2) a resident who might live 30 meters (98.4 feet) from the rail line

Table A-6. Calculational methods used to obtain exposures for population groups of interest.

Shipment Type	Origin	Destination(a) a)	Mode	General Population			Occupational	
				Off-Link and On-Link	Stops	Maximum Individuals	Workers	Escorts
Spent Nuclear Fuel to ECF or Equivalent	Kesselring Site	Ballston Spa	Truck	(1)	(3)	(6)	(3)	(3)

Calculational Methods:
(1) RADTRAN 4 calculations.
(2) RADTRAN 4 rail calculations for inspection exposure and simple calculations based on rail transportation data supplied by the government escorts for rail transit exposure.
(3) Simple calculation model based on truck transportation data supplied by site personnel.
(4) Simple calculation model based on ship transportation data supplied by Pearl Harbor Naval Shipyard.
(5) Exposures based on historical TLD readings.
(6) Simple calculation model based on scenarios provided in RISKIND.
(a) The methods provided in this table apply to the destination for all the alternatives evaluated.

where the shipping container was being transported, and (3) a resident who could be living 200 meters (656.2 feet) from a rail stop where the shipping container was sitting for 20 hours. The government escorts and crew members from the rail, heavy-lift transporter, and ship were evaluated for the transportation workers (occupational). Based on records of past escorted rail shipments, the government escort might be the same individual for as many as two-thirds of the shipments in a 5-year period. The crew members were postulated to be the same individuals for all shipments in the 40-year period.

For off-site truck shipments, the three scenarios for the general population were: (1) a person who might be caught in traffic and located 1 meter (3 feet) away from the surface of the shipping container for one-half hour, (2) a resident who might be living 30 meters (98.4 feet) from the highway used to transport the shipping container, and (3) a service station worker who might be working at a distance of 20 meters (65.6 feet) from the shipping container for 2 hours. The hypothetical maximum exposed individual radiological exposures were accumulated over the 40-year period. However, for the situation involving an individual who might be caught in traffic next to a truck transporting spent nuclear fuel, the radiological exposures were only calculated for one event since it was considered unlikely that the same individual would be caught in traffic next to all containers for all shipments. For truck shipments, the occupational maximum exposed individual is the driver. For each of the categories of truck shipments described in Sections A.4.2 through A.4.4, the calculations used a single individual as the driver for all shipments made in the past. For shipments in the 40-year period being evaluated, a single person was also used in the calculations as the driver for all shipments of each category.

The hypothetical maximum exposed individual scenarios for the general population described above were not applicable for on-site shipments of naval spent nuclear fuel and test specimens for two reasons. The first is that there are no members of the general population in the vicinity during the on-site shipments. The second reason is that an obstruction, if encountered, would be safely avoided under the direction of the escorts. Two alternate scenarios were developed. They were: (1) a site employee in a disabled vehicle along the transport route, located 10 meters (32.8 feet) from the container and (2) a site employee trailing the slow-moving transport vehicle for the entire trip. These scenarios were considered to be single-event occurrences.

As noted in Table A-6, simple methods were also used to calculate radiological exposures. For radiological exposures to personnel at a fixed distance from the shipping container, the following equation was used.

Exposures to personnel at a fixed distance from the container:
= N x NBA x T x SF x K x TI / D2

where:
N = number of people
NBA = factor to account for exposure decrease at increased distance from the source (attenuation/buildup). (Refer to Neuhauser and Kanipe 1993.)
T = time

SF = shielding factor
K = transport index to exposure rate conversion factor
TI = transport index (see Section A.7.1.1.2)
D = distance from the centerline.

For the radiological exposures associated with the ship transport of spent nuclear fuel from the Pearl Harbor Naval Shipyard to the Puget Sound Naval Shipyard, the following general equations were used:

Exposures to personnel aboard ship during transport:

$$= N \times NBA \times T \times SF \times K \times TI \times (1/(X1 + X2)2 + 1/X22)$$

where:

X1 = distance between the centerlines of the two shipping containers
X2 = distance between centerline of the nearest shipping container and the exposed individual

Exposures to personnel aboard ship during inspections:

$$= (N \times T \times TI) + (N \times NBA \times T \times K \times SF \times TI / (X1 - R - 1)2)$$

where:

R = effective radius to account for the exposure from the second shipping container.

Table A-7 provides an estimate of the number of people included in the analyses. To determine this number, the basic equation used was:

(Distance Traveled) x (Exposure Path Width) x (Density of People).

In each alternative, there are many shipments from several different origin/destination combinations. Since the route would be the same for each shipment from the same origin/destination combination, the people along the route would also not change, therefore, the distance used was from one trip for each origin/destination combination. The exposure path width is 1.6 kilometers (1 mile), consistent with the RADTRAN 4 computer code methodology for incident-free calculations. The population density was calculated by summing the product of the fraction of travel times the density in each population area (rural, suburban, and urban). The fraction of travel and density were obtained from HIGHWAY and INTERLINE. The total number of people was then calculated by summing the results of all origin/destination combinations for each alternative.

Table A-7. Estimated number of people included in incident-free transportation analyses.

Alternative	Number of People
No Action	890,000
Decentralization - No Examination	890,000
Decentralization - Limited Examination	9,240,000
Decentralization - Full Examination	6,820,000
1992/1993 Planning Basis	7,290,000
Regionalization or Centralization at INEL	7,290,000
Regionalization or Centralization at Hanford	8,370,000
Regionalization or Centralization at Savannah River	6,950,000
Regionalization or Centralization at Oak Ridge	5,660,000
Regionalization or Centralization at Nevada Test Site	8,320,000

A.5.2 Technical Approach for Transportation Accidents

The RADTRAN 4 computer code was used to calculate the radiological risk to the general population and transportation (occupational) crew under accident conditions. The RADTRAN 4 computer code evaluates six pathways for radiation exposures resulting from an accident. The six potential pathways are:

- Direct Radiation Exposure from the Damaged Container
- Inhalation Exposure from the Plume of Radioactive Material Released from the Damaged Container
- Direct Radiation Exposure from Immersion in the Plume of Radioactive Material Released from the Damaged Container
- Direct Radiation Exposure from Ground Deposition of the Radioactive Material Released from the Damaged Container
- Inhalation Exposure from Resuspension of the Radioactive Material Deposited on the Ground
- Ingestion Exposure from Food Products Grown on the Soil Contaminated by Ground Deposition of Radioactive Material Released from the Damaged Container.

For each pathway, a specific formula is used to determine an estimate of the radiological risk, expressed in exposure, from that particular pathway with the total radiation exposure equal to the sum of the exposure for each pathway. The total accident radiation exposure accounts for the probability of an accident occurring and the probability of an accident of a particular severity. It should be noted that all consequences are included in the risk assessment, regardless of the probability. The general equation for the population exposure from all pathways is:

DR = -c,r (Nc x Lr,c x Pr x -i,j,k (Pj x RFj x Di,j,k))

where: DR = population exposure from the accident
Nc = number of naval spent nuclear fuel modules shipped of fuel type c
Lr,c = shipment distance for fuel type c shipped through state r
Pr = frequency of traffic accidents
Pj = probability of occurrence of accident severity category j
RFj = fraction of curies released from shipping container by severity category j
Di,j,k = radiation exposure resulting from accident severity category j through pathway i in population density zone k.

The accident risk evaluation was performed using neutral and stable atmospheric conditions (Pasquill Stability Classes D and F, respectively). The neutral atmospheric condition results provide a best estimate of the risk. Stable atmospheric conditions resulted in values approximately twice the neutral conditions, ignoring the lower probability of occurrence.

In addition to the estimation of the radiological risk of an accident described above, an evaluation of the consequences of an accident of the highest severity was performed. The consequences, expressed as radiological exposure, are calculated for the maximum exposed individual and the general population. Exposures to the general population were calculated for each of the three population density regions (rural, suburban, and urban). The maximum exposed individual was placed in the population area which resulted in the highest exposure.

The RISKIND computer code, modified by its authors to accept the fission product inventory unique to naval spent nuclear fuel, was used to calculate the maximum consequences. The pathways evaluated by RISKIND are identical to those used in the RADTRAN 4 computer code for the risk evaluation.

The maximum consequence evaluation presents the consequences for design basis accidents, defined as those accidents which have a probability of greater than 1 x 10y6 per year, and beyond design basis accidents, defined as those which have a probability of 1 x 10y6 to 1 x 10y7 per year. Accidents with a probability of less than 1 x 10y7 were not analyzed in the maximum consequence evaluation.

To determine the overall probabilities, the probability of an accident, the probability of the consequences, fraction of travel in each population area, and probability of the meteorological conditions had to be determined.

The probability of the accident was calculated by multiplying the accident rates for each state times the distance traveled in each state times the number of shipments. The results were summed for each combination of origin and destination for the alternative.

As described later in Section A.7, a study performed by Lawrence Livermore National Laboratory entitled "Shipping Container Response to Severe Highway and Railway Accident Conditions" (NUREG 1987) grouped accidents into categories by strain and container mid-wall temperatures and calculated the probabilities of accidents of each category. Section A.7 also describes the consequences associated with each accident category for the naval spent nuclear fuel and test specimen shipments. The probabilities were summed for the categories which have the same consequences.

The fraction of travel in each population area (rural, suburban, and urban) was obtained from INTERLINE and HIGHWAY for each origin/destination combination. Each alternative consists of many shipments from various origin/destination combinations; therefore, an overall fraction was calculated. The overall fraction, by alternative, was calculated by multiplying each origin/destination fraction (from INTERLINE and HIGHWAY) by the number of shipments from that particular origin/destination combination, summing the results and dividing by the total number of shipments.

To calculate the probability of the meteorological conditions, Pasquill Class D was considered to be equivalent to 50% meteorology; that is, 50% of the time, conditions are expected to be more severe, and 50% of the time, conditions are expected to be less severe. Pasquill Class F was considered to be equivalent to 95% meteorology; that is, 5% of the time, it is more severe, and 95% of the time, it is less severe. Since the difference in 50% (1 chance in 2) and 95% (1 chance in 20) is a factor of 10, the probability of encountering Pasquill Class F was concluded to be a factor of 10 less than Pasquill Class D. Analyses performed by the National Oceanic and Atmospheric Administration (Doty et al. 1976) confirm that this assumption is reasonable.

The overall probability of the consequence of an accident for each population area was then calculated by multiplying the accident probability times the consequence probability times the fraction of distance traveled. Starting with the highest consequences, the probabilities were then compared to the 1 x 10y6 per year criterion for the design basis accidents and 1 x 10y7 per year criterion for the beyond design basis accidents. If the probability was greater than 10 times the criterion (1 x 10y6 or 1 x 10y7), the most severe Pasquill Class F results were presented. If not, and the probability was greater than the criterion (1 x 10y6 or 1 x 10y7), Pasquill Class D was presented. If the probability was less than the cutoff, the probabilities having the next most severe consequences were compared to the same criterion and this step was repeated until all consequences were evaluated. As a minimum, the consequences resulting from release of 1% of the corrosion products (Pasquill Class D) were presented.

Careful attention was paid to ensure that the probabilities were not calculated for such small categories that the resulting probabilities were less than the criterion and results would inadvertently present less severe consequences. When the highest consequence accident did not meet the criterion, the probability of the next highest accident was determined by summing both the accident consequence being evaluated and the probability of the higher consequence accidents previously shown to have a probability less than the criterion. This same technique was applied to the fraction of travel (urban fraction is equivalent to highest consequence, suburban fraction is next highest, etc.) as demonstrated in the following example.

Probability of the accident of Consequence A - 1.17 x 10y7
Fraction of distance traveled in rural area - 0.85
Fraction of distance traveled in suburban area - 0.11
Fraction of distance traveled in urban area - 0.04

The urban fraction was multiplied by the probability, and the resultant probability of an accident of Consequence A in an urban area was 4.68 x 10y9. The consequences of this accident would not be evaluated. For the suburban area, the suburban and urban fractions were added and then multiplied by the probability (1.75 x 10y8). Again, the consequences of this accident would not be evaluated since the probability is less than 1 x 10y7. Likewise, for the rural area, the rural, suburban, and urban fractions were added and multiplied by the probability. Using this technique, the probabilities would indicate that the rural probability was 1.17 x 10y7, which is greater than the 1 x 10y7 criterion and the Consequence A results would be presented. If the fractions were used at face value, however, the probability of an accident of Consequence A would have been 4.68 x 10y9 in an urban area, 1.29 x 10y8 in a suburban area, and 9.95 x 10y8 in a rural area. When individually compared to the 1 x 10y7 criterion, this accident would not have been presented for any area.

Accident results are presented for both the maximum exposed individual and the general population. These results include members of the transportation crew.

A.6 ROUTING ANALYSIS

In order to assess the radiological risks associated with transportation, it was necessary to determine route characteristics based on the origin and destination of each shipment.

For naval spent nuclear fuel shipments, the origin is the prototype or shipyard location where the naval spent nuclear fuel is removed from a prototype or shipboard reactor. The destination is ECF, Savannah River Site, Hanford Site, Oak Ridge Reservation, Nevada Test Site, or Puget Sound Naval Shipyard, depending on the alternative. For each origin and destination pair, the potential rail routes have been generated and analyzed using the INTERLINE computer code (Johnson 1993a). For shipments originating from Pearl Harbor Naval Shipyard, the containers travel by ship to Puget Sound Naval Shipyard, where they are transferred to rail for shipment to the destination following the same routes as the naval spent nuclear fuel shipments originating from Puget Sound Naval Shipyard. The shipment travel time by ocean was based on historical data on the time in transit, independent of the actual route. For heavy-lift transporter shipments from the Kesselring and Windsor prototype sites to the closest rail siding, the actual street routes and shipment duration times based on previous shipments were used.

INTERLINE is an interactive computer program designed to simulate routing using the U.S. rail system. The INTERLINE code used is the latest available from Oak Ridge National Laboratory and contains the 1990 census data. The INTERLINE data base consists of networks representing various competing rail companies in the U.S. The routes used for the transportation evaluation use the standard INTERLINE model which simulates the selection procedure that railroad companies would use to direct shipments of spent nuclear fuel. The code is updated periodically to reflect current track conditions and has been benchmarked against reported mileages and observations. INTERLINE also provides the weighted population densities for rural, suburban, and urban populations for each state and averaged over all states along the shipment route and the percentage of mileage traveled in each population density. The distance traveled, weighted population density, and percentage of distance in each population density are input variables in the RADTRAN 4 code.

For the off-site transportation of the test specimen assemblies and test specimens, all shipments are made by exclusive-use truck which includes no other freight. The destinations are ECF, Savannah River Site, Hanford Site, Oak Ridge Reservation, Nevada Test Site, Puget Sound Naval Shipyard, Bettis Atomic Power Laboratory, and Knolls Atomic Power Laboratory for the various alternatives. For each origin and destination pair, the potential truck routes have been generated and analyzed using the routing model HIGHWAY.

HIGHWAY is an interactive computer code designed to simulate routing using the U.S. highway system. The HIGHWAY code used for this report is the latest available from Oak Ridge National Laboratory. The code is updated periodically as new roads are added. HIGHWAY provides the distance between the origin and destination, the weighted population densities along the route, and the percentage of distance traveled in each population density, all input variables for the RADTRAN 4 computer code.

For the on-site transportation, HIGHWAY only has two of the sites on the INEL. This origin/destination pair was run using HIGHWAY to determine the population densities and percentage of travel in each population density. The actual distance between sites on the INEL was measured.

A.7 INPUT PARAMETERS

The major input parameters and models used to evaluate the radiological risks associated with the five alternatives described in Section A.3 are provided in this section. Standard RADTRAN 4 computer code values, as well as actual data gathered from historical naval spent nuclear fuel and test specimen shipments, were used as the basis for the input parameters. For those situations where historical data were available, the actual data were used in place of the standard RADTRAN 4 computer code values to provide the best estimate of the radiological risks associated with each alternative.

A.7.1 Shipments of Naval Spent Nuclear Fuel from Shipyards and Prototypes

A.7.1.1 Incident-free Transportation of Spent Nuclear Fuel from Shipyards and Prototypes. This section provides the input parameters used to determine the radiological impacts associated with the routine, incident-free (i.e., no accident) transportation of spent nuclear fuel for each of the five alternatives.

A.7.1.1.1 Planned Shipments. The list of planned shipments of naval spent nuclear fuel by origin is provided in Table A-8.

Table A-8. Planned shipments of naval spent nuclear fuel from shipyards and prototypes.

Alternative	Generating Site East Coast	West Coast	NRF	TOTAL	Origin or Destination
No Action, Decentralization - No Exam	204	0	0	204	To Norfolk
Decentralization - Limited Exam	53	0	1	54	To Puget Sound
	181	0	0	181	To Norfolk
	234	0	1	235	
Decentralization - Full Exam	314	261	0	575	To ECF
	314	261	0	575	From ECF
	628	522	0	1150	
1992/1993 Planning Basis, Regionalization at INEL and Centralization at INEL	314	261	0	575	To ECF
All other Regionalization and Centralization Alternatives	314	261	3	578	To Regionalization or Centralization site

A.7.1.1.2 Transport Index. Historical information from prior shipments was used to estimate the expected external radiation exposure rates for future shipments. This information included actual measured radiation levels and the recorded Transport Indexes (TIs) from past shipments. The TI used in this analysis is the sum of the maximum neutron and gamma radiation measured at 1 meter (3.3 feet) from the surface of the cask. The TIs that were used ranged from 0.1 to 1.8.

A.7.1.1.3 Transportation Distances and Population Densities. Section A.6 provided a description of the general methodology used for determining transportation distances and the population densities along the transportation routes. Historical data were obtained on the distance traveled for shipments from the shipyards and prototype sites to ECF. These data were averaged by origin and compared to the value calculated by INTERLINE. The actual data were approximately 11% higher than the distance predicted by INTERLINE on average. In order to provide the best estimate exposure, which is based on the distance traveled, the INTERLINE distances were increased by 11% for the 1992/1993 Planning Basis alternative. One of the primary reasons the actual distances traveled were judged to be longer than the INTERLINE prediction was the escort responsibility to avoid potential delays due to track or security problems. The shipments to the alternative sites will also be escorted and therefore the same increased travel distance is expected. The 11% increase in distance traveled was also applied to all other alternatives. This technique allowed for comparison of the alternatives on an equal basis. The percentages of distance traveled in each population density calculated by INTERLINE were applied to the distances increased by 11%.

A.7.1.1.4 Train Speed. The RADTRAN 4 computer code provides standard values for train

speeds that are dependent on the population density. For rural areas, the standard value is 64.4 kilometers per hour (40 miles per hour (mph)). For suburban areas, the standard value is 40.2 kilometers per hour (25 mph), and for urban areas, the standard value is 24.1 kilometers per hour (15 mph). However, naval spent nuclear fuel shipments are required to be transported at speeds not to exceed 56.3 kilometers per hour (35 mph). Government escort logs from historical spent nuclear fuel shipments support use of 24.1 kilometers per hour (15 mph). This 24.1 kilometers per hour (15 mph) train speed estimate was used to evaluate all five alternatives.

A.7.1.1.5 Train Stop Time. The RADTRAN 4 computer code provides standard values for train

stop times that are either dependent or independent of the distances traveled. For naval spent nuclear fuel transported by rail, the government escorts are responsible for ensuring that the shipments are made in the most efficient and safe manner. The government escort logs for historical spent nuclear fuel shipments were reviewed, and actual stop times were determined to be much shorter than the standard RADTRAN 4 computer code values. The recorded stop times were divided by the actual distance traveled from historical data over the last 3 years and an average of 0.02 hour per kilometer (0.032 hour per mile) was calculated. This value was used to evaluate all five alternatives since the rail transportation of spent nuclear fuel will always be accompanied by government escorts and all alternatives originate from the same locations.

A.7.1.1.6 Number of Train Crew Members. The standard RADTRAN 4 computer code value for the

number of train crew members is five. For all shipments to NRF, all rail companies with the exception of Burlington Northern have two crew members during shipments, located in the locomotive. Burlington Northern adds a third crew member in a caboose immediately behind the government escort caboose. In the RADTRAN 4 computer code, exposure to the crew members is not calculated since the distance to the crew members is large. In actuality, the distance to the Burlington Northern crew member located in the caboose is less than that used in the RADTRAN 4 computer code and therefore simple calculations were performed to determine the radiological exposure. In addition, naval spent nuclear fuel shipments also are shipped periodically by "special train." In the special train configuration, the two crew members in the locomotive are one car from the railcar with the shipping container. Historically, these shipments occur approximately 42 percent of the time. The majority of shipments by "special" train are arranged by the railroad companies to meet railroad schedules. On occasion, the Navy requests "special" train service for shipments with high-priority examination material. Simple calculations were also performed to determine the radiological exposure during these special shipments. For shipments to the sites other than NRF, there was no experience with all railroad companies which would have to be used; however, there is no reason to expect the rail companies to change their standard practices. In these cases, there would be two train crewmen, both located in the engine area. Forty-two percent of the shipments would be shipped by special train to the alternate sites. When applicable, the third Burlington Northern crew member was also accounted for.

A.7.1.1.7 Transport Index to Exposure Rate Conversion Factors. Container transport index to exposure rate conversion factors for the M-130 and M-140 shipping containers were calculated using the standard equation in the RADTRAN 4 computer code. The results were compared to detailed computer analyses performed using SPAN4, and the RADTRAN 4 results were found to overestimate the exposure by a factor of two to three. Using the SPAN4 computer code results, the effective package dimensions of the containers used in the RADTRAN 4 calculations were adjusted to provide a conservative yet more realistic value of the transport index to exposure rate conversion factor. Due to similarities in the construction and fuel shipped, the M-130 conversion factor was applicable to the M-160. The values used are provided in Table A-9.

Table A-9. Transport index to exposure rate conversion factors for the M-130, M-140, and M-160 shipping containers.

Container	Effective Package Dimension (meters)	Transport Index to Exposure Rate Conversion Factor
M-130/M-160	2.50 (8.2 feet)	5.06
M-140	3.20 (10.5 feet)	6.76

A.7.1.1.8 Train Stop Shield Factors. For train stops, the standard RADTRAN 4 computer code gamma and neutron radiation shield factors are both assigned as 0.1. This value includes the presence of substantial railyard steel structures equivalent to approximately 4 inches of steel. Four inches of steel reduces gamma radiation by more than a factor of 10; however, the steel only reduces neutron radiation by a factor of approximately 2. Therefore, a shield factor of 0.5 was conservatively used for neutron radiation. In order to incorporate this shielding into the RADTRAN 4 computer code, separate gamma and neutron radiation exposure calculations were performed. However, since RADTRAN 4 does not permit separate shielding factors to be used for different types of radiation, the stop times for the neutron radiation evaluations were increased by a factor of 5 to provide an equivalent increase in neutron exposure. These more realistic changes to the standard RADTRAN 4 computer code values were incorporated for all five alternatives.

A.7.1.1.9 Radiation Exposure Decrease Due to Distance. The RADTRAN 4 computer code provides standard values for determining the gamma and neutron radiation exposure decrease at increasing distance from the source. For gamma radiation, the RADTRAN 4 computer code uses the 1/x2 decrease due to distance. The RADTRAN 4 computer code also specifically calculates the decrease in neutron exposure at increased distances. The adequacy of the RADTRAN 4 radiation exposure decrease was evaluated. The gamma radiation decrease factor used by RADTRAN 4 was consistent with the results predicted for naval fuel. The RADTRAN 4 prediction for neutron radiation slightly overpredicts the decrease in exposure at far distances for the shipping containers used for naval shipments.

Using the same basic equation used by RADTRAN, a value of 2.0 x 10y10 was used for the RADTRAN 4 constant a4 in lieu of 0. The value of 2 x 10y10 produces results which are slightly higher than the standard method and agree with measurements of neutron exposure rates from naval spent nuclear fuel shipments.

A.7.1.1.10 Shipment Storage Time. As noted previously, the government escorts accompanying the rail shipments of spent nuclear fuel are responsible for ensuring that the naval spent nuclear fuel shipments are made in the most efficient and safe manner. Naval spent nuclear fuel is not stored while being shipped; therefore, there was no intermediate shipment storage time associated with any of the alternatives. There is also no intermediate storage time during the heavy-lift transport shipments from the prototype sites and the ocean shipments from Pearl Harbor Naval Shipyard.

A.7.1.1.11 Heavy-lift Transporter Transportation Crew. Information from records of naval spent nuclear fuel shipments was reviewed to determine a realistic estimate of the number of people involved, the amount of time required, and the distances between individuals and the shipping container. The number of hours worked ranged from 1 to 10 and the distance from the container ranged from 1.5 to 91 meters (5 to 300 feet). For simplicity, weighted averages of the number of hours and distances from the shipping container were calculated and are provided in Table A-10.

Table A-10. Summary of the number of people involved and distance from the container during heavy-lift transporter shipments to the rail siding at the prototype sites.

Prototype	Number of People	Number of Hours per Worker	Distance from the Shipping Container (meters)
Windsor Site	37	5.08	25.0 (82 feet)
Kesselring Site	36	5.11	32.3 (106 feet)

This information was used to evaluate all five alternatives.

A.7.1.1.12 Time to Ship by Heavy-lift Transporter. Based on discussions with personnel at the prototype facilities who have made shipments and a review of records, the average duration of the heavy-lift transporter shipment from the prototype sites to the local rail siding is 2 hours.

A.7.1.1.13 Number of Heavy-lift Transporter Inspections. The shipments are inspected prior to leaving the prototype's site boundaries, and no additional inspections are performed during the short heavy-lift transporter shipment. As a result, there are no inspections during the heavy-lift transporter shipment in the evaluation of the five alternatives.

A.7.1.1.14 Heavy-lift Transporter Stop Time. Shipments of spent nuclear fuel from the two prototype locations are first transported by heavy-lift transporter to the nearest rail siding. Information from records of naval spent nuclear fuel shipments was reviewed to determine a realistic estimate of the heavy-lift transporter stop times. For naval spent nuclear fuel heavy-lift transporter shipment from the Windsor Site, a heavy-lift transporter stop time of 24 hours was used. For heavy- lift transporter shipments from the Kenneth A. Kesselring Site, a stop time of 10 hours was used. The heavy-lift transporter shipments from the prototypes to the rail sidings occur through suburban populations only. These heavy-lift transporter stop times were used to evaluate all five alternatives.

A.7.1.1.15 Standard RADTRAN 4 Computer Code Values Used. The following standard RADTRAN 4 computer code value was reviewed and determined to reflect the best estimate of current railroad industry practice:

- Number of Inspections of the Shipping Container and Railcar.

The following standard RADTRAN 4 computer code estimates of the populations that could be affected by the shipment of spent nuclear fuel were also used for the five alternatives:

- Number of People per Vehicle Sharing the Transport Route (On Link)
- Traffic Count Passing a Specific Point - Rural, Suburban, and Urban Zones
- Average Exposure Distance When Stopped
- Persons Exposed While Stopped
- Fraction of Travel During Rush Hour, on City Streets, and on Freeways.

A.7.1.1.16 Number of Ship Inspections. Shipments of spent nuclear fuel from Pearl Harbor Naval Shipyard must first be transported by ship to the Puget Sound Naval Shipyard. Using the standard values in the RADTRAN 4 computer code, the radiological exposures to the crew and government escorts are negligible since the distances from these individuals to the shipping containers are large. As a result, the radiological exposure estimates are only expected to occur during inspections. Based on radiation monitoring results for past naval spent nuclear fuel shipments, this is not realistic for naval spent nuclear fuel, and a separate calculational model was developed to account for this potential radiation exposure. The model uses the standard point source formula (see Section A.5.1) to calculate the crew and government escort exposures during transport by ship. The model took into account the ship used, transport index, transport time, distance between shipping containers, distance from the shipping containers and living quarters, distance from the shipping containers and the engine room, the number of crew members and government escorts, and the time required for inspections based on records from historical shipments of spent nuclear fuel. After reviewing historical shipment records, it was determined that three different sized ships have recently been used. The smallest one, Ship 1, was used once and is not expected to be used in the future. Only the other two, Ships 2 and 3, would be used in the future, in equal proportion. Table A-11 below provides the information used to calculate the radiological exposures resulting from transporting naval spent nuclear fuel by ship. This model was used to evaluate all five alternatives.

Table A-11. Parameters used to calculate crew and escort exposure during ocean travel from Pearl Harbor Naval Shipyard to Puget Sound Naval Shipyard.

Parameter	Ship 1	Ship 2	Ship 3
Transport Time, T, in days	11	8	9
Separation Between M-130s, X1, in feet	92	43	20
Nearest Distance to Living Quarters, X2, in feet	40	80	300
Nearest Distance to Engine Room, X3, in feet	20	80	300
Number of Crew Members, Nc	11	22	26

A.7.1.2 Accident During Transportation of Spent Nuclear Fuel. This section provides the input parameters used to calculate the radiological impacts for accidents during transportation of spent nuclear fuel for evaluation of the five alternatives. The planned shipments, transportation distances, population densities, and the percentages of travel in each population density described in Section A.7.1.1 were also used for the accident analyses. Unless otherwise described in this section, the standard values provided by the RADTRAN 4 and RISKIND computer codes were used.

A.7.1.2.1 Accident Probability. The probability of a rail accident used for evaluation of all alternatives was obtained from "Longitudinal Review of State-Level Accident Statistics for Carriers of Interstate Freight" (Saricks and Kvitek 1994). The probabilities are provided both by state and a national average. The state dependent probabilities were used for the accident risk assessment. Past naval spent nuclear fuel shipments have traveled approximately 2 million kilometers (1.24 million miles) by rail without an accident, which is consistent with the national average of 5.57 x 10y8 accident per kilometer.

A.7.1.2.2 Accident Severity Categories and Probabilities. In the "Shipping Container Response to Severe Highway and Railway Accident Conditions" (NUREG 1987), referred to as the "Modal Study," Lawrence Livermore National Laboratory categorized the potential damage to shipping containers according to the magnitude of the thermal and mechanical forces that could result from an accident. The structural and thermal forces were categorized into 20 regions. Given that an accident occurs, the probability that the accident would be in each region was calculated for both rail and truck shipments. Table A-12 provides the probabilities for rail accidents by region.

Table A-12. Accident severity probabilities for rail shipments.

	R(4,1) 1.786 x 10y9	R(4,2) 3.290 x 10y13	R(4,3) 2.137 x 10y13	R(4,4) 1.644 x 10y13	R(4,5) 3.459 x 10y14
S3 (30)	R(3,1) 5.545 x 10y4	R(3,2) 1.0217 x 10y7	R(3,3) 0.634 x 10y8	R(3,4) 5.162 x 10y8	R(3,5) 5.296 x 10y8
S2 (2)	R(2,1) 2.7204 x 10y3	R(2,2) 5.011 x 10y7	R(2,3) 3.255 x 10y7	R(2,4) 2.531 x 10y7	R(2,5) 1.075 x 10y8
S1 (0.2)	R(1,1) 0.993962	R(1,2) 1.2275 x 10y3	R(1,3) 7.9511 x 10y4	R(1,4) 6.140 x 10y4	R(1,5) 1.249 x 10y4
				T4 (1050)	

Thermal Response (lead mid-thickness temperature, yF)

A.7.1.2.3 Naval Spent Nuclear Fuel Integrity Following an Accident. Detailed structural and thermal analyses were performed for the shipping containers used for naval spent nuclear fuel shipments up to an equivalent strain of 30% and mid-wall temperature of 1050yF. For these cases, the naval spent nuclear fuel was not damaged. For the thermal and structural regions above 1050yF and 30% strain, the modal study defines the upper limits as unbounded. The naval spent nuclear fuel was postulated to be damaged and the fission products and corrosion products would be released in the quantities described in

Table A-13 for the risk analyses.

A.7.1.2.4 Release Fractions. The release fractions were derived based on the results presented in the NRC modal study (NUREG 1987) and the results of the structural and thermal analyses described above. Although the naval spent nuclear fuel is stronger, the release fractions for the boiling water reactor (BWR), pressurized water reactor (PWR), and aluminum-clad fuel from the modal study were used. From the modal study, the release fraction in lower left region R(1,1) is zero for the risk evaluation. For the maximum consequence evaluation, 1% of the corrosion products might be released for the lower left region, R(1,1). Based on the results of the structural and thermal analyses up to 30% strain and 1050yF mid-wall temperature, the naval spent nuclear fuel is not damaged; therefore, regions R(1,2), R(1,3), R(2,1), R(2,2), R(2,3), R(1,4), R(2,4), R(3,4), R(3,1), R(3,2) and R(3,3) do not release fission products. Ten percent of the corrosion products might be released. In the remaining regions, 10% of the fission products might be available for release and released at the fractions specified below, also using a release of 10% of the corrosion products. Table A-13 provides the release fractions used.

Table A-13. Cask release fractions used for the RADTRAN 4 risk analyses.

	Release Fraction[a]					
Cask Response Region	Inert Gas	Iodine	Cesium	Ruthenium	Particulates	Corrosion Products
R(1,1)	0.0	0.0	0.0	0.0	0.0	0.0
R(1,2), R(1,3)	0.0	0.0	0.0	0.0	0.0	1.0
R(2,1), R(2,2), R(2,3)	0.0	0.0	0.0	0.0	0.0	1.0
R(1,4), R(2,4), R(3,4)	0.0	0.0	0.0	0.0	0.0	1.0
R(3,1), R(3,2), R(3,3)	0.0	0.0	0.0	0.0	0.0	1.0
R(1,5), R(2,5), R(3,5) R(4,5), R(4,1), R(4,2) R(4,3), R(4,4)	6.3 x 10y1	4.3 x 10y2	2.0 x 10y3	4.8 x 10y4	2.0 x 10y5	1.0

---

[a] The release fraction represents the fraction of the fuel inventory available for release in the shipping container that would be released into the atmosphere following an accident of the given severity.

A.7.1.2.5 Plume Release Height. For the accident risk assessment, a ground level release was used. For the maximum consequence assessment, a plume release height of 10 meters (32.8 feet) was used.

A.7.1.2.6 Direct Exposure from a Damaged Shipping Container. A radiation level following the accident at the 10CFR71 regulatory limit of 1 rem at 1 meter (3.3 feet) from the container surface was used.

A.7.1.2.7 Food Transfer Factors. Food transfer factors were derived for the isotopes related to naval spent nuclear fuel in accordance with the methods described in Nuclear Regulatory Commission Guide 1.109 (NUREG 1977).

A.7.1.2.8 Distance from the Accident Scene to the Maximum Exposed Individual. No shielding

was accounted for as the plume passes for the calculation of the exposure to the maximum individual. This location was determined using RISKIND based on the atmospheric stability and plume release height used.
The maximum exposed individual could be a member of the rail crew or the general population.

A.7.1.2.9 RISKIND Population Density. The standard national average for each population

density from the RADTRAN 4 computer code was used for the RISKIND maximum consequences assessment (6 people per square kilometer for rural, 719 for suburban, and 3861 for urban).

A.7.1.2.10 Radionuclide Inventory. The amount of radionuclides which would be released from

an average shipment are provided in Table A-14. The values factor in the damage fraction described in Section A.7.1.2.3 and release fractions described in Section A.7.1.2.4. The radionuclides listed result in 99 percent of the exposure in all pathways.

Table A-14. Radionuclides which would be released from an average shipment of naval spent nuclear fuel from a shipyard or prototype.

For Accidents which Release Both Fission and Corrosion Products		For Accidents which Release Only Corrosion Products	
Nuclide	Activity (Ci)	Nuclide	Activity (Ci)
Kr-85	9.85 x 102	Co-58	1.61 x 10y1
Cs-134	3.72 x 101	Mn-54	2.22 x 10y2
Cs-137	3.44 x 101	Fe-55	6.62 x 10y1
H-3	1.39 x 101	Co-60	3.63 x 10y1

Sr-90	3.41 x 10y1		
Pu-238	1.02 x 10y2		
Pu-241	3.43 x 10y3		
Cm-244	1.36 x 10y4		

A.7.2 Transfers of Naval Spent Nuclear Fuel to Storage Following

Examination

A.7.2.1 Incident-free Transportation of Naval Spent Nuclear Fuel to Storage. This section provides the

input parameters used to determine the radiological impacts associated with the routine, incident-free (i.e., no accident) transportation of naval spent nuclear fuel to storage for each of the five alternatives.

A.7.2.1.1 Planned Shipments. Table A-15 provides the number of planned transfers in each cask.

Table A-15. Planned transfers of naval spent nuclear fuel to storage.

	NFS-100	Peach Bottom	Large Cell

1992/1993 Planning Basis,	196	64	468

All Regionalization Alternatives,
All Centralization Alternatives

A.7.2.1.2 Transport Index (TI). A TI of 0.3 was used for all NFS-100 cask transfers. This value was determined from recorded measurements over the last 3 years for the same fuel types planned to be transferred in the future. The Peach Bottom and Large Cell casks have not previously been used for the planned transfers and therefore historic data were not available. Based on a comparison of predicted TI values from conservative safety analyses to the actual measured TI's for similar casks and fuel types, a TI of 1.0 was calculated for both the Peach Bottom and Large Cell casks.

A.7.2.1.3 Transportation Distances and Population Densities. Section A.6 provided a description of the general methodology used for determining transportation distances and the population densities along the transportation routes. The distance between ECF and ICPP is 9.7 kilometers (6 miles). From the HIGHWAY computer code, the transfer of naval spent nuclear fuel to storage occurs in a rural area. As stated in Section A.3.5, the storage facility at the alternative sites was identical to ICPP. Therefore, for the evaluation of the alternatives, the distance traveled and population density of the ECF to ICPP transfer were also used for the evaluation of the other alternatives.

A.7.2.1.4 Truck Speed. The standard RADTRAN 4 computer code speed for truck shipments in a rural population is 88.5 kilometers per hour (55 miles per hour). One of the reasons an on-site worst credible accident is less severe than the 10CFR71 hypothetical accident is that the speed is severely limited by the on-site transportation procedures. An average speed of 24.1 kilometers per hour (15 miles per hour) was used.

A.7.2.1.5 Truck Stop Time. The standard RADTRAN 4 computer code provides values for truck stop times that are either dependent or independent of the distances traveled. The logs for historical transfers of naval spent nuclear fuel to storage were reviewed, and it was determined that the actual stop times (10 minutes) were much shorter than the standard RADTRAN 4 computer code values. A stop time of 10 minutes was used to evaluate all five alternatives.

A.7.2.1.6 Radiation Exposure Decrease Due to Distance. The radiation exposure decrease due to distance described in Section A.7.1.1.9 was also applied to the truck transfers of naval spent nuclear fuel to storage.

A.7.2.1.7 Distance from Source to Crew. A distance of 6.1 meters (20 feet) was measured between the shipping cask and the driver for the exclusive-use truck transfers of naval spent nuclear fuel shipments to storage. Two escorts, one located approximately 46 meters (150 feet) in front and one the same distance behind the transport vehicle, are also present. These data were used in the

RADTRAN analyses for all alternatives.

A.7.2.1.8 Transport Index to Exposure Rate Conversion Factors. Transport index to exposure rate conversion factors for the casks used for transfers of naval spent nuclear fuel to storage were calculated using the standard equation in RADTRAN 4. The results were compared to detailed computer analyses performed using SPAN4, and RADTRAN 4 results were found to overestimate the exposure. Using the SPAN4 computer code results, the effective package dimensions of the casks used in the RADTRAN 4 calculations were adjusted to provide a conservative yet more realistic value of the transport index to exposure rate conversion factor. The values used are provided in Table A-16.

Table A-16. Transport index to exposure rate conversion factors for the NFS-100, Peach Bottom, and Large Cell casks.

Cask	Effective Package Dimens (meters)	Transport Index to Exposure Rate Conversion Factor
NFS-100	3.8 (12.5 feet)	8.41
Peach Bottom	2.8 (9.2 feet)	5.76
Large Cell	3.2 (10.5 feet)	6.76

A.7.2.1.9 Storage. There is no intermediate storage time during transfers of naval spent nuclear fuel to its destination.

A.7.2.1.10 Persons Exposed While Stopped. The only stop time for the transfer of naval spent nuclear fuel to storage occurs during routine surveys at the destination entrance. This area is well removed from highway and general population and therefore no people were considered to be exposed during the short 10-minute stop. The escorts are not present during the surveys and the driver remains in the cab of the truck, 6.1 meters (20 feet) from the cask during the surveys. The people performing the surveys are badged and all exposure received during the surveys is included in the normal occupational exposure which is regularly monitored.

A.7.2.1.11 Traffic Count Passing a Specific Point. The RADTRAN 4 computer code uses 470 vehicles per hour passing the transport vehicle. Travel on the transport path is restricted to INEL employees by a security checkpoint, the majority of INEL employees ride the INEL site buses to work, and the transfers are not made during high traffic times (i.e., shift changes when buses are in service); therefore, using the standard 470 vehicles per hour value would be extremely conservative. A more realistic estimate of 25 vehicles per hour was used.

A.7.2.1.12 Standard RADTRAN 4 Computer Code Values Used. The following standard RADTRAN 4 computer code value was reviewed and determined to reflect the best estimate of current industry practice and was consistent with historical data from transfers of naval spent nuclear fuel to storage:

- Minimum Number of Inspections.

The following standard RADTRAN 4 estimate of the population that could be affected by the transfer of naval spent nuclear fuel to storage was used to evaluate the five alternatives:

- Number of People per Vehicle Sharing the Transport Route (On Link).

A.7.2.2 Accident During Transportation of Spent Nuclear Fuel to Storage. This section provides the

input parameters used to calculate the radiological impacts for accidents during transportation of spent nuclear fuel to storage for evaluation of the five alternatives. The planned transfers, transportation distances, population densities, and the percentages of travel in each population density described in Section A.7.2.1 were also used for the accident analyses. Unless otherwise described in this section, the standard values provided by the RADTRAN 4 and RISKIND computer codes were used.

A.7.2.2.1 Accident Probability. The probability of a truck accident used for evaluation of all

alternatives was obtained from "Longitudinal Review of State-Level Accident Statistics for Carriers of Interstate Freight" (Saricks and Kvitek 1994). The truck accident rates are state dependent. The states in which naval spent nuclear fuel would be transferred to storage for the alternatives described in Section A.3 are Idaho, Washington, South Carolina, Tennessee, and Nevada. The corresponding accident rates for travel on rural interstates in accidents per kilometer are 2.30 x 10y7 for Idaho, 2.50 x 10y7 for Washington, 1.83 x 10y7 for South Carolina, 1.48 x 10y7 for Tennessee, and 1.57 x 10y7 for Nevada. The values correspond to 3.70 x 10y7 (Idaho), 4.02 x 10y7 (Washington), 2.94 x 10y7 (South Carolina), 2.38 x 10y7 (Tennessee), and 2.53 x 10y7 (Nevada) accidents per mile.

A.7.2.2.2 Accident Severity Categories and Probabilities. In the modal study, Lawrence

Livermore National Laboratory categorized the potential damage to shipping containers according to the magnitude of the thermal and mechanical forces that could result from an accident. The structural and thermal forces were categorized into 20 regions. Given that an accident occurs, the probability that the accident would be in each region was calculated for both rail and truck shipments. Table A-17 provides the probabilities for truck accidents by region.

Table A-17. Accident severity probabilities for truck shipments.

	R(4,1)	R(4,2)	R(4,3)	R(4,4)	R(4,5)
	1.532 x 10y7	3.926 x 10y14	1.495 x 10y 1	7.681 x 10y16	<1 x 10y16
S3	R(3,1)	R(3,2)	R(3,3)	R(3,4)	R(3,5)
(30)	1.7984 x 10y3	1.574 x 10y7	2.034 x 10y7	1.076 x 10y7	4.873 x 10y8
S2	R(2,1)	R(2,2)	R(2,3)	R(2,4)	R(2,5)

S1	R(1,1)	R(1,2)	R(1,3)	R(1,4)	R(1,5)
(0.2)	0.994316	1.687 x 10y5	2.362 x 10y5	1.525 x 10y5	9.570 x 10y6
	T1 (500)	T2 (600)	T3 (650)	T4 (1050)	

Thermal Response (lead mid-thickness temperature, yF)

A.7.2.2.3 Naval Spent Nuclear Fuel Integrity Following an Accident. Detailed structural and

thermal analyses have been performed for the casks used for shipments of naval spent nuclear fuel to storage. As described in Section A.4.5, these analyses are performed using a worst credible accident which is defined based on the site specific terrain and administrative controls during the short onsite shipment.

The probability of the worst credible accident is equal to that listed in region R(1,1). For accident conditions in excess of the worst credible accident, the fission product and corrosion product release fractions described in the next section were used.

A.7.2.2.4 Cask Release Fractions. The cask release fractions were derived based on the results

presented in the NRC modal study (NUREG 1987). Although the naval spent nuclear fuel is stronger, the release fractions for the BWR, PWR, and aluminum-clad fuel from the modal study were used. From the modal study, the release fraction for lower left region R(1,1) is zero for the risk evaluation. For the maximum consequence evaluation, 1% of the corrosion products were released for the lower left region, R(1,1). The remaining regions used 10% of the fission products available for release, released at the fractions specified below, and release of 10% of the corrosion products. Table A-18 provides the release fractions used. The release fractions in Table A-18 for the less severe conditions differ from those in Table A-13 because supplementary structural and thermal analyses have not been performed for the casks discussed in this section.

Table A-18. Cask release fractions used for the RADTRAN 4 risk analyses.

	Release Fraction[a]					
Cask Response Region	Inert Gas	Iodine	Cesium	Ruthenium	Particulates	Corrosion Products
R(1,1)	0.0	0.0	0.0	0.0	0.0	0.0
R(1,2), R(1,3)	9.9 x 10y3	7.5 x 10y5	6.0 x 10y6	8.1 x 10y7	6.0 x 10y8	1.0
R(2,1), R(2,2), R(2,3)	3.3 x 10y2	2.5 x 10y	4 2.0 x 10y5	2.7 x 10y6	2.0 x 10y7	1.0
R(1,4), R(2,4), R(3,4)	3.9 x 10y1	4.3 x 10y3	2.0 x 10y4	4.8 x 10y5	2.0 x 10y6	1.0
R(3,1), R(3,2), R(3,3)	3.3 x 10y1	2.5 x 10y3	2.0 x 10y4	2.7 x 10y5	2.0 x 10y6	1.0
R(1,5), R(2,5), R(3,5) R(4,5), R(4,1), R(4,2) R(4,3), R(4,4)	6.3 x 10y1	4.3 x 10y2	2.0 x 10y3	4.8 x 10y4	2.0 x 10y5	1.0

---

a The release fraction represents the fraction of the fuel inventory available for release in the cask that would be released into the atmosphere following an accident of the given severity.

A.7.2.2.5 Plume Release Height. For the accident risk assessment, a ground level release was

used. For the maximum consequence assessment, a plume release height of 10 meters (32.8 feet) was used.

A.7.2.2.6 Direct Exposure from a Damaged Shipping Container. A radiation level following the

accident at the 10CFR71 regulatory limit of 1 rem at 1 meter (3.3 feet) from the cask surface was used.

A.7.2.2.7 Food Transfer Factors. Food transfer factors were derived for the isotopes related to

naval spent nuclear fuel in accordance with the methods described in Nuclear Regulatory Commission Guide 1.109 (NUREG 1977).

A.7.2.2.8 Distance from the Accident Scene to the Maximum Exposed Individual. No shielding

was accounted for as the plume passes for the calculation of the exposure to the maximum individual. This location was determined using RISKIND based on the selected atmospheric stability and plume release height. The maximum exposed individual could be a member of the track crew or the general population.

A.7.2.2.9 RISKIND Population Density. From the HIGHWAY computer code, the population

density for the on-site shipment was determined to be one person per square kilometer (2.6 persons per square mile) in a rural area. For on-site transportation at INEL, the population density in the most populated sector, from 1990 census data, is 55 people per square kilometer, with the majority of these people in the area 64.4 to 80 kilometers (40 to 50 miles) from the site. This population density is just into the lower region of the suburban density range of 53.7 to 1284.7 people per square kilometer (139 to 3326 people per square mile) used in HIGHWAY and INTERLINE. The standard value of 6 (rural) and 719 (suburban) people per square kilometer (15.5 and 1861 people per square mile, respectively) was used for the evaluation of all alternatives.

A.7.2.2.10 Radionuclide Inventory. The transfers of naval spent nuclear fuel to storage contain

the same radionuclides as listed in Table A-14. On average, there is approximately 80 percent of the activity of each radionuclide.

A.7.3 Transfers of Naval Test Specimen Assemblies Between the

Examination Facility and the Test Reactor Area

A.7.3.1 Incident-free Transportation of Naval Test Specimen Assemblies. This section provides the

input parameters used to determine the radiological impacts associated with the routine, incident-free (i.e., no accident) transportation of naval test specimen assemblies for each of the five alternatives.

A.7.3.1.1 Planned Shipments. Table A-19 provides the number of planned transfers in each cask.

Table A-19. Planned transfers of naval test specimen assemblies.

	NR/ATR	Test Train
No Action, Decentralization - No Exam, Decentralization - Limited Exam	0	0
Decentralization - Full Exam 1992/1993 Planning Basis, Regionalization at INEL, and Centralization at INEL	38	922
All other Regionalization and Centralization Alternatives	0	960

A.7.3.1.2 Transport Index. A TI of 130.0 was used for all NR and ATR cask transfers. This

value was derived from historic measurements over the last several years. The new Test Train casks, which are currently being designed, would have a TI of 1.0.

A.7.3.1.3 Transportation Distances and Population Densities. Section A.6 provided a

description of the general methodology used for determining transportation distances and the population densities along the transportation routes. The distance between ECF and TRA is 8.0 kilometers (5 miles). From the HIGHWAY computer code, this on-site transfer of naval test specimen assemblies occurs in a rural area. For shipments from TRA to the centralization sites, the HIGHWAY computer code was used to calculate the distance traveled, the population densities, and the percent distance traveled in each population density. As described in Section A.7.4.1.3, the HIGHWAY predicted distances for off-site shipments were increased by 3%.

A.7.3.1.4 Truck Speed. The standard RADTRAN 4 computer code speed for truck shipments in a

rural population is 88.5 kilometers per hour (55 miles per hour). One of the reasons an on-site worst credible accident is less severe than the 10CFR71 hypothetical accident is that the speed is severely limited. An average speed of 16.1 kilometers per hour (10 miles per hour) was used for the on-site shipments. For off-site shipments to the centralization sites, the standard RADTRAN 4 computer code values were used.

A.7.3.1.5 Truck Stop Time. The standard RADTRAN 4 computer code provides values for truck

stop times that are either dependent or independent of the distances traveled. The logs for historical on-site transfers of naval test specimen assemblies were reviewed, and it was determined that the actual stop time (one and one-half hours) was less than the standard RADTRAN 4 computer code values. For the alternative in which on-site transfers would continue, the one and one-half hour stop time was used. For the off-site shipments of test specimen assemblies to the centralization sites, a stop time of 0.006 hour per kilometer (0.01 hour per mile) was used, consistent with the value used for other past truck shipments outside the boundaries of DOE facilities (see Section A.7.4.1.4).

A.7.3.1.6 Radiation Exposure Decrease Due to Distance. The radiation exposure decrease due to

distance described in Section A.7.1.1.9 was also applied to the truck transfers of test specimen assemblies.

A.7.3.1.7 Distance from Source to Crew. A distance of 3.6 meters (12 feet) was measured

between the NR/ATR shipping cask and the driver for the exclusive-use truck transfers of test specimen assemblies on-site. Two escorts, one located approximately 46 meters (150 feet) in front and one the same distance behind the transport vehicle, are also present for on-site shipments.

For off-site shipments to the centralization sites, the standard RADTRAN 4 computer code value for the number of crew members was used (2). The value used for the distance from the crew to the centerline of the cask for off-site shipments was 5.85 meters (20 feet), based on the conceptual design of the new Test Train cask.

A.7.3.1.8 Transport Index to Exposure Rate Conversion Factors. Transport index to exposure

rate conversion factors for the casks used for test specimen assembly transfers were calculated using the standard equation used by RADTRAN 4. The results were compared to detailed computer analyses performed using SPAN4, and RADTRAN 4 results were found to overestimate the exposure. Using the SPAN4 computer code results, the effective package dimensions of the casks used in the RADTRAN 4 calculations were adjusted to provide a conservative yet more realistic value of the transport index to exposure rate conversion factor. The values used are provided in Table A-20.

Table A-20. Transport index to exposure rate conversion factors for the NR/ATR and Test Train casks.

Cask	Effective Package Dimension (meters)	Transport Index to Exposure Rate Conversion Factor
NR/ATR	0.61 (2 feet)	1.70
Test Train	1.70 (5.6 feet)	3.42

A.7.3.1.9 Storage. There is no intermediate storage time during transfers of naval test specimen

assemblies.

A.7.3.1.10 Persons Exposed While Stopped. The only stop time for the transfer of naval test

specimen assemblies on-site occurs during routine surveys at the destination entrance. This area is well removed from highway and population and therefore no people were considered to be exposed during the one and one-half hour stop. The escorts are not present during the surveys and the driver is positioned approximately 46 meters (150 feet) from the source during the surveys. The people performing the surveys are badged and all exposure received during the survey is included in the normal occupational exposure which is regularly monitored. For off-site shipments, the standard RADTRAN 4 computer code values were used.

A.7.3.1.11 Traffic Count Passing a Specific Point. The RADTRAN 4 computer code uses 470

vehicles per hour passing the transport vehicle. Travel on the on-site transport path is restricted to INEL employees, the majority of INEL employees ride the INEL site buses to work, and the transfers are not made during high traffic times (i.e., shift changes); therefore, using the standard 470 vehicles per hour value would excessively overestimate the number of persons involved. A more realistic estimate of 25 vehicles per hour was used for on-site shipments. For off-site shipments, the standard RADTRAN 4 computer code values were used.

A.7.3.1.12 Standard RADTRAN 4 Computer Code Values Used. The following standard RADTRAN 4

computer code value was reviewed and determined to reflect the best estimate of current industry practice and was consistent with recorded data from transfers of naval test specimen assemblies:

- Minimum Number of Inspections.

The following standard RADTRAN 4 estimate of the population that could be affected by the transfer of test specimen assemblies was used for evaluation of the five alternatives:

- Number of People per Vehicle Sharing the Transport Route (On Link).

A.7.3.2 Accident During Transportation of Naval Test Specimen Assemblies. This section provides the

input parameters used to calculate the radiological impacts for accidents during transportation of naval test specimen assemblies for evaluation of the five alternatives. The planned transfers, transportation distances, population densities, and the percentages of travel in each population density described in Section A.7.3.1 were also used for the accident analyses. Unless otherwise described in this section, the standard values provided by the RADTRAN 4 and RISKIND computer codes were used. All variables described in Section A.7.2.2 are applicable to these transfers with the exception of the RISKIND population density.

A.7.3.2.1 RISKIND Population Densities. For the Decentralization, 1992/1993 Planning Basis,

Regionalization at INEL, and Centralization at INEL alternatives, the test specimen assembly transfers would occur on the INEL site. For these transfers, the same conditions described in Section A.7.2.2.9 were used. For the other Regionalization and Centralization alternative risk assessments, the population densities from RADTRAN 4 were used.

A.7.3.2.2 Release Fractions. For the Decentralization, 1992/1993 Planning Basis, and

Regionalization at INEL, and Centralization at INEL alternatives, the test specimen assembly transfers would occur on the INEL site. For these transfers, the same conditions described in Sections A.7.2.2.3 and

A.7.2.2.4 were used. For the other Regionalization and Centralization alternatives, the conditions

described in Sections A.7.1.2.3 and A.7.1.2.4 were used.

A.7.3.2.3 Radionuclide Inventory. The radionuclides which would be released from an average

transfer are listed in Table A-21, along with the activity. The values factor in the damage fractions and release fractions described in Section A.7.3.2.2. The radionuclides listed result in 99 percent of the exposure in each pathway.

Table A-21. Radionuclides which would be released from an average transfer of test specimen assemblies.

For Accidents which Release Both Fission and Corrosion Products		For Accidents which Release Only Corrosion Products	
Nuclide	Activity (Ci)	Nuclide	Activity (Ci)
I-131	1.30 x 103	Eu-156	3.75 x 101
H-3	3.51 x 102	Lu-177	1.59 x 101
I-132	3.10 x 102	Eu-152	1.41 x 101
Eu-156	3.75 x 101	Zr-95	1.07 x 101
Eu-152	1.41 x 101	Zn-65	9.80 x 100
Zr-95	1.09 x 101	Co-60	7.68 x 100
Zn-65	9.80 x 100	Ce-141	6.60 x 100
Co-60	7.68 x 100	Eu-154	6.15 x 100
Eu-154	6.15 x 100	Cs-136	4.69 x 100
Sc-46	3.25 x 100	Sc-46	3.25 x 100
Cs-137	1.78 x 100	I-131	2.37 x 100
Ru-106	3.36 x 10y1	Hf-181	2.35 x 100
Nb-95	2.64 x 10y1		
Pr-144	2.19 x 10y1		
Ce-144	2.19 x 10y1		

A.7.4 Shipments of Naval Irradiated Test Specimens to Examination

and Testing Facilities

A.7.4.1 Incident-free Transportation of Test Specimens. This section provides the input parameters used to determine the radiological impacts associated with the routine, incident-free (i.e., no accident) transportation of test specimens for evaluation of the five alternatives.

A.7.4.1.1 Planned Shipments. Table A-22 provides the estimated number of shipments used in the analysis.

Table A-22. Planned shipments of naval test specimens.

	NRBK-41/WAPD-40				
Alternative	ICPP	PSNS	Centralization Site	BETTIS	KAPL
No Action	29	0	0	0	320
Decentralization - No Exam					
Decentralization - Limited Exam	26	3	0	0	320
Decentralization - Full Exam	0	0	0	0	320
1992/1993 Planning Basis, Regionalization at INEL, and Centralization at INEL Alternatives	0	0	0	120	641
All other Regionalization and Centralization Alternatives	0	0	29	120	641

A.7.4.1.2 Transport Index. A TI of 0.1 was used for all NRBK-41 and WAPD-40 shipping container shipments. These values were derived from recorded measurements over the last several years.

A.7.4.1.3 Transportation Distances and Population Densities. Section A.6 provided a description of the general methodology used for determining transportation distances and the population densities along the transportation routes. Historical data were obtained for shipments of test specimens. The distance traveled was averaged based on the point of origin and compared to the value calculated by HIGHWAY. The actual distance traveled was approximately 3% higher on the average. In order to provide the best estimate exposure, which is based on the distance traveled, the HIGHWAY distances were increased by 3% for all alternatives. This technique allowed for comparison of the alternatives on an equal basis. The percentages of distance traveled in each population density calculated by HIGHWAY applied to the distances which were increased by the 3%.

A.7.4.1.4 Truck Stop Time. The RADTRAN 4 computer code provides standard values for truck stop times that are either dependent or independent of the distances traveled. The shipping logs for historical test specimen shipments were reviewed, and it was determined that the actual stop times were much shorter than the standard RADTRAN 4 computer code values. The recorded stop times were divided by the actual distance traveled from historical data over the last three years and an average of 0.006 hour per kilometer (0.01 hour per mile) was calculated. This value was used to evaluate all five alternatives.

A.7.4.1.5 Radiation Exposure Decrease Due to Distance. The radiation exposure decrease due to distance described in Section A.7.1.1.9 was also applied to the truck shipments of test specimens.

A.7.4.1.6 Transport Index to Exposure Rate Conversion Factors. Container transport index to exposure rate conversion factors for the casks used for test specimen shipments were calculated using the standard equation used by RADTRAN 4. The results were compared to detailed computer analyses performed using SPAN4, and RADTRAN 4 results were found to overestimate the exposure. Using the SPAN4 computer code results, the effective package dimensions of the containers used in the RADTRAN 4 calculations were adjusted to provide a conservative yet more realistic value of the transport index to exposure rate conversion factor. The values used are provided in Table A-23.

Table A-23. Transport index to exposure rate conversion factors for the NRBK-41 and WAPD-40 shipping containers.

Container	Effective Package Dimens (meters)	Transport Index to Exposure Rate Conversion Factor
NRBK-41	0.74 (2.4 feet)	1.88
WAPD-40	3.2 (10.5 feet)	6.76

A.7.4.1.7 Storage. The test specimen shipping containers are not stored during shipment.

A.7.4.1.8 Standard RADTRAN 4 Computer Code Values Used. The following standard RADTRAN 4 computer code values were reviewed and were determined to reflect the best estimate of current industry practice and were consistent with historical data from shipments of naval test specimens:

- Truck Speed
- Distance from Source to Crew
- Number of Crewmen
- Minimum Number of Inspections.

The following standard RADTRAN 4 estimates of the populations that could be affected by the shipment of test specimens were also used to evaluate the five alternatives:

- Persons Exposed While Stopped
- Average Exposure Distance While Stopped
- Number of People per Vehicle Sharing the Transport Route (On Link)
- Traffic Count Passing a Specific Point - Rural, Suburban, and Urban Zones
- Fraction of Travel During Rush Hour, on City Streets, and on Freeways.

A.7.4.2 Accident During Transportation of Test Specimens. This section provides the input parameters used to calculate the radiological impacts for accidents during transportation of test specimens to evaluate the five alternatives. The planned shipments, transportation distances, population densities, and the percentages of travel in each population density described in Section A.7.4.1 were also used for the accident analyses. Unless otherwise described in this section, the standard values provided by the RADTRAN 4 and RISKIND computer codes were used. All the conditions and variables described in Section A.7.1.2 are applicable to these shipments with the exception of the Accident Probability.

A.7.4.2.1 Accident Probability. The probability of a truck accident used for evaluation of all alternatives was obtained from "Longitudinal Review of State-Level Accident Statistics for Carriers of Interstate Freight" (Saricks and Kvitek 1994). The truck accident rates are state dependent. The states in which naval spent nuclear fuel would be shipped to storage for the alternatives described in Section A.3 were obtained from HIGHWAY. The accident rate values are consistent with past test specimen shipments which have traveled approximately 2.4 million kilometers (1.5 million miles) without an accident.

A.7.4.2.2 Test Specimen Integrity Following an Accident. Detailed structural and thermal

analyses were performed for the shipping containers used for naval test specimen shipments up to an equivalent strain of 30% and mid-wall temperature of 1050yF. For these cases, the sealed inner container was not damaged; therefore, only the activity on the outside of the inner container, which would be corrosion products, was released. For the thermal and structural regions above 1050yF and 30% strain, the modal study defines the upper limits as unbounded. For these cases, the sealed inner container holding the test specimens was postulated to be damaged and the fission products and corrosion products would be released in the quantities described in Section A.7.1.2.4.

A.7.4.2.3 Radionuclide Inventory. The test specimen shipments contain the same radionuclides

as listed in Table A-21. On average, there is approximately 1.5 percent of the activity of each nuclide.

A.8 SUMMARY OF RESULTS

A.8.1 Historical - Incident Free

This section summarizes the results of the calculations for the radiological and non-radiological impacts of the incident-free transportation of naval spent nuclear fuel and test specimens. Table A-24 shows the radiological impact on the general population, transportation workers (occupational), and the maximum exposed individual, and the non-radiological impact on all persons. The radiological impact on the general population for all historical shipments is 1.95 person-rem, which statistically corresponds to 0.00098 cancer fatalities in the entire population over the 40-year period considered. The radiological impact on transportation workers for all historical shipments is 16.6 person-rem, which statistically corresponds to 0.0066 cancer fatalities. As can be seen from Table A-24, the radiological impact to the general population is greatest for the highway transportation of test specimens. Incident-free radiological impacts tend to be greater for highway transportation than for rail transportation since both the general population and transportation workers are closer to the shipping container in transit. In all cases, the maximum exposed individual is a transportation worker, since the workers are closer to the shipment for a longer time than any member of the general population. The maximum exposed individual for all shipments is a driver for the trucks transferring test specimen assemblies between ECF and TRA. Under the limiting modeling approach that the same person drove every shipment for the entire period, this person received a total exposure of 7.5 rem over the approximate 40-year period, or about 0.19 rem per year, which is within DOE limits for occupationally exposed individuals. By comparison, the maximum exposed individual for the general population received only 0.062 rem over the entire historical period, which is much less than the exposure to the maximum exposed individual transportation worker and corresponds to 0.0016 mrem exposure per year. It should be noted that the majority of the exposure to the transportation worker and maximum exposed worker is already accounted for since most transportation workers are badged and therefore this exposure is included with all other exposure they would receive on the job. The rail employees and off-site truck drivers are the only transportation workers who are not badged. Their exposure was calculated to be only approximately 30% of the total.

The estimated non-radiological fatalities due to vehicle emissions is 0.028 for the entire 40-year period.

A.8.2 Incident Free

Table A-25 provides a summary of the annual exposures and risks from incident-free transportation of naval spent nuclear fuel and test specimens for all alternatives. The values are calculated by dividing the values in Table A-26 by the 40 years evaluated to obtain the average annual values.

The annual radiological impact on the general population ranges from 0.0085 to 0.30 person-rem. The general population annual radiological risk ranges from 0.0000043 to 0.00015 for cancer fatalities.

The radiological impact on the transportation crew (occupational) ranges from 0.038 to 0.38 person-rem. The transportation crew annual radiological risk ranges from 0.000015 to 0.00015 for cancer fatalities.

Table A-25. Summary of annual incident-free impacts during transportation of naval spent nuclear fuel and test specimens.

For all alternatives, the maximum exposed individual is a transportation worker who drives the truck shipments. The annual radiological impact on the maximum exposed individual ranges from 0.0087 to 0.12 rem. These values were calculated based on the modeling approach that for each of the categories of shipments described in Sections A.4.2 through A.4.4, the same person would drive all shipments. The maximum exposed individual annual radiological risk ranges from 0.0000035 to 0.000048 for cancer fatalities. The annual exposure to the maximum exposed individual of the general population ranges from 0.00098 to 0.0043 rem for the various alternatives. The estimated exposure and health effects to the maximum exposed individual for the general population correspond to approximately a factor of 10 less than those estimated for the transportation worker.

The annual non-radiological risk ranges from 0.00015 to 0.00093 fatalities.

The summary of exposures and risks from incident-free transportation of naval spent nuclear fuel and test specimens for all alternatives are included in Table A-26 for the 40-year period.

The radiological impact on the general population ranges from 0.34 to 12 person-rem. The general population radiological risk for the entire 40-year period ranges from 0.00017 to 0.006 for cancer fatalities.

The radiological impact on the transportation crew (occupational) ranges from 1.5 to 15 person-rem. The transportation crew radiological risk for the entire 40-year period ranges from 0.0006 to 0.006 for cancer fatalities.

For all alternatives, the maximum exposed individual is a transportation worker who drives the truck shipments. The radiological impact on the maximum exposed individual ranges from 0.35 to 4.7 rem. These values were calculated based on using the same driver for all shipments for each of the categories of shipments described in Sections A.4.2 through A.4.4. The maximum exposed individual radiological risk for the entire 40-year period, 1995 through 2035, ranges from 0.00014 to 0.0019 for cancer fatalities. The exposure to the maximum exposed individual of the general population ranges from 0.039 to 0.17 rem for the various alternatives. The estimated exposure and health effects to the maximum exposed individual for the general population correspond to approximately a factor of 10 less than those estimated for the transportation worker.

The non-radiological risk ranges from 0.0059 to 0.037 fatalities for the entire 40-year period.

There are appreciable differences in exposure to the general population, transportation crew, and the maximum exposed individual among the various alternatives. Part of these differences is due to the varying number of shipments. For example, for the Decentralization - Full Examination alternative, all shipments of naval spent nuclear fuel are shipped to the INEL and then returned to the shipyards and prototypes, thereby doubling the number of shipments. However, the single most important contributor to the differences among the alternatives is the shipment of test specimen assemblies. For the No

Action, Decentralization - No Examination, and Decentralization - Limited Examination alternatives, there are no shipments; for the Decentralization - Full Examination, 1992/1993 Planning Basis, Regionalization at INEL, and Centralization at INEL alternatives, the exposure is minimal since the shipments remain on the INEL site. However, for the other Regionalization and Centralization alternatives, the test specimen assemblies would be shipped off-site between the INEL and the alternative sites. While the exposure rates on the casks are low, the number of shipments and the distances involved increase the radiological impact on the transportation crew and the general population.

Tables A-27 and A-28 provide the 40-year cumulative incident-free results separately for on-site and off-site shipments. For all alternatives, the shipments of naval spent nuclear fuel from shipyards and prototypes and shipments of naval irradiated test specimens are off-site. Likewise, the transfers of naval spent nuclear fuel to storage following examination are on-site for all alternatives. The transfers of naval test specimen assemblies are off-site for the Regionalization and Centralization alternatives at Hanford, Savannah River, Oak Ridge, and the Nevada Test Site, otherwise they would be on-site.

As described in Section 3.8 of the main body of this Appendix, all alternatives which do not make use of the existing Expended Core Facility at INEL would require a transition period while new facilities for examination and storage of naval spent nuclear fuel were developed. During the transition period, approximately 80 shipments from Navy sites to ECF would be needed. These shipments are not included explicitly in the detailed analyses; however, the appropriate number of shipments needed by each alternative during this period is explicitly included, so the range of environmental effects of these shipments is bounded. For example, the estimated fatalities for the No Action, Decentralization - No Examination, and Decentralization - Limited Examination alternatives would actually increase slightly if the transition shipments were included. The estimated fatalities for the alternatives in which the INEL continues to receive shipments would remain the same. For the Regionalization and Centralization alternatives at sites other than INEL, the estimated fatalities would

Regionalization or Centralization at Oak Ridge	11	5.5 x 10y3	14	5.6 x 10y3	0.16	8.0 x 10y5	4.1	1.6 x 10y3	2.8 x 10y2
Regionalization or Centralization at Nevada Test Site	6.0	3.0 x 10y3	11	4.4 x 10y3	0.16	8.0 x 10y5	1.7	6.8 x 10y4	3.7 x 10y2

also remain approximately the same since the number of shipments is approximately evenly distributed between the east and west coast origins and therefore the total distance traveled is the same.

A.8.3 Accident Risk

This section summarizes the results of the calculations for radiological and non-radiological risks from accidents which could occur during shipments of naval spent nuclear fuel and test specimens. Tables A-29 and A-30 provide the results of the accident risk assessment for each alternative. The risks are provided for the general population in terms of exposure and estimated cancer fatalities. The risks are presented for 50% meteorological conditions, Pasquill Stability Class D. Table A-29 provides the risks on an annual basis and Table A-30 provides the total risks over the entire 40-year period.

The annual radiological impact, from Table A-29, on the general population ranges from 0.00021 to 0.021 person-rem. These exposures equate to 0.00000011 to 0.000011 estimated cancer fatalities. For non-radiological impacts, the estimated annual fatalities from traffic accidents range from 0.0012 to 0.022.

The cumulative radiological impact, from Table A-30, on the general population ranges from 0.0082 to 0.84 person-rem. These exposures equate to 0.0000041 to 0.00042 estimated cancer fatalities. For non-radiological impacts, the estimated fatalities from traffic accidents range from 0.047 to 0.84.

There are appreciable differences in exposure to the general population, transportation crew, and the maximum exposed individual among the various alternatives. Part of these differences is due to the varying number of shipments. For example, for the Decentralization - Full Examination alternative, all shipments of naval spent nuclear fuel are shipped to the INEL and then returned to the shipyards and prototypes, thereby doubling the number of shipments. As in the incident-free assessment, the shipment of test specimen assemblies is a large factor. For the No Action, Decentralization - No Examination, and Decentralization - Limited Examination alternatives, there are no shipments; for the Decentralization - Full Examination, 1992/1993 Planning Basis, Regionalization at INEL, and Centralization at INEL alternatives, the exposure is minimal since the shipments remain on the INEL site. However, for the other Regionalization and Centralization alternatives, the test specimen assemblies would be shipped off-site between the INEL and the alternate sites. While the exposure rates on the containers are low, the number of shipments and the distances involved increase the radiological impact on the transportation crew and the general population. In addition, the routes themselves are an important factor. While differences in distance and population densities are important, the higher risk for the Regionalization at Savannah River and Centralization at Savannah River alternatives, in particular, is due to the higher accident rates along the route taken and higher food transfer factors for shipments through farming states with much higher ingestion rates.

Table A-29. Summary of annual accident risk for transportation of naval spent nuclear fuel and test specimens.

	General Population Collective Dose (person-rem/yr)	Estimated Cancer Fatalities (per year)	Estimated Traffic Fatalities (per year)
	Class D	Class D	
No Action	0.00021	1.1 x 10y7	1.2 x 10y3
Decentralization - No Exam	0.00021	1.1 x 10y7	1.2 x 10y3
Decentralization - Limit Exam	0.00043	2.2 x 10y7	1.6 x 10y3
Decentralization - Full	0.0028	1.4 x 10y6	2.2 x 10y2
1992/1993 Planning Basis	0.0020	1.0 x 10y6	1.3 x 10y2
Regionalization or Centralization at INEL	0.0020	1.0 x 10y6	1.3 x 10y2
Regionalization or Centralization at Hanford	0.0033	1.7 x 10y6	1.3 x 10y2
Regionalization or Centralization at Savannah River	0.0210	1.1 x 10y5	1.5 x 10y2
Regionalization or Centralization at Oak Ridge	0.015	7.5 x 10y6	1.4 x 10y2
Regionalization or Centralization at Nevada Test Site	0.0070	3.5 x 10y6	1.5 x 10y2

Table A-30. Summary of cumulative accident risk over the 40-year period for transportation of naval spent nuclear fuel and test specimens.

	General Populatio Collective Dose (person-rem)	Estimated Cancer Fatalities	Estimated Traffic Fatalities
	Class D	Class D	
No Action	0.0082	4.1 x 10y6	4.7 x 10y2
Decentralization - No Exam	0.0082	4.1 x 10y6	4.7 x 10y2
Decentralization - Limited Exam	0.017	8.5 x 10y6	6.5 x 10y2
Decentralization - Full Exam	0.11m	5.5 x 10y5	8.6 x 10y1
1992/1993 Planning Basis	0.079	4.0 x 10y5	5.1 x 10y1
Regionalization or Centralization at INEL	0.079	4.0 x 10y5	5.1 x 10y1
Regionalization or Centralization at Hanford	0.13	6.5 x 10y5	5.3 x 10y1
Regionalization or Centralization at Savannah River	0.84	4.2 x 10y4	6.0 x 10y1
Regionalization or Centralization at Oak Ridge	0.61	3.1 x 10y4	5.7 x 10y1
Regionalization or Centralization at Nevada Test Site	0.28	1.4 x 10y4	6.1 x 10y1

Table A-31 provides the 40-year cumulative risk, separated by on-site and off-site shipments.

As described in Section 3.8 of the main body of this Appendix, a transition period could be necessary which would require approximately 80 shipments from Navy sites to ECF. These shipments are not included explicitly in the detailed analyses; however, the appropriate number of shipments engendered by each alternative during this period is explicitly included, so the range of environmental effects of these shipments is bounded. The addition of the transition shipments would increase the distance traveled for the No Action, Decentralization - No Examination, and Decentralization - Limited Examination alternatives. Since the accident risk is proportional to the distance traveled, the risk would increase slightly for these alternatives, which were the lowest of all alternatives. All other alternatives would remain the same. Therefore, incorporating the transition period would actually reduce the difference between alternatives from the standpoint of transportation effects.

A.8.4 Accident Maximum Consequences

This section summarizes the results of the calculations of maximum consequences of accidents which could occur during shipments of naval spent nuclear fuel and test specimens. Tables A-32 and A-33 provide the results of the maximum consequence assessment for each alternative. The maximum consequences are provided for the general population by population area (rural, suburban, and urban) and the maximum exposed individual in terms of exposure. The members of the transportation crew may be the maximum exposed individual.

Table A-31. Summary of cumulative risk over the 40-year period for transportation of naval spent nuclear fuel and test specimens (on-site/off-site).

	ON-SITE General Population			OFF-SITE General Population		
	Collective Dose (person-rem)	Estimated Cancer Fatalities	Estimated Traffic Fatalities	Collective Dose (person-rem)	Estimated Cancer Fatalities	Estimated Traffic Fatalities

Decentralization No Exam	0.014	7.0 x 10y6	4.0	2.0 x 10y3	25	1.3 x 10y2	23	1.2 x 10y2
Decentralization Limited Exam	0.045	2.3 x 10y5	7.4	3.7 x 10y3	25	1.3 x 10y2	130	6.5 x 10y2
Decentralization Full Exam	1.8	9.0 x 10y4	2700	1.4	3300	1.7	130	6.5 x 10y2
1992/1993 Planning Basis	2.2	1.1 x 10y3	3300	1.7	4100	2.1	130	6.5 x 10y2
Regionalization or Centralization at INEL	2.2	1.1 x 10y3	3300	1.7	4100	2.1	130	6.5 x 10y2
Regionalization or Centralization at Hanford	2.2	1.1 x 10y3	3300	1.7	4100	2.1	560	2.8 x 10y1
Regionalization or Centralization at Savannah River	2.2	1.1 x 10y3	3300	1.7	4100	2.1	1700	8.5 x 10y1
Regionalization or Centralization at Oak Ridge	2.2	1.1 x 10y3	3300	1.7	4100	2.1	1700	8.5 x 10y1
Regionalization or Centralization at Nevada Test Site	2.2	1.1 x 10y3	3300	1.7	4100	2.1	1700	8.5 x 10y1

For design basis accidents, the calculated exposure to the general population ranges from 0.51 person-rem in a rural area to 560 person-rem in an urban area. The risk associated with these exposures ranges from 0.00026 to 0.28 cancer fatalities. The exposure to the maximum exposed individual ranges from 0.0034 rem to 0.25 rem. The risk to the maximum individual ranges from 0.0000017 to 0.00013 cancer fatalities.

For beyond design basis accidents, the exposure to the general population ranges from 4.0

person-rem in a rural area to 4100 person-rem in a suburban area (in this case, the probability of the accident of the same consequence in the urban area was less than 1 x 10y7). The risk associated with these exposures ranges from 0.002 to 2.1 cancer fatalities. The exposure to the maximum exposed individual ranges from 0.014 rem to 2.2 rem. The risk to the maximum individual ranges from 0.000007 to 0.0011 cancer fatalities.

The shipments of naval spent nuclear fuel from shipyards and prototypes, transfers of naval spent nuclear fuel to storage, transfers of test specimen assemblies to the examination facility, and shipments of test specimens to test facilities were evaluated for the maximum consequences of an accident. Although the naval spent nuclear fuel shipments contain a higher amount of activity per shipment, there are cases where the test specimen shipment consequences are larger. The consequences are larger primarily due to the higher number of shipments which increases the probabilities such that a more severe consequence is evaluated.

Tables A-34 and A-35 provide the maximum consequences, separated by on-site and off-site shipments, respectively.

As described in Section 3.8 of the main body of this Appendix, a transition period could be necessary which would require approximately 80 shipments from Navy sites to ECF. These shipments are not included explicitly in the detailed analyses; however, the appropriate number of shipments engendered by each alternative during this period is explicitly included, so the range of environmental effects of these shipments is bounded. Since all alternatives ship the same basic fuel types, the maximum consequences are determined by the probability of the accident which is a function of the distance traveled. As described in Section A.8.3, only the No Action, Decentralization - No Examination, and Decentralization - Limited Examination alternatives, which have the lowest estimated maximum consequences, would increase the distance traveled if the

transition shipments were included. Therefore, incorporating the transition period would actually reduce the difference between alternatives from the standpoint of transportation effects.

A.9 EFFECT ON ENVIRONMENTAL JUSTICE

The only method used to ship naval spent nuclear fuel to INEL in the past and the only method proposed for future shipments is by rail. The only exceptions to this are that naval spent nuclear fuel from Pearl Harbor Naval Shipyard is transported by ship from Hawaii to Puget Sound Naval Shipyard where the shipping containers are transferred to railcars for the journey to INEL, and a heavy-lift transporter is used to move the shipping containers from the Kesselring Site a few miles to the nearest railhead. The mode of shipment used for naval spent nuclear fuel tends to limit the exposure to members of the general public during transportation. The shipments pass through urban, suburban, and rural areas, using routes selected by the railroads in accordance with applicable regulations and the requirements of the load. The fractions of the distance traveled in urban, suburban, and rural areas range from about 2.5% urban, 12.5% suburban, and 85% rural to approximately 4% urban, 35% suburban, and 61% rural, depending on the alternative considered.

As shown in the analyses in this Attachment, the impacts on human health or the environment resulting from routine transport of naval spent nuclear fuel and hypothetical transportation accidents would be small for all of the alternatives considered. For example, it is unlikely that a single additional cancer would occur as a result of the transportation of naval spent nuclear fuel under any alternative. Shipping accidents could occur at any location along the routes used, so it is not possible to identify the minority or low-income composition of the populations along the routes. However, the fact that the potential impacts due to an accident for any of the alternatives considered would present no significant risk and do not constitute a credible adverse impact on the population along the shipping routes makes it possible to state that no adverse effects from accidents associated with the management of naval spent nuclear fuel would be expected for any specific segment of the population, minorities and low-income groups included.

To place the impacts on environmental justice in perspective, the risk from routine shipping activities or hypothetical accidents associated with transportation of naval spent nuclear fuel under any of the alternatives considered would amount to less than one additional fatality per year in the entire population. For comparison, in 1990 there were approximately 40,000 traffic fatalities in the United States population and there were about 7,400 deaths caused by traffic accidents among people of color in the U. S. Even if all of the additional cancer deaths associated with an accident for any of the alternatives considered for naval spent nuclear fuel management were assumed to occur only among people of color, that group would experience far less than one additional fatality per year. The same conclusion can be drawn for low-income groups.

ATTACHMENT B - DESCRIPTION OF NAVAL SPENT NUCLEAR FUEL RECEIPT AND

HANDLING AT THE EXPENDED CORE FACILITY AT THE
IDAHO NATIONAL ENGINEERING LABORATORY

TABLE OF CONTENTS

LIST OF FIGURES

ATTACHMENT B

DESCRIPTION OF NAVAL SPENT NUCLEAR FUEL RECEIPT AND HANDLING AT THE EXPENDED CORE FACILITY AT THE IDAHO NATIONAL ENGINEERING LABORATORY

B.1 GENERAL DESCRIPTION AND OPERATION OF FACILITIES

The Expended Core Facility (ECF) is located within the confines of the Naval Reactors Facility (NRF) at the Idaho National Engineering Laboratory (INEL). It is a large laboratory facility used to receive, examine, prepare for storage, and ship naval spent nuclear fuel and irradiated test specimen assemblies. The information derived from the examinations performed at ECF provides engineering data on nuclear reactor environments, material behavior, and design performance. These data are used to develop new technology and to improve the cost-effectiveness of existing designs.

Naval spent nuclear fuel is prepared at ECF for storage and shipment to the Idaho Chemical Processing Plant (ICPP). Some naval equipment contaminated by radioactive material during use in the fleet is refurbished for reuse.

The building which houses ECF is a concrete block structure approximately 1000 feet by 194 feet. This space provides offices and enclosed work areas, including an array of interconnected reinforced concrete water pools which permit visual observation of naval spent nuclear fuel during handling and inspection while shielding workers from radiation. Adjacent to the water pools are shielded cells used for operations which must be performed dry. Access to ECF for receipt and shipping of large containers is provided by large roll-up doors that allow railcar and truck entry. A schematic view of ECF is shown in Figure B-1 and a photograph of the water pool area is provided in Figure B-2.

ECF has been specifically designed to provide the unique physical and administrative controls required by the Naval Nuclear Propulsion Program to ensure safe handling of irradiated and contaminated nuclear fuels and components with a high degree of worker safety and protection for the environment. The original ECF building was constructed in 1957, and consisted of a water pool and a shielded cell with a connecting transfer canal. The facility has been modified as necessary to accomplish the expanding mission of the facility since then, including the addition of three more water pools, several shielded cells, and other capabilities dictated by the nature of the work required.

Figure B-1. Schematic view of Expanded Core Facility. Figure B-2. Expanded Core Facility water pool area.

B.1.1 Water Pools

The purpose of the four interconnected water pools is to permit viewing and examination of radioactive reactor components and specimens while providing radiation shielding for workers.

Walls and stainless steel gates divide the water pools into smaller work areas called zones. This partitioning makes it possible to drain a small portion of the total water pool volume when facility equipment maintenance or repair is required. It also would permit isolation of an individual zone if a leak were to develop which, combined with transfer of the water from that pool to holding facilities, would minimize the loss of water.

B.1.1.1 Water Pit No. 1. This pool is used for the removal of spent fuel from shipping containers, and for preparation of fuel and low-level waste for shipment to ICPP. It also contains fuel and non-fuel storage areas.

B.1.1.2 Water Pit No. 2. This water pool is used for handling irradiation test assemblies.

Various components are tested for their reaction to radiation. Test assemblies returned from the Advanced Test Reactor (ATR) at INEL are unloaded from the shipping cask and disassembled. Verification of test integrity and connection of electrical and mechanical monitoring devices are performed.

B.1.1.3 Water Pit No. 3. Radioactive components are separated by milling machines into smaller units for examination in this water pool. Dimensional measuring equipment is used to examine selected components. Fuel storage racks are also located in Water Pit No. 3.

Observation rooms are located along the northern wall of this water pool. These rooms are below the level of the water surface and have viewing windows into the water pool. Components may be visually examined and remotely handled underwater for shielding purposes from these rooms.

B.1.1.4 Water Pit No. 4. Operations performed in this water pool include spent fuel removal from transfer containers, temporary fuel storage in racks, fuel examination, and preparations for spent fuel shipments. Observation rooms are located along the northern wall of the water pool. This water pool also contains the transfer canals that would link the water pools with the proposed Dry Cell Project, which would prepare spent fuel for shipment in a dry, enclosed environment.

B.1.1.5 Construction. All of the water pools are constructed of reinforced concrete in such a

manner that they are watertight. The water pool floors are designed to support installed equipment and shielded shipping containers weighing up to 100 tons with a minimum base area of 8 square feet. Water pool zone depths range from 20 feet to 45 feet. Water pool walls and floors are coated with a thermo-setting plastic coating which is highly resistant to radiation damage, is easy to decontaminate, and serves as an extra barrier to water leakage.

B.1.1.6 Water Treatment and Minimizing Radioactive Contamination. Radioactive contaminants which

have accumulated in the ECF water pools through the introduction of corrosion products from irradiation test assemblies and the unloading of spent fuel are removed by various filtration techniques. The design basis for the ECF water treatment system is to allow no discharge of radioactive material to the environment, maintain water clarity, and minimize the amount of radioactive contaminants in the water.

The design goals are accomplished through the use of water purification modules, water pool surface skimming to remove film and floating material, and water recycling systems. The water purification modules prefilter the water to remove particles larger than 60 microns in diameter, remove any dissolved solids in ion-exchange resin beds, and remove any organic or suspended material by absorption in an activated carbon bed. Spent resin, carbon, and filter elements are disposed of as solid radioactive waste.

B.1.1.7 Water Management. The total volume of the ECF water pools (excluding the two new

transfer canals that are empty) is 3,000,000 gallons. A 1-inch difference in the water pool level is equivalent to approximately 9,300 gallons.

The water pools are maintained at a nearly constant level. Alarms are installed to indicate both high and low level conditions. The total water volume is accounted for monthly. Any addition of water to the system is reported to a separate NRF site organization for an independent verification of water volume.

Water leaves the water pools via evaporation, temporary filling of shipping containers, decontamination of equipment, and transfers to retention basins. The water pool evaporation rate has been calculated theoretically and confirmed by experiment. Water returns to the water pools by transfers from the retention basins and by draining shipping containers. Water removed from the system due to evaporation and equipment decontamination is replaced by adding demineralized water.

ECF has the capability of storing 235,000 gallons of water pool water in three underground, steel-reinforced, concrete storage basins. Two of the vaults each have a 40,000-gallon capacity, and the third has a 155,000-gallon capacity. These basins provide the capability to replenish the water pools and receive water pool water if draining a water pool zone is necessary.

B.1.2 Shielded Cells

There are 14 concrete shielded cells in the facility. These shielded cells are used for examination of smaller components, such as specimens which have been removed from irradiation tests that have been exposed to a neutron flux in the ATR, and fuel and non-fuel components from the water pools.

The shielded cells are constructed of concrete, with walls 3 feet thick to provide shielding from radiation. Ventilation in the cell bank maintains negative pressure inside the cells in relation to the rest of the facility. This ensures that radiological contamination is contained within the cells.

All work in the shielded cells is performed remotely by equipment controlled from the cell gallery, and is viewed through shielded lead glass windows. The windows are 3 feet thick, and provide the same shielding value as the concrete walls. The interior of the cells can also be viewed through wall periscopes that permit undistorted viewing of equipment and components.

B.2 RECEIPT AND HANDLING OF NAVAL SPENT NUCLEAR FUEL

B.2.1 Receipt of Spent Fuel

Nuclear-powered ship assignments for refueling, defueling, and overhaul are currently performed by the six nuclear-capable public shipyards (Mare Island, Puget Sound, Pearl Harbor, Portsmouth, Norfolk, and Charleston) and one nuclear-capable private shipyard (Newport News). In 1993, the federal base closing commission included Mare Island and Charleston Naval Shipyards among the bases to be closed in the near future. The spent fuel is removed from nuclear-powered ships and loaded into shipping containers designed specifically for naval spent nuclear fuel. The spent fuel containers are loaded and sealed at the shipyard and shipped to ECF via railcars, as described in Attachment A. A maximum of 48 containers can be staged on the rail siding at NRF outside ECF while awaiting transfer of the spent fuel to the water pools. ECF also receives spent fuel from naval prototype plants in a similar manner.

B.2.2 Handling of Spent Fuel

The shipping containers are brought into the ECF building at one of the two defueling stations and are prepared for defueling by removing the dust cover, leveling, and filling with water. Appropriate containments to prevent release of radioactive material are installed and the container access plug is removed to allow access to the fuel modules.

The containers are unloaded at either the west end defueling station or the east end defueling station. Regardless of the defueling station used, the fuel modules are removed from their shipping container one at a time using a fuel handling machine which draws the module out of the container into a shielded volume, and the entire machine is transferred to the water pools. The fuel module is then discharged into a receiving receptacle in the water pools. Photographs of the two fuel handling machines used are provided in Figures B-3 and B-4.

Every item containing nuclear fuel received at ECF has a unique serial number. When the fuel is removed from its shipping container, two ECF fuel handlers independently read the serial number and compare it to the shipping paperwork. After the serial number is confirmed, the fuel is moved to a uniquely numbered storage port location. Two fuel handlers then independently verify that the fuel is stored in the correct storage location. ECF has a computer-based fuel accountability system which maintains a record of the location and type of every piece of nuclear fuel and how many grams of uranium are contained within the fuel. This system tracks every fuel movement during the time that the fuel is at ECF.

Figure B-3. M-140 container fuel handling machine.

Figure B-4. M-130 container fuel handling machine.

All naval fuel modules have metal structures which contain no fuel above and below the fuel region to facilitate coolant flow and maintain proper support and spacing within the reactor. These upper and lower non-fuel bearing structures must be removed to provide access to the fuel-bearing sections to permit inspection of the module. Removal also reduces the storage space ultimately required for the fuel by approximately 50 percent. The upper and lower non-fuel bearing structures removed during the preparation of fuel modules are evaluated using the waste classification criteria established by federal regulations in 10CFR61 and DOE Order 5820.2. These non-fuel bearing structures do not contain any fuel, or fission products from fuel, and therefore cannot be considered "spent nuclear fuel." They also do not contain transuranic elements or fission products and thus cannot be considered high-level waste or transuranic waste. Therefore, the amounts of radioactivity in the end boxes cause them to be classified as low-level waste. As indicated in Section 5.2.15, the amount of low-level waste generated each year at the Expended Core Facility is 425 cubic meters. The radioactive isotopes which represent 99 percent of the activity in this material are identified as follows:

ISOTOPE	HALF-LIFE (Years)	PRIMARY MODE OF DECAY
Fe-55	2.73	Electron Capture (x-ray)
Co-60	5.271	Beta and Gamma
Ni-59	76,000	Electron Capture
Ni-63	100	Beta

U.S. Nuclear Regulatory Commission 10CFR61 identifies three classes of low-level wastes which are generally suitable for near-surface disposal, namely, Classes A, B, and C. Those meeting the requirements for near-surface disposal are shipped to the INEL Radioactive Waste Management Complex using a shielded cask. Wastes with concentrations greater than those specified for Class C for certain short- and long-lived isotopes were found to be not generally suitable for near-surface disposal. These wastes are classified as Greater Than Class C Low-Level Radioactive Waste. In May 1989, the Nuclear Regulatory Commission promulgated a rule that requires disposal of commercially generated low-level waste with concentrations of radioactivity greater than Class C in a deep geologic repository, unless disposal elsewhere is approved by the Nuclear Regulatory Commission.

Currently, a small amount (about 25 cubic meters) of greater than Class C low-level waste in material removed from the ends of naval spent nuclear fuel modules over the years is being stored at the Naval Reactors Facility pending availability of a disposal facility licensed by the Nuclear Regulatory Commission. This material has been collected and held at the Expended Core Facility for many years. This practice is expected to continue over the period of time covered by this Environmental Impact Statement.

After these upper and lower metal structures have been removed from a fuel module, a lifting fixture is installed to facilitate handling. Prepared fuel may then be inspected immediately or it may be held for a time prior to inspection in storage racks in the water pool. In the event that the fuel is temporarily stored while awaiting inspection, spacers are placed at the bottom of the selected port in the storage rack to maintain the position of the fuel module close to the top of the rack to make movement of the module easier.

Visual examinations of all modules are performed to verify that the fuel has performed as expected. As discussed in Section 2.4.1, about 10 to 20 percent of the spent reactor cores are selected for more detailed examination or destructive analysis in accordance with the needs of the Naval Reactors fuel development program. The more extensive examinations performed in the water pools include measurements of key dimensions of the modules and collection of specimens to be examined in the shielded cells. The specialized equipment used to perform examinations of naval spent nuclear fuel are described in more detail in the section of this attachment devoted to equipment.

Destructive analyses are performed at the Expended Core Facility or at other laboratories, but all material subjected to such analysis must be removed from the spent fuel modules at the Expended Core Facility.

The last steps of spent fuel handling performed at ECF are staging the module for shipment and loading the module into the shipping cask used to transport spent fuel from ECF to ICPP. The spent fuel may be temporarily stored in the racks in the ECF water pools until a cask becomes available to transfer the material to ICPP.

B.2.3 Shipment of Fuel to the Idaho Chemical Processing Plant

A lead-filled, stainless steel shipping cask is used to transport naval and prototype spent fuel modules from ECF to ICPP. The cask is removed from its transport truck and lowered into the ECF water pool until it rests on the floor of the pool. The closure head is removed, and inserts are placed in the cask to provide proper spacing of fuel and to maintain proper positioning during transport of the modules. The modules are inserted into the cask, the closure head is reinstalled, and the cask is lifted from the water. The cask is drained, the exterior is decontaminated, and the cask is loaded onto the truck for shipment. The transport of the cask to ICPP is described in Attachment A.

B.2.4 Library of Naval Reactor Components

As the first modules of a given fuel design are received at the Expended Core Facility for examination, selected key operating components are retained in "library" storage in the water pools to provide a source of reference. These older components are kept to ensure that there will be a representative item available to assist in diagnosis of problems which may occur in any operating power plant in the fleet. The items chosen for this library are usually those that have been in service the longest so that they display the most pronounced effects of use. As the various fuel design types are replaced in fleet service by newer designs, fuel components related to the fuel design being retired are removed from library storage and shipped to ICPP.

B.3 HANDLING OF IRRADIATED TEST SPECIMENS

The irradiated materials program evaluates small specimens of materials for use in naval reactor systems. The specimens are loaded in sample holders, and the holders are placed in test assemblies at ECF. The assemblies are irradiated at ATR, and returned to ECF for disassembly. The specimens are cleaned, examined, reloaded in a test assembly, and returned to the ATR for continued irradiation. A typical specimen undergoes several cycles of irradiation and examination over several months or years. Examinations include nondestructive and destructive tests. Destructive tests have historically included sectioning of specimens for mechanical testing and metallography. Metallographic work was performed in the ECF hot cells in the past and is planned to be performed on specimens in the future.

After completion of the final examination, specimens are shipped to ICPP for storage or to the INEL Radioactive Waste Management Complex for disposal. Other specimens are shipped to either the Bettis Atomic Power Laboratory near Pittsburgh, Pennsylvania, or the Knolls Atomic Power Laboratory near Schenectady, New York for more detailed examinations.

B.4 DESCRIPTION OF MAJOR ITEMS OF EQUIPMENT

The normal method for moving the fuel in the water pools to designated examination equipment areas is by use of one of five bridge cranes which move on rails located on the tops of the walls of the water pools. The fuel is handled remotely. All fuel movements are controlled by trained personnel, and accountability is maintained both by computer and by personnel using fuel transfer forms.

B.4.1 Water Pool Equipment

ECF has unique equipment in the water pools that has been designed for remote operation underwater to perform specific examinations on naval spent nuclear fuel and irradiated test specimens. Special consideration was given during equipment design to provide for remote repair and replacement of components. A description of the water pool spent nuclear fuel and irradiation test examination equipment is presented below.

B.4.1.1 Water Pool Band Saws. There are two underwater band saws in the ECF water pools.

These band saws are used to remove the non-fuel bearing structural material from the top and bottom of fuel cells in preparation for inspection. The fuel region of the fuel cell remains intact during the cutting procedure.

B.4.1.2 Water Pool Milling Machines. Three milling machines in the water pools are used to

separate spent nuclear fuel components into smaller sections for examination in the shielded cells. The fuel region of the fuel cell remains intact during the machining. The mills are used to section spent fuel into pieces which can be handled in the shielded cells for examinations, such as gamma radiation measurement, or for obtaining smaller specimens for metallurgical analysis or fuel depletion measurement. The mill head of the largest milling machine can be remotely interchanged with a band saw attachment to convert the machine into a cutoff saw.

B.4.1.3 Universal Inspection Station. This equipment is used to obtain dimensional measure-

ments using specially designed probes that are inserted in the fuel module. This equipment can position and rotate the probe in any orientation by a dedicated computer. This information is used to assess dimensional changes in the fuel module.

B.4.1.4 Vertical Inspection Gage. The vertical inspection gage is used for obtaining dimensional

measurements or to trace the contour of the external surfaces of fuel cell assemblies or control rods. This information can be used to provide a three-dimensional image of the fuel cell or control rod at the end of fuel life to determine the effects of fuel element changes on the overall fuel cell assembly dimensions over fuel life and the effects of radiation on control rod dimensions over fuel life.

B.4.1.5 Video Visual Equipment. Underwater television cameras and lighting can be set up in

any zone in the water pools to obtain images of the external surfaces of the fuel cell assemblies and control rods. These visual inspections are used to search for anomalies such as excessive corrosion or wear on external surfaces. The bottom end of the fuel cell assemblies can also be inspected for flow blockage, corrosion, and wear.

B.4.1.6 Assembly and Disassembly Tables. These tables are used to assemble and disassemble

irradiated test assemblies that are inserted in the ATR. There are two identical assembly and disassembly tables installed side by side in the water pools. Each is mounted on a tilt platform that is used to rotate the table from a horizontal position for test assembly and disassembly to a vertical position for loading and unloading the test assembly.

B.4.1.7 Headwork Station. The Headwork Station provides containment and shielding for the

mechanical connection and disconnection of components to and from the unirradiated portion of the assembly and disassembly of irradiations tests for the ATR. There are two independent work stations; each consists of an elevator platform which raises the top unirradiated portion of the test above the water surface. A containment is positioned above the water surface to prevent the spread of contamination while the examination is performed above the water.

B.4.1.8 Fuel Storage Racks. Storage racks are required at ECF since, at times, fuel is received

into the facility faster than fuel can be prepared and shipped out of the facility. Racks are also used to store the small amount of naval spent nuclear fuel selected for retention as library specimens for future reference and study. Ensuring that the racks are conservatively designed to withstand any credible accident and continue to provide adequate nuclear separation are the major criteria for storage racks.

The basic configuration of a fuel storage rack is a rectangular structural array of storage ports. Each port has a square opening, but depth is variable. All storage ports in use at ECF are stainless steel. Stainless steel is used exclusively to resist corrosion during the life of the storage racks. The storage ports are designed to withstand the weight of the heaviest fuel module which can be placed in the port, and the frame assembly is designed to support the entire weight of all the fuel ports fully loaded with the heaviest fuel type.

All the fuel racks are designed to maintain their structural integrity during a design basis earthquake and to withstand the impact of a fuel module dropped onto the fuel racks. Analyses of all fuel racks in the event of seismic activity has demonstrated that they will not collapse during the postulated earthquake. ECF also performed a full analysis of the strength of the ports if a fuel module were dropped over the fuel racks, including the kinetic energy which the dropping fuel module would impart to the rack. It was determined that all fuel racks at ECF were adequately designed to withstand the energy of dropped fuel. The analysis also identified that some equipment handled at ECF was heavy enough that the racks might be deformed if the equipment were dropped. Thus, operating rules and procedures prohibit the movement of large loads over the fuel racks to ensure that no accidental damage to the racks can occur.

Fuel storage racks were also designed to prevent arrangement of the modules into a potentially critical configuration. The fuel racks are designed so that each port separates the module it contains from every other module by a distance great enough to prevent criticality under the most limiting conditions possible. To assure that only one piece of fuel is placed in a port, all fuel storage ports are equipped with lids which can be locked and sealed. Finally, the frame assemblies of all fuel storage racks are covered with stainless steel sheeting to prevent fuel from inadvertently being placed between fuel storage ports.

B.4.2 Water Pool to Shielded Cell Transfer Systems

Components that have been removed from spent nuclear fuel cells or test assemblies can be transferred into the shielded cells using one of the three available water pool to shielded cell transfer systems. The transfer systems use carts that are driven through underwater tunnels.

B.4.3 Shielded Cell Examination Equipment

ECF has specialized equipment installed in the shielded cells which is designed to perform examinations on fuel elements and components removed from spent fuel cell assemblies and test specimens that have been irradiated in the ATR. A description of the major shielded cell equipment follows.

B.4.3.1 Electronic Balances. These are commercially available electronic balances that have been

modified to operate remotely in the shielded cells. Components on these balances that are known to deteriorate from exposure to radiation have been replaced using materials that are less susceptible to radiation damage. The equipment is interfaced with computer data acquisition systems to aid the operators in tracking and reducing the data. These balances are used primarily to assess weight changes that result from corrosion testing of materials in the ATR.

B.4.3.2 Descale Tanks. Corrosion removal is performed for test specimens that have been

irradiated in the ATR and structural components and fuel elements removed from spent nuclear fuel modules. These tanks use heat, chemicals, and ultrasound to dislodge corrosion that has accumulated on the specimens or components. The corrosion removal aids in visual examination of these specimens.

B.4.3.3 Bridgeport Milling Machine. This is a high-precision milling machine that has been

modified for remote operation in the ECF shielded cells. The mill is controlled by a programmable controller located in the shielded cell gallery. The Bridgeport mill is used for precise machining of non-fuel components removed from spent nuclear fuel cell assemblies.

B.4.3.4 Specimen Coordinate Automated Measuring Machine. The specimen coordinate

automated measuring machine is a fully automated unit specifically designed to perform three-dimensional measurements on irradiated test specimens and structural components removed from spent nuclear fuel cells. The equipment is completely computer controlled and has an accuracy of 0.00005 inch (50 microinches). The information obtained from this equipment is used to assess the effect of radiation on material growth and fuel burnup on swelling of specimens.

B.4.3.5 Fiducial Automated Measuring Machine. This machine is used to measure the distance

between scribe marks that are put on some types of specimens during fabrication. The machine accurately measures the position of the scribe marks in relation to other fiducial marks on the specimen. These data are used to assess the effects of radiation on specimen growth and distortion, as well as the effect of fuel depletion on fuel element swelling.

B.4.3.6 Gamma Scan System. This system measures gamma radiation emitted by fission

products to identify isotopes present in the fuel as a result of fuel depletion. The system is controlled by a dedicated computer which positions the specimen, provides for data acquisition and evaluation, and provides an output of the isotopes detected by the system at each location along the axes of the specimen.

B.4.3.7 Alpha Box. The Alpha Box is a carbon steel containment inside the shielded cells. It

provides isolation within the shielded cells for fuel cutting to prevent the spread of fission products. This is the only location in the facility where cutting through the fuel region of spent nuclear fuel is allowed.

B.5 FACILITY DESIGN AND INTEGRITY REQUIREMENTS

B.5.1 Flood

A flood at ECF due to overflow of any source of surface water within the INEL boundaries is a low probability event. With the construction of the INEL flood control diversion system in 1958, the threat of a flood from overflowing of the Big Lost River, the primary source of surface water at the INEL, has become very small.

The maximum water elevation postulated at ECF would be caused by a hypothetical Probable Maximum Flood resulting from failure of the Mackay Dam, located approximately 35 miles northwest of the INEL. The hypothetical flood could result in a maximum water level approximately 3 feet above the floor elevation of the ECF building. This flood is postulated to result from water flowing over the top of the Mackay Dam and causing it to fail due to high water levels. This flood is highly unlikely. (Koslow and Van Haaften 1986)

Dam failure due to other causes, such as seismic activity, is more likely. Although the Mackay Dam survived the 1983 Borah Peak earthquake without damage, it was built without seismic design criteria. Additionally, it is not clear how resistant the dam structure is to seismic events. A fault segment runs within 6 kilometers of the Mackay Dam.

Flooding of the ECF building is possible should the Mackay Dam fail. Flooding of the ECF building would not create a nuclear criticality hazard. Flooding of the building could result in the release of water containing low levels of radioactive contamination to the environment and damage to equipment in flooded areas. Following the dam break, it would take over 16 hours for the flood water to reach NRF. This is adequate time to complete emergency procedure preparations, such as filling and placing sandbags, for the expected flood conditions.

B.5.2 Earthquake

The ECF building structure was built in accordance with the Uniform Building Code for each particular phase of construction. Water Pit No. 1, Water Pit No. 2, and Water Pit No. 3 were built to "Zone 2" earthquake requirements which were judged to be appropriate under the U.S. Geologic Survey classification of the area at the time of their construction. Water Pit No. 4 and its two transfer canals were built to the more restrictive "Zone 3" earthquake requirements in effect at the time they were built.

A seismic assessment has been performed for the ECF using the actual characteristics of the existing facility. Based on this assessment, a design basis seismic event at ECF could have a peak ground acceleration of 0.24 g (Rizzo 1994). This peak ground acceleration is derived on the basis that a moment magnitude 6.9 seismic event centered near Howe on the Lemhi fault would cause a rupture of approximately 34 kilometers along the Lemhi fault. The Howe epicenter is the epicenter located closest to ECF, and 6.9 was the moment magnitude of the Borah Peak earthquake in 1983. This approach for postulating the location of the seismic event is consistent with the Nuclear Regulatory Commission methodology used for commercial power plants. The beyond design basis seismic event was based on the entire 150 kilometers of the Lemhi fault rupturing. This beyond design basis earthquake might have a peak ground acceleration of 0.4 g at ECF.

B.5.3 Tornado

A tornado at ECF is a low probability event. The document "Technical Basis for Interim Regional Tornado Criteria," WASH-1300, provides the technical basis for Nuclear Reactor Commission Regulatory Guide 1.76, "Design Basis Tornado for Nuclear Power Plants." The WASH-1300 document identifies the probability of occurrence of a tornado at ECF to be 7.8 x 10-5 per year based on historical records. Regulatory Guide 1.76 identifies the maximum wind speed appropriate to ECF to be 240 mph. Data collected by Dr. T. Fugita of the University of Chicago performed at the request of the DOE for the period between 1950 and 1976 indicate the probability of a tornado with winds of that speed occurring at the INEL is about 1.3 x 10-9 per year. Based on a threshold wind speed for tornado damage of 75 mph (refer to P. L. Doan, "Tornado Considerations for Nuclear Power Plant Structures," Nuclear Safety, Volume 11, No. 4) and a probability of 0.80 for the occurrence of tornado-induced wind speeds greater than or equal to 75 mph (WASH-1300, Table 3), the probability of a damaging tornado occurring at ECF is 7.8 x 10-5 per year x 0.80 = 6.2 x 10-5 per year.

A tornado could not affect the fuel storage area in ECF in such a way that the fuel would be rearranged into a critical configuration. The article by Doan cited above analyzes the effects of tornados for the general case of spent fuel in water pools and concludes "... massive loss of water due to either tornado-induced wind forces or tornado-generated missiles cannot happen. It is credible, however, that a couple of feet of water could be lost owing to the combination of water splashing, water entrainment, and pressure differentials. The spent fuel at the bottom of the water pools would, however, remain completely covered.... By the same token, the radiation dose level above the water surface would not increase by any meaningful amount."

B.5.4 Fires

The entire ECF facility is protected against fires by one of several types of sprinkler systems. A large, intense fire in fuel handling areas is a low probability event because of the nature of the materials of construction in these areas, the amounts and kinds of material present, and the fire protection system. Most of the spent fuel is under many feet of water, providing additional protection against a fire which might involve fuel. Fires at other locations in the facility would be extinguished by the sprinkler system and by manual fire protection equipment (e.g., fire extinguishers or fire hoses). An extensive fire involving the ECF building structure is highly unlikely because it has been constructed of non-combustible or fire-resistive material to the greatest extent possible, in accordance with applicable Atomic Energy Commission, Energy Resource and Development Administration, and DOE design criteria.

B.5.5 Loss of Water Pool Water

Loss of all water in a section of the water pool is extremely unlikely. However, should a heavy object be dropped onto a water pool floor, a crack could develop. If this were to occur, the cracked water pool area would be isolated and drained in a controlled manner to one of the retention basins before a substantial loss of water to the environment would occur. Even in the event that severe damage to a water pool floor were to result in the loss of substantial amounts of water pool water, no nuclear criticality hazard would result and no melting of fuel would occur.

B.6 CRITICALITY CONTROL

There has never been an inadvertent criticality at the Expended Core Facility. This is the result of strict application of the following principles.

A fundamental principle of nuclear safety is Criticality Control. When a mass of nuclear fuel reaches a condition at which its atoms are capable of undergoing a self-sustaining chain reaction, or splitting (fissioning) into new elements, the result is called a criticality. Nuclear fission releases energy in the form of radiation and heat. Controlled criticality within a shielded reactor vessel produces energy within a confined space without harm to personnel or the environment. Although the water pools, the shielded cells, and the ECF building are designed to shield and contain radiation and radioactive contamination, an uncontrolled criticality (or nuclear excursion) within ECF is unacceptable, and comprehensive measures are taken to prevent such an occurrence. Criticality control at ECF could be described more accurately as "absolute criticality prevention." Conditions are identified, equipment or processes are designed, rules and procedures are formulated, and personnel are trained to prevent occurrence of an accidental criticality.

Safety analyses are performed on all fuel types and system designs where all single plausible and unlikely accidents are considered. Conservatism is employed in establishing limits and controls, and spent fuel is handled to the more restrictive as-built values. Then a "double accident criterion" is applied to all fuel handling equipment and procedures. The double accident criterion states

"Fuel must be handled and equipment designed so that acceptable margins to criticality exist after two most limiting, unlikely, independent, and concurrent accidents. In this context, two errors in a routine administrative procedure are considered to be a single accident, not two." As a result of application of this criterion to equipment and procedures at ECF, the amount of fuel which may be handled in any operation is typically restricted to one quarter of the minimum amount which could achieve criticality minus a safe margin to criticality.

All nuclear fuel operations must be performed in accordance with approved criticality control procedures. Nuclear safety analyses are carefully reviewed by the responsible management and two independent nuclear safety committees. Naval Reactors must approve each analysis before it is used. Strict reviews and approvals are also applied to implementation of safety analyses in fuel handling procedures.

The successful criticality control program at ECF is also due to thorough training and supervision of fuel handling personnel. Employees are educated concerning the principles of criticality, associated hazards, and prevention. A system of checks to ensure that the rules and limits are strictly observed is employed. It includes detailed training documentation, qualification and testing standards, a self-assessment (audit) program, and an array of accountability and nuclear safety drills.

B.7 PROPOSED DRY CELL FACILITY

The Dry Cell Facility consists of a shielded, radiologically controlled area with remotely operated equipment. The facility is designed for a 40-year life, built of structural steel and concrete, and would be integral with the existing ECF building.

The major element of the Dry Cell Facility is a large reinforced concrete shielded cell with interior dimensions of 22 feet wide by 84 feet long by 21 feet high, containing all the equipment necessary to inspect and disassemble fuel modules. The facility will have the capability to prepare and load one fuel module per shift in a shipping cask. Based on a two shift per day operation (500 shifts per year), and a 25-percent maintenance downtime, the Dry Cell Facility yearly capacity is expected to be 375 modules. Shielded decontamination and repair cells will be attached to the main shielded cell to allow remote decontamination and repair of equipment used throughout ECF. Artist's views of the Dry Cell Facility and the associated Cask Loading System are shown in Figures B-5 and B-6.

The dry cell design incorporates 4-foot thick, radiation shielding walls constructed of high-density and normal-density concrete. The shielding is designed to limit radiation levels in normally occupied areas around the cell to 0.1 millirem per hour or less. At the INEL Site boundary, there would be no measurable elevation above the naturally occurring background radiation levels. The dry cell design meets the latest seismic requirements and includes negative pressure air ventilation for radiological contamination control. Shielded lead glass windows and viewing aids are provided as required at the workstations. Power, lighting, and a fire suppression system are also provided.

The Dry Cell Facility is also designed to facilitate decontamination and decommissioning of the facility at some future date. This is achieved by including cell liner contamination barriers, no fixed embedded piping, a minimum of cracks and crevices, smooth surfaces, and wall penetrations large enough to be radiologically surveyed to verify decontamination effectiveness.

COMPARISON OF STORAGE IN
NEW WATER POOLS VERSUS
DRY CONTAINER STORAGE

C.1 INTRODUCTION

This attachment discusses the advantages and disadvantages of water pools versus dry container storage should construction of additional interim storage be required. The discussion considers the generic safety aspects of water pools and dry container storage based on evaluations performed by the Nuclear Regulatory Commission (NRC) and the Department of Energy (DOE) as well as experience with naval spent nuclear fuel.

C.2 WATER POOLS

During the last four decades, the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) has demonstrated the safety and reliability of water pools under the control of the Naval Reactors Program. Water pools have historically been the method of choice for interim storage and fuel handling because: (1) water has a high thermal capacity for the removal of heat from the fuel, (2) the transparency of water facilitates the inspection and movement of the fuel, (3) water is an excellent gamma and neutron shield, (4) water is easy to purify and recycle, and (5) water provides a means to prevent release of radioactive material into the air.

The safety of spent fuel storage in a water pool can be considered in terms of three generic criteria. They are: (1) the integrity of spent fuel under water pool storage conditions, (2) the structure and component safety of the facility, and (3) the potential risks of accidents and acts of sabotage at the spent fuel facility.

The NRC conducted an extensive investigation into the storage of spent fuel and documented the findings in the Waste Confidence Decision (NUREG 1984). Based on the technical evaluations cited in that document, the NRC found that the Zircaloy cladding which encases spent fuel is highly resistant to failure under pool storage conditions and concluded that Zircaloy-clad commercial fuel satisfied the first generic criterion. This conclusion is consistent with the extensive experience with naval spent nuclear fuel. Naval fuel is Zircaloy clad and thus is highly resistant to corrosion in water. In addition, a Navy fuel assembly has much higher mechanical integrity than commercial fuel since it is designed for military application and is capable of withstanding shock loadings which may be encountered in battle conditions.

The NRC also conducted an extensive evaluation of the structural and component safety of water pools. The NRC found no reason why spent fuel storage pools would not be capable of performing their cooling and storage functions for a number of years past the design life of 40 years if the water pools are properly maintained; therefore, the second generic criterion would be satisfied. This conclusion is consistent with the naval fuel experience of over 35 years of operation of the ECF.

The risk of major accidents at spent fuel storage pools resulting in off-site consequences is remote because of the secure and stable character of the spent fuel in the storage pool environment, and the absence of driving forces (i.e., high pressure or temperature) which might result in dispersal of radioactive material (NUREG 1984). The consequences of terrorist attacks on a spent fuel storage pool would be limited by the realities that the radioactive content of spent fuel is in the form of material encapsulated in high-integrity metal cladding and stored underwater in a reinforced concrete structure. Under these conditions, the radioactive content of spent fuel is relatively invulnerable to dispersal to the environment (NUREG 1984).

These considerations led the NRC to conclude that storage pools can be designed to safely withstand accidents caused either by natural or man-made phenomena such that there would be no impact to the environment. Therefore, the third generic criterion would be satisfied.

The NRC concluded that all areas of safety and environmental concern (e.g., maintenance of systems and components, prevention of material degradation, protection against accidents and sabotage) have been addressed for water pools, and that spent fuel can be stored with no environmental impact. This conclusion is supported by the Organization for Economic Co-Operation and Development of the Nuclear Energy Agency (NEA 1993).

C.3 DRY CONTAINER STORAGE

Dry container storage technologies have been in use in the United Kingdom since 1972 (MOCSG 1993). In the United States, demonstration projects have been underway since 1982. In dry container storage, multiple barriers prevent gaseous as well as particulate fission product releases. Two separate barriers must fail before fission products can be released: (1) the fuel cladding, and (2) the outer secondary seal. In addition, dry storage systems provide metal or concrete shielding to reduce the external radiation to acceptable limits.

The NRC concluded that dry container storage involves a simpler technology than that represented by water storage systems. Water storage relies to a certain extent upon active systems such as pumps, renewable filters, and cooling systems to maintain safe storage. Favorable water chemistry must also be maintained to retard corrosion. Dry container storage uses convective circulation of an inert atmosphere in a sealed dry system so there is little opportunity for corrosion (NUREG 1984).

The NRC also found that dry container storage of spent fuel in dry wells, vaults, silos, and metal casks is relatively invulnerable to sabotage and the forces of nature, because of the weight and size of the sealed, protective enclosures, which may include 100-ton steel casks, large concrete-lined casks, and surface concrete silos (NUREG 1980).

The NRC concluded that for dry interim storage, all areas of safety and environmental concern (e.g., maintenance of systems and components, prevention of material degradation, protection against accidents and sabotage) have been addressed and shown to present no more potential for adverse impact on the environment and the public health and safety than storage of spent fuel in water pools. This conclusion is supported by the Organization for Economic Co-Operation and Development of the Nuclear Energy Agency (NEA 1993).

As stated earlier, naval fuel uses Zircaloy cladding and has a much higher mechanical integrity than commercial fuel since naval fuel is designed for military application. Therefore, the generic conclusions reached for commercial spent fuel are directly applicable to naval spent fuel.

C.4 NON-RADIOLOGICAL CONSEQUENCES OF SPENT FUEL

STORAGE

The NRC concluded (NUREG 1984) that "there are no significant non-radiological consequences due to the extended storage of spent fuel which could adversely affect the environment." The construction of an interim spent fuel storage facility (i.e., the construction of a water pool, a concrete pad, a building, rail spur, etc.) would have little impact on the environment. The amount of heat given off by spent fuel decreases with time as the fuel ages and decays radioactively, and the amount of additional energy and water needed to maintain spent fuel storage is also small.

C.5 LAND UTILIZATION

With the use of water pool storage or dry container storage at an existing shipyard, land already devoted to industrial use is planned to be used for the spent fuel storage facility. The amount of land required for storage at specific shipyards is addressed in Attachment D.

C.6 COST

The use of alternate sites other than INEL would involve the construction of additional storage facilities. Both water pools and dry container storage could be used, with little environmental impact; therefore, the relative cost between these two options could be relevant. Conceptual cost estimates have been prepared for each storage option at each location that is being evaluated. These cost comparisons are found in Attachments D and E.

C.7 SUMMARY

Based on the above discussion, both a new water pool and dry container storage would be suitable for the interim storage of spent naval fuel with no important radiological or non-radiological environmental impact. If a facility would be required to be used for the inspection of spent fuel, as well as storage, then a water pool offers an advantage since water is an inexpensive and convenient form of transparent shielding. If it were not necessary for a new facility to be used to inspect spent fuel, then the cost of the facility and the amount of land required could be factors in selecting an option.

DESCRIPTION OF STORAGE OF
NAVAL SPENT NUCLEAR FUEL AT SERVICING
LOCATIONS
(SHIPYARDS AND PROTOTYPES)

D.1 STORAGE OF NAVAL SPENT NUCLEAR FUEL IN CONTAINERS AT SHIPYARDS AND PROTOTYPES

D.1.1 Introduction

This attachment examines the alternative of storing naval spent nuclear fuel at shipyard and prototype sites where the fuel is removed from the reactor plant. Water pool storage, immobile dry storage containers, and dry storage in shipping containers are evaluated for each shipyard and prototype location. Under the No Action alternative, naval spent nuclear fuel would be stored in shipping containers. For the other alternatives where naval spent nuclear fuel would be stored at shipyard and prototype sites, the storage mode would be selected by the Record of Decision. Attachment C has addressed the generic safety of water pool and dry storage and concluded that both methods would be suitable for the interim storage of naval spent nuclear fuel with very little environmental impact. This attachment addresses the design requirements, operational considerations, costs, and land requirements for the Puget Sound Naval Shipyard, Pearl Harbor Naval Shipyard, Norfolk Naval Shipyard, Portsmouth Naval Shipyard, and the Kesselring Site.

The interim storage facilities for naval spent nuclear fuel at shipyards and prototype locations would be designed to comply with applicable requirements. The storage facilities would be monitored and maintained in compliance with Naval Reactors Program requirements for radiation protection of workers and the public and the environment. Specifically, exposure to workers at the storage site would be maintained as low as reasonably achievable and would be controlled to Naval Reactors Program radiation exposure standards. As with current naval practices, no measurable increase in radiation levels at the site boundary would result from the storage of naval spent nuclear fuel at any alternate site.

D.1.2 Shipping Containers

D.1.2.1 Container Design Features. Shipping containers and immobile dry storage containers

position the spent naval fuel modules within sealed structures designed to physically constrain, support, and remove residual heat from the fuel in an environment that prevents corrosion of the fuel. The massive size of the containers provides not only strength, but also shielding against exposure to radiation from the spent fuel within.

The shipping containers might be M-140 shipping containers with long-lived seals suitable for storage of spent nuclear fuel for the duration of the period covered by this Environmental Impact Statement (EIS). A description of the M-140 shipping container is provided in Attachment A. This container is already certified to meet the requirements of the U.S. Nuclear Regulatory Commission, contained in 10CFR71, for the transportation of naval spent nuclear fuel. With installation of a long-lived seal, the M-140 container could be qualified for storage for 40 years. The shipping containers could either be positioned on railcars at the storage site or on concrete pads. The process of designing the shipping container long-lived seal would commence with the Record of Decision if this option were selected. The cost associated with the design and recertification of the shipping container would range from approximately $1 million to $5 million. The cost to manufacture each shipping container would be about $5 million. Some uncertainties in estimated costs exist due to the fact that a detailed design for the shipping container long-lived seal is not yet available.

If the Record of Decision were to choose shipping containers, a more detailed evaluation would need to be performed to determine whether it is more appropriate to modify the M-140 shipping container design or whether a new container design should be used. Since the M-140 was designed as a shipping container, the modifications that would need to be made to convert an M-140 to accommodate interim storage might involve substantial new design work and recertification for shipping.

About 500 additional containers with holding capacity equivalent to the M-140 container would need to be fabricated to cover the projected reactor servicing from 1995 through 2035. If an alternative using the shipping containers were to be chosen, an expanded manufacturing vendor base would need to be developed to meet the projected container requirements. With the current manufacturing capabilities, 3 years are required to build an M-140 container and the output capacity is about 6 containers per year.

The shipping containers loaded during the period preceding the Record of Decision would also need to be modified to meet the storage container design criteria. An evaluation would be performed to determine whether these modifications could be safely made with spent nuclear fuel present in the containers. In the event that the spent nuclear fuel must be removed from the shipping containers, the containers would be unloaded and the spent nuclear fuel would be transferred into modified shipping containers at a suitable facility under controls which would protect workers, the public, and the environment. The unloading of spent nuclear fuel from the original shipping containers and reloading into modified shipping containers would introduce additional spent nuclear fuel handling, transportation, and risks.

D.1.2.2 Operations. The process of loading spent nuclear fuel into shipping containers for storage

would be similar to that used for loading M-140 shipping containers. During reactor refueling operations, spent nuclear fuel is normally loaded into M-140 shipping containers that are filled with water. The spent nuclear fuel is staged in this configuration for sufficient time to ensure that heat produced by radioactive decay of fission products is adequately dissipated. When the water is removed from the M-140 container, the loaded M-140 can be shipped. After water is drained from the shipping container, it would be transported to the storage site. The water is processed for reuse.
The transportation procedures would be essentially unchanged from current procedures except that containers would be moved to the interim storage site instead of being shipped to the Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL) for inspection. For railcar storage, the railcar would be positioned in the storage area. For cases where the shipping container is stored on a concrete pad, the container would be off-loaded from the railcar or truck, positioned, and then secured to the pad (if securing would be required). In order to accomplish this transfer, a large capacity crane would be needed at each site, and the site would need to be prepared as necessary to accommodate the mode of storage.

D.1.3 Immobile Dry Storage Containers

D.1.3.1 Container Design Features. There are currently no immobile dry storage containers

designed for interim storage of naval spent nuclear fuel. The container design would be similar to that of containers which are presently certified by the Nuclear Regulatory Commission for storage of spent nuclear fuel from commercial reactors. The design, approval, and construction of an immobile dry storage container would commence with the Record of Decision if this option were selected. This effort could require up to 5 years to complete. The cost associated with the design and approval of the immobile storage container would be about $2 million. The cost to construct each immobile dry storage container would be about $2 million. These estimates are based on costs of commercially available containers with contingencies added to account for additional design features that may be required.

Two concepts for storing naval spent nuclear fuel in immobile dry storage containers have been developed in order to provide a baseline for assessing the impacts. Other dry storage approaches (such as dry storage vaults) exist and would be considered in more detail if the Record of Decision were to choose the immobile dry container storage alternative. The first approach (referred to as the minimum fuel loading concept) is based on the number of spent fuel assemblies stored in the immobile dry storage container being about the same as that which is loaded into M-140 shipping containers. This approach results in the need for about 500 immobile dry storage containers. The second approach (referred to as the maximum fuel loading concept) maximizes the number of fuel assemblies that would be stored in the immobile dry storage containers. The number of containers required for the second approach is about 300.

The minimum fuel loading concept results in a container with a comparatively simpler

design, less maintenance, and lower unit costs (~$1.9 million/container). Under the maximum fuel loading concept, the container would need to be equipped with additional active cooling features such as water circulation to ensure that the heat produced by radioactive decay of fission products is adequately removed. These additional cooling features would be needed for a period of several years after the spent nuclear fuel is removed from the reactor vessel. For the minimum fuel loading concept, additional active cooling features such as recirculating water would not be required to remove heat.
As with the shipping containers, an expanded vendor base would be necessary in order to construct the immobile dry storage containers at the rate they would be needed.

Figures D-1 and D-2 provide conceptual layouts of candidate immobile dry storage containers for naval spent nuclear fuel.

Figure D-1. Conceptual concrete immobile dry storage container for naval spent nuclear fuel.

Figure D-2. Conceptual vertical metal immobile dry storage container for naval spent nuclear fuel.

The dimensions of the immobile dry storage container that would be used for naval spent nuclear fuel would be approximately the same as the M-140 shipping container (i.e., approximately 10 to 16 feet high and 8 to 10 feet wide). The fuel spacing within the container and the container itself would be designed to prevent any nuclear chain reaction, to ensure that decay heat is adequately dissipated, and to ensure that the spent fuel would be protected from hazards associated with natural phenomena or human activities for each storage site.

D.1.3.2 Operations. Operations commence following the defueling of the reactor, after fuel

modules are in a suitable holding container such as an M-130 or M-140 shipping container. The immobile dry storage container would be positioned at the storage location. Transfer of a spent fuel module from the holding container to the dry storage container would be accomplished one fuel module at a time using a shielded transfer container. All fuel transfers would be conducted in strict accordance with procedures which would have been written, reviewed, and approved by personnel trained, qualified, and specifically authorized to perform such work. The transfer container would be landed on the holding container, and a module would be withdrawn from the holding container. The module would be secured and the loaded transfer container closed, moved into position over the dry storage container, and landed. The transfer container would be reopened and the module lowered and seated in the immobile storage container. The transfer container would then be removed. This process would be repeated until the container is filled with spent fuel modules. The container would then be sealed.

Transfers of spent nuclear fuel to the immobile dry storage container would be conducted in accordance with Naval Reactors Program requirements for radiation protection. Radiological containment devices would be used where necessary to prevent radioactivity from spreading to the workplace and from becoming airborne. The transfer and storage containers would contain radiation shielding that minimizes radiation exposure to the workers during transfer and storage operations and ensures that radiation levels at the site perimeter are indistinguishable from natural background.

D.1.4 Water Pool Storage

D.1.4.1 Water Pool Design Features. If the Record of Decision were to choose the alternative of

storing naval spent nuclear fuel in water pools, five water pools could be constructed, one at each designated storage site. Each water pool facility would be designed, built, and operated in accordance with DOE Order 6430.1A and consistent with the intent of Nuclear Regulatory Commission requirements in 10CFR72 and associated Regulatory Guides. The siting, design, construction, and approval of a water pool storage facility would commence with the Record of Decision and could take 6 to 9 years to complete. The design and construction of each water pool facility would also conform with local construction standards for each site.

Water pools operate by holding spent fuel modules in a deep pool of water. The water provides cooling for the spent fuel, a transparent medium for work activities, and protection from radiation (see Attachment C). The structural materials of the fuel modules and naval fuel cladding, as well as temperature and chemistry control of the water, would result in the spent fuel being highly resistant to corrosion. Corrosion-resistant racks below the water surface would be used to support and position the fuel modules in place for handling and to prevent a critical mass being formed. The water depth would be sufficient to provide shielding to protect workers and the environment during module movement and storage.

D.1.4.2 Operations. The naval spent nuclear fuel would be transferred to the water pool in a

suitable container, such as an M-130 or M-140 shipping container. The fuel modules would then be transferred into the water pool using equipment and procedures that are similar to well-proven procedures used at ECF for unloading spent nuclear fuel from shipping containers. The spent nuclear fuel modules would be individually lowered and secured in the storage racks located on the water pool floor. The use of a water pool for storage of naval spent nuclear fuel would provide an opportunity for limited visual inspection of the exterior of the fuel modules after removing them from the naval vessels. This opportunity would not exist to the same extent for the dry storage container alternatives.

D.1.5 Design Basis Considerations for Storage Containers and Water

Pools

The design of both the shipping and immobile dry storage containers would be in accordance with DOE Order 6430.1A and consistent with the intent of Nuclear Regulatory Commission requirements for independent spent fuel storage installations found in 10CFR72 and associated Regulatory Guides. Attachment F describes the exposures which would be expected during normal operational exposures and the exposures calculated for hypothetical accidents that might occur during interim storage of spent fuel at each shipyard and prototype location. The accidents that would be used to establish the requirements for the design of the interim storage facilities are discussed below.

D.1.5.1 Design Basis Considerations for Storage Containers.

(1) Natural Phenomena. The fuel spacing within the container and the container itself would be designed to prevent a nuclear criticality, to ensure that heat produced by radioactive decay of fission products is adequately dissipated, and to ensure that the container would safely survive hazards associated with natural phenomena such as storms or flooding for each storage site. The shipping containers and the immobile dry storage containers would be designed to withstand the most severe design basis seismic event expected for the storage sites. The seismic analysis would evaluate the internal and external structures of the containers and the components associated with stability of the containers. The containers and associated components would be designed to protect the environment during other natural phenomena such as tornado winds, tornado missiles, hurricanes, volcanic activity, design basis floods, and very large waves. If the Record of Decision involves the need for new facilities for the interim storage of naval spent nuclear fuel, detailed site-specific seismic evaluations would be conducted for those sites, and the results would be incorporated into the design of new facilities. The construction of any new facilities for naval spent nuclear fuel management would meet strict seismic standards for the interim storage of naval spent nuclear fuel. The design and construction of these facilities to seismic standards which take into consideration the seismic character of the area would ensure that structures could withstand a major seismic event. The adequacy of the storage facility would be documented in a safety assessment report for each location.

(2) Man-made Hazards. The containers would be arranged to allow access for routine inspections, maintenance, and emergencies. This includes sufficient accessibility for pressure, temperature, and radiological monitoring as well as for fire fighting equipment and ambulances.

The containers would be designed to withstand a fire without losing fission product containment. Flammable liquids and gases as well as explosive materials would be prohibited in the storage area with the exception of fuel in motor vehicles needed to support operations. Combustible materials such as wood, paper, and plastic would be kept to a minimum in the spent nuclear fuel storage areas.

The fuel spacing within the container and the container itself would be designed to prevent nuclear criticality, to ensure that the heat produced by radioactive decay is adequately dissipated, and to ensure that it would safely survive credible man-made accidents for each storage site. Other man-made hazards such as truck accidents, airplane crashes, and objects dropped by cranes would also be addressed in the safety assessment report.

D.1.5.2 Design Basis Considerations for Water Pools.

(1) Natural Phenomena. The spent nuclear fuel spacing within the water pool and the water pool itself and the building support structures would be designed to prevent criticality, to ensure that heat produced by radioactive decay is adequately dissipated, and to ensure that it would protect the fuel from the hazards associated with the design basis natural phenomena for each storage site (i.e., seismic, tornados, missiles generated by a tornado, hurricanes, volcanic activity, maximum expected floods, and very large waves). The water pools would be equipped with spent fuel storage racks for restraining the modules. The racks would be designed to safely survive the above hazards. If the Record of Decision involves the need for new facilities for the interim storage of naval spent nuclear fuel, detailed site-specific seismic evaluations would be conducted for those sites, and the results would be incorporated into the design of new facilities. The construction of any new facilities for naval spent nuclear fuel management would meet strict seismic standards for the interim storage of naval spent nuclear fuel. The design and construction of these facilities to seismic standards which take into consideration the seismic character of the area would ensure that structures could withstand a major seismic event. The adequacy of the water pool facility would be documented in a safety assessment report for each location.

(2) Man-made Hazards. The water pool facility would be designed to withstand fire without damage to the spent fuel within the water. Flammable liquids and gases as well as explosive materials would be prohibited in the vicinity of the storage area with the exception of incidental quantities of flammable solvents necessary to support operations. Combustible materials such as wood, paper, and plastic would be kept to a minimum in the water pool facility.

The fuel spacing within the water pool would be designed to prevent criticality, and to ensure that it would safely survive credible man-made accidents for each storage site. Other man-made hazards such as truck accidents, airplane crashes, and crane drop accidents would also be addressed in the safety assessment report.

D.1.6 Shipyard and Prototype Locations

This section describes conceptual locations at the shipyard and prototype sites where storage facilities could be located to service refuelings and defuelings of naval ships. This section also lists land requirements for each storage method at each location, the construction cost for each method, and the associated operating cost.

D.1.6.1 Land Requirements. This section provides a summary of the land required for each of

the storage methods at each of the locations where refueling and defueling are planned from 1995 through 2035.

These locations are the Portsmouth Naval Shipyard, the Puget Sound Naval Shipyard, the Pearl Harbor Naval Shipyard, the Norfolk Naval Shipyard, and the Kesselring Site. A map of each of these sites is provided in Figures D-3 through D-7, indicating a possible storage location at each of these facilities.

Figure D-3. Conceptual location of the interim storage site at Puget Sound Naval Shipyard. Figure D-4. Conceptual location of the interim storage site at Norfolk Naval Shipyard. Figure D-5. Conceptual location of the interim storage site at Kesselring Prototype Site. Figure D-6. Conceptual location of the interim storage site at Pearl Harbor Naval Shipyard. Figure D-7. Conceptual location of the interim storage site at Portsmouth Naval Shipyard. Table D-1 provides a summary of the amount of land needed for each of the storage methods at each of the locations where storage of naval spent nuclear fuel could be located. It should be noted that the number of containers and land required could be slightly less than identified in Table D-1 as a result of actions taken during the transition period. As shown in Table D-1, storage utilizing shipping containers on railcars would typically require dedication of the most land.

Table D-1. Square feet of land required for storage facility.

Pool Facility(4) Location	Number of Immobile Dry Storage Containers(1)	Number of Shipping Containers	Immobile Dry Storage Containers(2) (ft2)	Shipping Containers on Concrete Pad(3) (ft2)	Shipping Containers on Railcars (ft2)	Water (ft2)
Portsmouth	27-51	61	10,000-19,000	18,000	72,000	20,000
Puget Sound	153-206	219	57,000-77,000	64,000	260,000	33,000
Pearl Harbor	21-30	42	8,000-11,000	12,000	50,000	20,000
Norfolk	132-219	247	49,000-82,000	72,000	293,000	31,000
Kesselring	5-6	6	1,900-2,000	1,700	7,100	17,000

---

(1) Range in required number of containers is due to options in conceptual design (see Section D.1.3.1).

(2) The immobile dry storage arrangement uses the containers stored on a concrete pad in double rows with one container diameter separation between adjacent containers. Each row is separated by a 15-foot wide accessway. Range in required land area is due to options in conceptual design.

(3) The shipping container arrangement uses the containers stored on a concrete pad in double rows with 4 feet between adjacent containers. Each row is separated by a 15-foot wide accessway.

(4) The water pool facility consists of a building that contains adequate space to house supporting equipment and facilities (approximately 17,000 ft2) and a water pool with adjacent work areas of sufficient size to accommodate the amount of spent nuclear fuel expected to be stored in the facility until 2035.

D.1.6.2 Site Construction, Container, and Operating Costs. This section provides estimated

costs associated with each alternative for storing spent nuclear fuel at the shipyard and prototype sites. The major cost factors include facility construction or site preparation costs, container costs, and operating costs over the lifetime of the facility. Cost estimates are based on 1995 dollars.

Table D-2 provides a summary of the estimated construction costs for each storage option at each shipyard and prototype location. The construction costs for immobile and shipping containers on concrete pads and shipping containers on railcars include estimated costs for concrete (labor and materials), rails (for railcars), or cranes for lifting and handling containers or fuel transfer containers (for concrete pad storage). The majority of the construction costs for concrete pad storage options

Table D-2. Estimated site construction costs (millions of dollars).

Location	Immobile Dry Storage Containers on Concrete Pad	Shipping Containers on Concrete Pad	Shipping Containers on Railcars	Construction and Installation of Water Pools
Portsmouth	11-12	10	2	96
Puget Sound	15-16	13	5	141
Pearl Harbor	10-11	9	1	95
Norfolk	14-17	14	6	135

Kesselring	10	8	1(1)	89
Total	60-66	54	15	556

---

(1)Estimate does not include costs associated with establishing railroad extension from the access railroad to the storage site.

are associated with the need for a high-capacity crane. Water pool construction costs include estimates of costs for construction of the water pool, building structure, and associated support equipment. The table shows that construction costs for a water pool facility exceed those of other alternatives, and that shipping containers on railcars involves the lowest construction costs. However, the water pool facility construction costs represent a complete facility ready to hold spent nuclear fuel for interim storage. The construction costs in Table D-2 for the other storage modes represent completed site construction without the cost of the containers (see Table D-3) to hold the spent nuclear fuel.

Table D-3 provides a summary of the estimated costs to build shipping containers and immobile dry storage containers through 2035. The table shows that the immobile dry storage containers are the least expensive containers, and that the cost to build shipping containers to rest on concrete pads is slightly lower than to rest on railcars. The difference in cost between the two shipping container options is due to the cost of a dedicated railcar during storage. The shipping container costs in Table D-3 would be reduced by about 13 percent due to actions taken during the transition period (these actions are described in Section 3.8) to ship containers from the shipyards to ECF. Consequently, the total costs for shipping containers on concrete pads and shipping containers on railcars considering the transition period would be about 2615 and 2760 million dollars, respectively.

Table D-3. Estimated container cost (millions of dollars).

Location	Immobile Dry Storage Containers on Concrete Pad(1)	Shipping Containers on Concrete Pad	Shipping Containers on Railcars(2)
Portsmouth	55-100	319	337
Puget Sound	314-406	1145	1209
Pearl Harbor	43-59	220	232
Norfolk	271-431	1292	1363
Kesselring	10-12	31	33
Total	693-1008	3007	3174

---

(1)Range in container costs due to options in conceptual designs (see Sections D.1.2.1 and D.1.3.1). The lower end of the range represents container costs for the maximum fuel loading option (which requires fewer containers).

(2)Includes the cost of an equal number of railcars and containers required for this option.

Table D-4 provides the estimated costs to operate a naval spent nuclear fuel storage area. The operating costs include estimates of cost for personnel to monitor the facility, handle the spent nuclear fuel when it arrives at the facility, and maintain the facility. These estimates do not include the costs associated with eventual preparation of spent fuel for shipment to a site for disposition. Disposition preparation costs cannot be estimated at this time because the method for preparing the spent fuel has not been defined. Table D-4 shows that the lowest operating costs are associated with shipping containers on concrete pads and that water pool storage requires the highest operating costs.

Table D-4. Estimated operating costs through the year 2035 (millions of dollars).

Location	Immobile Dry Storage Containers on Concrete Pad	Shipping Containers on Concrete Pad	Shipping Containers on Railcars(2)	Water Pool
Portsmouth	11	3	8	180
Puget Sound	23	4	24	206

Norfolk	21	4	27	206
Kesselring	9	2	3	124
Total	75	16	68	896(1)

(1)For comparison, the estimated operating cost (personnel to monitor and handle fuel and maintain the facility) for the ICPP Building 666 for the same period is 232 million dollars.
(2)Includes cost to replace or refurbish railcar after prolonged storage.

D.1.6.3 Total Construction and Operating Costs. Table D-5 is a compilation of the data

contained in Tables D-1 through D-4, and calculated based on the entire 40-year period from the Record of Decision (1995 through 2035). This table shows that the total costs associated with the use of immobile dry storage containers are the lowest of all the storage options considered except for storage at Puget Sound and Norfolk where the largest amounts of spent fuel would be stored. In these cases, the total costs for using water pool storage are within the same range of approximation as immobile dry container storage.

Table D-5. Total costs through the year 2035 (millions of dollars).

Location	Immobile Dry Storage Containers on Concrete Pad(1)	Shipping Containers on Concrete Pad	Shipping Containers on Railcars	Water Pool
Portsmouth	77-123	332	347	276
Puget Sound	352-445	1162	1238	347
Pearl Harbor	64-81	232	239	275
Norfolk	306-469	1310	1396	341
Kesselring	29-31	41	37	213
Total Cost	828-1149	3077	3257	1452

---

(1)Range in total costs due to options in conceptual design (see Section D.1.3.1). The lower cost is associated with the maximum loading concept.

D.1.7 Time Required to Implement Each Storage Method

If the Record of Decision were to choose one of the alternatives involving storage of naval spent nuclear fuel at shipyards and prototype sites, some period of time would be required after the decision to fully implement the selected storage alternative. This section examines the time required to implement each storage method.

D.1.7.1 Container Storage. Implementation of the alternatives involving use of immobile dry

storage containers and shipping containers could be viewed as a three-phase process. The first phase would cover the time required to design the container or container modification, to review and accept the design, to approve the container, to establish contracts for container fabrication, and fabricate the first container. During this phase, the shipyards and prototype sites where the containers would be stored would also construct or modify the container storage location as appropriate for the alternative chosen. For immobile dry storage containers, this phase would take about 5 years, if 2 years are required to design and accept the container design, 1 year is needed for approval of the container, and 2 years are required to build the container. For containers designed for both storage and shipping, this process would take about 5 years, based on 1 year to design the modifications, 1 year to approve the container, and 3 years to build the container.

The second phase would involve establishing funding. This will take approximately 3 years to complete. The third phase of the implementation period would involve fabrication of the remaining required containers. The estimate of the number of containers is based on the projected schedule for naval vessel refuelings and current estimates of the amount of spent nuclear fuel that would be placed into the containers. Although production rates for immobile dry storage containers and shipping containers are unknown, they can be approximated from existing production rates for M-140 shipping containers. With current manufacturing capabilities, 3 years are required to build an M-140 container, and the manufacturing capacity is about six containers per year. This production rate would need to be accelerated to 18 to 24 containers per year by increasing the number of manufacturers and by making fabrication process improvements. If the production rate of immobile dry storage containers and shipping containers is the same as that of M-140 containers and production rates can be increased as noted above, the supply of immobile dry storage or shipping containers would meet the demand for these containers at some point after the first several years. During the transition period, when an insufficient number of containers would be available to store all the spent fuel planned to be removed from U.S. Navy nuclear-powered vessels, some other means of storing naval spent nuclear fuel would be needed. As described in Section 3.8 of this EIS, it is expected that a transition period of 3 years of shipping followed by 3 years of allowing naval spent nuclear fuel to be stored in shipping containers at shipyards would provide the necessary storage space.

D.1.7.2 Water Pool Storage. If 6 to 9 years would be required to design, approve, and construct

a water pool facility and this process would be initiated for each location within a year after the Record of Decision, water pools would be available for storage of naval spent nuclear fuel about 7 to 10 years following the Record of Decision. During the transition period, when water pools would be under construction at selected locations, some other means of spent nuclear fuel storage would be needed, such as the method described in Section 3.8.

D.1.8 Summary

Table D-6 summarizes the major advantages and disadvantages of the spent nuclear fuel storage alternatives previously discussed in this attachment.

Table D-6. Comparison of naval spent nuclear fuel storage alternatives.

Storage Mode	Advantages	Disadvantages
1. Shipping Container		
A. Storage on Railcars	1. Least amount of container handling after arrival at storage location. 2. Eliminates the need to remove spent fuel modules from the transfer container upon arrival at the storage site.	1. Railcars must be refurbished or replaced after prolonged storage. 2. Requires the largest land area of the storage options, except for Kesselring. 3. Shipping containers are more expensive than immobile dry storage containers and water pools (water pools cost more when small fuel quantities are stored such as at Kesselring).
B. Storage on Concrete Pads	1. Eliminates the need to remove spent fuel modules from the transfer container upon arrival at the storage site. 2. Concrete pads are less expensive than railcar storage if railcars must be replaced or refurbished.	1. More container handling required compared to railcar storage option (if containers will not need to be removed from railcar). 2. Higher total cost than immobile dry storage containers and water pools* (*when large quantities of fuel are stored).

Table D-6 (Cont).

Storage Mode	Advantages	Disadvantages
2. Immobile Dry Storage Containers	1. Lowest total costs of all the storage options.	1. The maximum fuel loading concept requires that the containers be filled with

		water for cooling purposes for several years after removal from the reactor. This requires additional maintenance and slightly increases risk of low-level contamination spillage during accidents. 2. Must remove spent fuel from transfer container and load it into immobile container.
3. Water Pool Storage	1. Has a lower total cost than shipping containers, except for Pearl Harbor and Kesselring which have less containers. 2. Provides opportunity for conducting visual examinations.	1. Has the highest operating costs of all the storage options. 2. Must remove spent fuel from transfer container and load into water pool.

D.2 INSPECT HIGH PRIORITY FUEL AT PUGET SOUND NAVAL SHIPYARD

D.2.1 Introduction

This section of the attachment discusses the alternative of inspecting a limited amount of naval spent nuclear fuel at Puget Sound Naval Shipyard (hereafter referred to as Puget Sound) to provide information on nuclear fuel performance for use in the development of advanced nuclear reactors. The inspections would be performed at the shipyard's existing Water Pit Facility. The limited amount of fuel inspected would be stored at Puget Sound following inspection, and all other spent fuel would be stored in a facility at or near the refueling or defueling sites until the time that permanent geologic storage becomes available.

D.2.2 Water Pit Facility Description

The Water Pit Facility is located at the west side of Dry Dock 5, within the industrial zone of Puget Sound. This zone consists of facilities involved in ship construction and repair, dry docking, and conversions. The area is bounded by Decatur Avenue on the north, the waterfront on the south, the Naval Supply Center on the west, and the main gate on the east. The Water Pit Facility is located approximately 411 meters (1350 feet) from the nearest shipyard public property boundary. Figure D-8 illustrates the layout of the Water Pit Facility.

The Water Pit Facility was originally constructed to provide the shipyard with the capability to refuel nuclear-powered aircraft carriers, with the work for the first such refueling at Puget Sound expected to commence in approximately 2006. To date, the facility water pool has been used for refueling equipment demonstrations and testing.

Figure D-8. Puget Sound Naval Shipyard Water Pit Facility. The following key features of the Water Pit Facility are presented in terms of the facility's original aircraft-carrier refueling mission. Because of these design features, the facility is also considered suitable for limited naval spent fuel inspection operations.

1. A water pool for disassembly, assembly, and holding of fuel cells. The layout of the water pool is described below.
2. A work area for unpackaging, inspection, and preparation of new fuel clusters and associated equipment
3. An area for loading of shipping containers
4. A general use work area to support miscellaneous refueling support operations.

The Water Pit Facility is divided into two distinctive structures. The high bay structure is a radiologically controlled area containing the water pool and general work areas discussed above. This structure is designed to withstand the effects of design basis natural phenomena and of postulated failures of adjoining or adjacent structures without damage to the water pool or components in the water pool. The high bay walls are constructed of concrete to a height of 3.7 meters (12 feet) above ground level. The second structure is the Personnel Support Building which houses offices and other support areas. This structure is designed to meet the requirements of established naval facilities standardized criteria for structural design.

The water pool measures 7.3 meters (24 feet) wide x 20.4 meters (67 feet) long x 11.1 meters (36.5 feet) deep with a water depth of 10.5 meters (34.5 feet). It includes four work areas on each side of the pool at the east end to support refueling operations and a fuel holding area at the west end of the pool. Three of the four work areas are a nominal 2.1 meters (7 feet) x 2.1 meters (7 feet) and the fourth area is a nominal 2.6 meters (8.5 feet) x 2.1 meters (7 feet). The transfer aisle down the center of the pool is provided for all fuel and non-fuel movements. The water pool design includes provisions for isolation gates for each work area, for the fuel holding area, and for the dry pit. This isolation gate arrangement provides the capability to separate the various areas of the water pool if required. The dry pit, measuring 7.3 meters (24 feet) wide x 4.9 meters (16 feet) long x 11.1 meters (36.5 feet) deep, permits expansion of the water pool as needed.

D.2.3 Limited Inspection Operations

If future naval spent fuel examinations could not be accomplished at current capacity, the capacity which was available would be used to best advantage. Only naval spent nuclear fuel identified as having the greatest scientific value would be selected for detailed examination. Generally, this is spent nuclear fuel which is the first of a kind design or which has a characteristic of special interest.

Naval nuclear-powered ships would continue to be refueled and defueled at various shipyards across the country. Most of the spent fuel would be stored in a facility at or near the refueling and defueling sites until the time that permanent geologic storage becomes available. Those few fuel cells identified as high priority would be transported by railcar to Puget Sound in standard shielded shipping containers. Following its receipt in the Water Pit Facility's railcar work area, a shipping container would be prepared for fuel cell removal (dust cover removed, leveled, filled with water, containment installed, access plug removed). The fuel cells would be removed from the shipping container, one at a time, and transferred to the water pool in a shielded transfer container. The cells would be discharged into the pool and placed in the holding racks to await examination work. Upon completion of examination work, the spent fuel would be stored at Puget Sound as described in Section D.1. Storage facilities would have to be designed and certified to accommodate module sections resulting from spent fuel examinations as well as intact modules.

The following major items of water pool equipment (or equivalent) are considered necessary to support a high-priority naval spent nuclear fuel examination program. Also necessary are the relatively small and portable cameras and light sources for visual inspections. This equipment would support those spent fuel examinations currently performed in the ECF water pools at INEL as described in Section B.4.1 of Attachment B and summarized below.

EQUIPMENT ITEM	PURPOSE	FLOOR SPACE REQUIRED
Bandsaw/	Remove non-fuel structurals above & below fuel region	46.4 m2 (500 ft2)
Upender	to provide access for inspection and to rotate cells between vertical and horizontal orientations	8.2 m x 5.6 m (27 ft x 18.5 ft)
Universal	Measure fuel cell dimensions	7.5 m2 (81 ft2)

Inspection Station		2.7 m x 2.7 m (9 ft x 9 ft)
Vertical Inspection Gage	Trace contour of surfaces of fuel cell assemblies and control rods	16.7 m2 (180 ft2) 3.0 m x 5.5 m (10 ft x 18 ft)
Milling Machine	Section fuel cells into subassemblies, preassemblies, and elements for other examinations	11.1 m2 (120 ft2) 3.7 m x 3.0 m (12 ft x 10 ft)

Based on floor space requirements, the Water Pit Facility water pool and dry pit could not accommodate spent nuclear fuel examinations without removal of work area partition walls and without removal of the aircraft carrier refueling equipment. As a result, Puget Sound would no longer have the capability to refuel nuclear-powered aircraft carriers. Expansion of the Water Pit Facility to accommodate simultaneous refueling and examination operations is undesirable due to the proximity of other shipyard facilities.

Puget Sound does not have a shielded cell examination capability. Two options were considered for implementing such a capability:

1. Transfer fuel sections from Puget Sound to a shielded cell facility at another Naval Reactors site such as the Knolls Atomic Power Laboratory near Schenectady, New York, or the Bettis Atomic Power Laboratory near Pittsburgh, Pennsylvania. This would require additional shipments of spent fuel sections across the country. The spent fuel would be transported in shipping casks which would have to be certified for this purpose.
2. Construct shielded cells at Puget Sound. These cells would necessarily be sited some distance from the Water Pit Facility since sufficient space is not available either within the facility or adjacent to it in the industrial zone of the shipyard. In addition, a means of transferring items for examination between the water pool and the shielded cells would have to be implemented. Shielded cask movements via truck and cart movements via underground tunnel are two possible means of transfer. This option is undesirable because it involves construction of a new facility but does not provide direct communication between the water pool and shielded cells.

Based on the above discussion, the alternative of examining a limited amount of naval spent nuclear fuel would include a full range of water pool visual and dimensional inspections at the Puget Sound Water Pit Facility and a full range of shielded cell examinations at another Naval Reactors site. This alternative would therefore include all INEL-ECF capabilities as described in Sections B.4.1 and B.4.3 of Attachment B.

D.2.4 Advantages and Disadvantages of this Alternative

Advantages

1. Portions of the naval spent nuclear fuel examination program could be moved from INEL-ECF without having to construct new facilities. A full range of water pool inspections could be accomplished at Puget Sound. A full range of shielded cell examinations could be accomplished at another Naval Reactors site.

Disadvantages

1. The small size of the water pool complicates placement of inspection equipment. As a result, the equipment would be limited in nature and would require removal of water pool work area partition walls and removal of aircraft carrier refueling equipment. As a result, Puget Sound would no longer have the capability to refuel nuclear-powered aircraft carriers.
2. Transferring items for examination between the water pool and shielded cells would involve additional spent fuel shipments across the country and would require design and certification of a container for this purpose.

D.2.5 Facility Support Systems

The systems which were intended to support the aircraft carrier refuelings will also support the limited naval spent fuel inspection efforts. These include the water pool fluid systems, the heating and ventilation systems, and the normal and emergency electrical power systems.

D.2.6 Radiation Sources

The primary sources of radiation in the Water Pit Facility would be the spent fuel and the associated irradiated components which are handled during inspection operations. Radiation results from the fission products which reside in the fuel region of the depleted clusters and are contained by the fuel cladding. The cladding around the fuel region would not be penetrated by any fuel cell cutting or sectioning operation in the Water Pit Facility. Irradiated non-fuel components are also sources of radiation, as are corrosion products which reside on all external surfaces. Handling operations could cause some of the corrosion products to become detached from the surfaces. Therefore, in addition to direct radiation, contamination must be considered in the control of radiation sources.

The water pool water is treated by the filtration and purification system to maintain the waterborne radioactivity as low as reasonably achievable, typically less than 1 x 10-6 microcurie Co-60/ml. This level of activity is below the concentration limit in 10CFR20, Attachment B, Table 2 for liquid effluents released to the general environment. The vessels and piping in the filter system then become potential radiation sources. The water must be considered a source even though its radiation level will be very low. The waterborne radioactive material causes equipment in the pools to become radiation sources, the water pool floor to become contaminated, and a radioactive scum ring to form on the walls of the water pool at the water surface. Even considering all of these sources contributing to the ambient radiation level in the water pool area, the controls which are exercised will ensure that the overall source is minimal and the occupational exposure remains as low as reasonably achievable.

There would normally be no airborne radioactivity generated by the handling of the cells in the water pool. However, very low levels of airborne activity (approximately 1 x 10-12 microcurie Co-60/ml) have been detected near the surfaces of other water pools. This level of activity is below the concentration limit in 10CFR20, Attachment B, Table 2 for airborne effluents released to the general environment. The presence of even low-level airborne contamination will eventually lead to the ventilation system ductwork and HEPA filters becoming sources of radiation. This would occur over a very long period of time and the radiation levels would be controlled to a very low level. As noted above, the controls which are exercised will ensure that the occupational exposure remains as low as reasonably achievable.

D.2.7 Radiological Protection Features

The facility is designed to protect workers and the general public from radiological risk. Controls are such that workers receive much less than the allowable limits for radiation and radioactivity. The ventilation system is designed to mitigate the consequences of an accidental release of radionuclides within the Water Pit Facility building and to limit the atmospheric release at the stack. The double-walled (reinforced concrete, stainless steel liner) water pool is designed to prevent leakage under design earthquake force loading conditions. The radioactive fluid systems will maintain zero liquid discharge to the environment during Water Pit Facility operations.

D.2.8 Estimated On-Site Dose Assessment

The occupational radiation exposure for workers performing limited spent fuel inspections in the Water Pit Facility is expected to be consistent with that of ECF workers performing similar operations at INEL. As discussed in Section 5.2.12.1, radiation exposures to ECF workers at INEL have averaged approximately 100 mrem per year. The person-rem per year for the Water Pit Facility will vary with the manning level which is dependent on the spent fuel inspection activity occurring in the facility. However, the maximum manning level is anticipated not to exceed 60 people.

D.2.9 Seismic Design

Structural loadings due to seismic activity were determined as follows. Building floor response spectra for the horizontal and vertical directions were obtained from a three-dimensional damping mass spring model of the high bay which included soil-structure interaction, subjected to a 0.35 g ground acceleration value resulting from the seismic design analysis. The high bay superstructure and substructure were analyzed using the floor response spectra in separate finite element computer models. The superstructure model was subjected to structural loads which included a 113.5-metric ton (125-ton) load lifted by the large overhead crane. The combined forces of these loads with the seismic loads were applied to the substructure model at the column base plate locations. The substructure model was subjected to the design earthquake response spectra. This method was repeated for other combinations of structural loads with wind or tornado loads. Members were checked and designed for the maximum stress from any of the loading combinations. In addition, the water pool is designed to contain the pool water under design earthquake force loading conditions.

ATTACHMENT E - DESCRIPTION OF RECEIPT, HANDLING, AND EXAMINATION OF

NAVAL SPENT NUCLEAR FUEL AT ALTERNATE DOE FACILITIES

TABLE OF CONTENTS

LIST OF FIGURES

ATTACHMENT E

DESCRIPTION OF RECEIPT,
HANDLING, AND EXAMINATION OF NAVAL SPENT
NUCLEAR FUEL AT ALTERNATE DOE FACILITIES

E.1 DISCUSSION

This attachment describes the options for establishing new or modified facilities that essentially duplicate the capabilities of the existing Expended Core Facility (ECF) at the Idaho National Engineering Laboratory (INEL). Also discussed herein are the differences from the existing facility, which is described in detail in Attachment B.

The capabilities of the ECF at INEL include detailed examinations of spent nuclear fuel from naval reactors and test specimens from the Advanced Test Reactor (ATR) at the INEL Test Reactor Area. It would be possible to provide ECF capabilities at an alternate DOE facility (Savannah

River Site, Hanford Site, Oak Ridge Reservation, or Nevada Test Site) by constructing an entirely new facility. At Savannah River or Hanford, ECF capabilities could also be provided by modifying an existing facility. The preferred locations for siting an ECF at Savannah River, Hanford, Oak Ridge, and the Nevada Test Site are described in Sections 4.3.1, 4.4.1, 4.5.1, and 4.6.1, respectively. The main advantage of new construction is that the facility can provide all capabilities currently available at the ECF at INEL without limitations. The new construction water pool and shielded cell complex would be constructed in such a manner as to duplicate, as much as possible, the capabilities of the ECF at INEL. The existing ECF is highly capable, having been designed to accomplish the tasks required by the Naval Nuclear Propulsion Program. Key disadvantages of new construction, however, are high cost and the time necessary to initiate and complete construction.

Modification of an existing facility at Savannah River or Hanford which has at least some of the features that are required in a functional ECF would enable reductions in cost and time to achieve full capability, depending on how many facility modifications are required. A disadvantage, however, is that some of the methods currently in use at the ECF at INEL may also require modification to effectively and promptly utilize an existing facility, and such modifications may compromise the capabilities of the examination facility. The existing facility that can be made a part of the Savannah River Site is the Barnwell Nuclear Fuel Plant (hereafter referred to as the Barnwell Plant) which is unused and available following acquisition from its present private corporate owners. The existing facility on the Hanford Site is the Fuels and Materials Examination Facility (FMEF) which is unused and available immediately. Sections E.2 and E.3 describe the modifications to existing facilities or to current processes that would be needed to provide the complete range of ECF capabilities at the Barnwell Plant and the FMEF. Section E.4 provides a discussion of how naval spent fuel and test specimen examination work would proceed through the interim period as this work is being transferred from the ECF at INEL to the ECF location at the alternate DOE facility.

Receipt and handling of naval spent fuel at the new ECF location at the alternate DOE facility would be similar to receipt and handling of spent fuel at the ECF at INEL as described in Section B.2 of Attachment B. Following all examinations at the new ECF, most of the spent fuel would be loaded in the water pool into shipping casks for transport to the long-term fuel storage location at the same DOE facility. The spent fuel would remain at this location until the time that ultimate disposition is possible.

The new ECF would also duplicate the capabilities of the ECF at INEL with respect to the assembly, disassembly, and examination of ATR irradiation test specimens.

E.2 USE OF THE BARNWELL PLANT AT SAVANNAH RIVER

FOR ECF WORK

The Barnwell Plant is not owned by DOE but could be acquired and incorporated into the Savannah River Site property. It has a water pool complex with about 433 square meters (4660 square feet) of surface area (see Figure E-1) that can be utilized with minor modifications to perform unloading of naval fuel transport casks in a manner virtually identical to that employed at the ECF at INEL. An overhead crane running the length of the water pool would have to be added. However, providing naval spent nuclear fuel and test specimen examination capabilities comparable to the ECF at INEL would entail an expansion of the Barnwell Plant water pool to at least two times its present size. The design of the Barnwell Plant facility provides for such an expansion in an easterly direction while the existing water pool remains functional in a reduced capacity mode.

Figure E-1. Plan view of the Barnwell Plant Fuel Receiving and Storage Station. It is envisioned that the full ECF shielded cell capabilities could be provided at the Barnwell Plant using a combination of the three remote maintenance cells and the eight sample and analytical cells. Material would be transferred from the water pool to the remote maintenance cells via a conveyor. The crane equipment maintenance gallery and the upper level of the remote process cell are connected by a shielded door; these cells are connected to the remote maintenance and scrap cell below by hatches (see Figure E-2). Additional work stations (viewing window and manipulator ports) would have to be added to service these cells. The remote maintenance cells are connected to the sample and analytical cells above via a waste chute which would have to be upgraded to improve transfer capability between these cell areas. Methods would have to be developed for material movement from one shielded cell elevation to another. The combined length of the ECF shielded cells at INEL is less than 57.9 meters (190 feet). The combined length of the Barnwell Plant remote maintenance cells and sample and analytical cells is greater than 67.1 meters (220 feet), so that sufficient cell work space should be available. There are also five contact maintenance cells available, although at present they have no workstations and are not connected to each other, to any other cell area, or to the water pool. An alternative to the Barnwell Plant water pool expansion would be to use the contact maintenance cells for some of the operations presently performed in the ECF water pool at INEL. Varying amounts of existing equipment and piping in the Barnwell Plant shielded cells would have to be removed and disposed.

Once modified, the Barnwell Plant would provide the full range of water pool and shielded cell examination capabilities. However, the arrangement of the cells in the fuel handling area could make material movement within the facility more difficult than material movement at the ECF at INEL. As a result, throughput in the Barnwell Plant could be adversely affected.

E.3 USE OF THE FUELS AND MATERIALS EXAMINATION FACILITY

AT HANFORD FOR ECF WORK

The FMEF on the DOE Hanford Site in Washington currently has a large shielded cell complex that is suitable for ECF-type shielded cell operations with several modifications. Those modifications primarily entail the logistics associated with installing the equipment in the cells and transporting items for examination to and from this equipment.

Figure E-2. Elevation looking north in the Barnwell Plant fuel handling area.

At present, there is no water pool at FMEF. One means of providing this portion of ECF capabilities would be to establish a dry cell facility. The FMEF main process cell, decontamination cell, and upper process cell were evaluated for such a facility (see Figure E-3). Conceptually, material would be transferred from shielded casks in the shipping and receiving crane bay into the decontamination cell via a ceiling port. At present, there are only small penetrations between the decontamination cell and main process cell; this would have to be upgraded to facilitate material transfer. The combined surface area of the three cells is about 706 square meters (7600 square feet), compared to at least 866 square meters (9320 square feet) for the conceptual expanded Barnwell Plant water pool discussed previously. This suggests that the full ECF water pool capabilities could not be provided in the dry cell facility. In addition, one or more of the process cells is intended for inclusion in the shielded cell complex (see next paragraph). Removal of decay heat from spent fuel and irradiation test specimens in temporary dry storage would have to be evaluated. It is concluded that duplication of ECF spent fuel and test specimen examination capabilities at FMEF would require construction of a new water pool at least two times the present size of the Barnwell Plant water pool. The location of the pool and the means for transferring items between the pool and the shielded cell complex would have to be evaluated.

It is envisioned that the full ECF shielded cell capabilities could be provided at FMEF using a combination of the main process cell and the 14 process support cells. The main process cell is connected to the process support cells below by hatches (see Figure E-3). There appear to be sufficient workstations (viewing window and manipulator ports) servicing all cells. Methods would have to be developed for material movement from one shielded cell elevation to the other. The combined length of the FMEF main process cell and process support cells is greater than 76.2 meters (250 feet), so that sufficient cell work space should be available. The decontamination cell and upper process cell would be available in support of shielded cell operations. The FMEF shielded cells are essentially empty.

Once modified, the FMEF would provide the full range of water pool and shielded cell examination capabilities. However, the arrangement of the cells in the fuel handling area and the separation of the water pool and shielded cells would make material movement within the facility more difficult than material movement at the ECF at INEL. As a result, throughput in the FMEF could be adversely affected.

E.4 INTERIM OPERATIONAL PERIOD

Figure E-3. FMEF fuel handling area.

A transitional period will exist between the date that the Record of Decision is issued and the date that the alternative selected can be fully implemented (unless the selected alternative maintains ECF operations at INEL). This transition period would be approximately 6 years. If it is desired that all ECF work be completely transferred to an alternate DOE facility, then actions would have to be taken to minimize the disruption in examination capability for naval spent nuclear fuel and ATR test specimens. This section discusses how this will be accomplished if the alternate DOE facility option is selected in the Record of Decision.

The Barnwell Plant would have to be acquired by the DOE from its present private corporate owners. It is estimated that less than $800 million in acquisition, modification, and construction costs would complete the Barnwell Plant for ECF usage.

The FMEF at Hanford is already owned by the DOE but it appears to require a greater amount of design effort to be a fully functional ECF since a large water pool would need to be constructed and tied in to the shielded cell complex in order to initiate fuel receipt. It is estimated that less than $800 million in modification and construction costs would complete the FMEF for ECF usage.

During the transitional period between the Record of Decision and full implementation of the selected alternative, shipments of naval spent nuclear fuel to the ECF at INEL would continue, pending construction of storage and examination facilities at the new site. All naval spent nuclear fuel would then be transferred to the new site.

ATTACHMENT F

ANALYSIS OF NORMAL OPERATIONS AND ACCIDENT CONDITIONS

This attachment presents estimated environmental consequences, event probabilities, and risk (a product of probability and consequence) for both normal operations and postulated accident scenarios related to the storage and examination of naval spent nuclear fuel. Normal operations and accidents are evaluated to estimate the potential for releases of both radioactive material and toxic chemicals. The results of these analyses are presented in terms of the health effects to facility workers and the public predicted due to the release of radioactive materials and toxic chemicals into the environment. Effects on environmental factors are also presented, based on the amount of land which could be impacted due to postulated accidents.

Analysis results are presented for several different Department of Energy (DOE) and naval shipyard locations which are being considered as alternative sites for future naval spent nuclear fuel storage and examination. The DOE facilities evaluated include the Idaho National Engineering Laboratory (INEL), Savannah River Site, Hanford Site, Nevada Test Site, Oak Ridge Reservation (hereafter referred to as Oak Ridge), and Kenneth A. Kesselring Site. Puget Sound Naval Shipyard, Pearl Harbor Naval Shipyard, Norfolk Naval Shipyard, and Portsmouth Naval Shipyard have also been evaluated for naval spent nuclear fuel operations.

SUMMARY

Analyses of normal operations and design basis and beyond design basis hypothetical accidents were performed to estimate the potential consequences due to release of radioactive materials and toxic chemicals. The analysis results for radiological operations have been summarized by the locations and alternatives being considered in the Environmental Impact Statement.

Historical Accidents

The Naval Nuclear Propulsion Program has an outstanding nuclear safety record. In over 4500 reactor-years of operation and more than 300 refuelings and defuelings of Naval reactors, there has never been a nuclear reactor accident, criticality accident, transportation accident, or any release of radioactivity having a significant effect on the environment.

Summary of Naval Spent Nuclear Fuel (SNF) Alternatives

Alternative	Description of SNF Activity
No Action	SNF retained at shipyards and Kesselring. Dry storage in containers only.
Decentralization No Examination	SNF retained at shipyards and Kesselring. Either dry containers or water pool storage would be used.
Decentralization Limited Examination	SNF retained at shipyards and Kesselring. Either dry containers or water pool storage would be used. Limited SNF shipments to Puget Sound Naval Shipyard for examination.
Decentralization Full Examination	All SNF shipped to INEL-ECF for examination. All SNF returned to origin for storage in either dry containers or water pools.
Planning Basis	SNF would be received, examined, and stored at INEL as in past years. The proposed dry cell facility would be completed at ECF.
Regionalization or Centralization	SNF would be received, examined, and stored at either INEL, Hanford, Savannah River, Nevada Test Site, or Oak Ridge.

Normal Operations

Table F-1 presents the estimated number of fatal cancers per year to the general population living within a 50-mile radius of each facility due to radiological releases from normal operations. The results in this table were calculated using the methods described in Section F.1.3. The number of fatal cancers is very low at all locations and for all alternatives.

The ISC2 computer code (EPA 1992b) was used to estimate the concentration of chemicals released during normal operations. The results show that for INEL, Hanford, Savannah River, the

Nevada Test Site, the Barnwell Plant, and Oak Ridge, no ambient air quality standards would be exceeded; therefore, no adverse effects are expected. Heating boilers and emergency diesel generators already exist at the Navy shipyard locations and thus selection of these alternate locations would not result in a measurable increase in emissions.

Hypothetical Accident Evaluations

Several hypothetical accidents were analyzed at each facility for each of the alternatives. The results are summarized in Tables F-2 and F-3. The results in these tables were calculated using the methods described in Section F.1.3. Both fatal cancers from the maximum foreseeable accident at each location and the most severe risk from a facility accident at each location are presented. Risk is defined as the product of the consequences of an event multiplied by the probability of that event. The risks associated with the accidents analyzed have not been added together in order to avoid creating the impression that all risks have been calculated. The risks presented in this appendix cover the complete range of accidents which might make a detectable contribution to overall risk and additional analyses would not be expected to result in increases in calculated risk. The facility accident which results in the highest risk is a drained water pool at INEL, Hanford, Puget Sound, Portsmouth, and Kesselring. For Savannah River, Pearl Harbor, Norfolk, the Nevada Test Site, and Oak Ridge, an airplane crash into a dry storage area or a dry cell facility results in the greatest risk. As was the case for the normal operations evaluation, the accident risk is very low at all locations and for all alternatives.

Table F-4 presents a summary of the risk of fatal cancers by alternative for normal operations and most severe facility accident for each alternative. Consistent with the detailed tables, this summary table shows that all alternatives and all locations associated with spent fuel examination have very low risk.

Tables F-5 through F-8 present a summary by alternative of the impacts from all naval spent nuclear fuel facility radiological accidents which were analyzed.

A shipping accident in Puget Sound, at a location in the shipping lane approximately 2 miles from Seattle, was also analyzed using the methods described in this Attachment. This hypothetical accident results in a fire onboard the ship which involves spent nuclear fuel shipping containers. When compared to the facility accidents analyzed at Puget Sound Naval Shipyard, this shipping accident has a slightly lower risk of fatal cancers than the most severe facility accident at the shipyard.

The EPI computer code (Homann 1988) was used to estimate the concentration of chemicals released in the event of two postulated accident conditions. One postulated accident involved a chemical spill and fire at ECF and the alternate DOE sites and the other postulated accident involved a diesel fuel fire at ECF, the alternate DOE sites, and the shipyard locations. The chemical

Table F-1. Number of fatal cancers per year from normal operations (fatalities per year to general population located within 50-mile radius of site).

concentrations were then compared against Emergency Release Planning Guide (ERPG) levels as a means of evaluating their effects. ERPG values are specific for each substance and provide an estimate of the airborne concentration thresholds above which one can reasonably observe adverse effects. Exposure to an ERPG-1 level could result in a very mild effect whereas exposure to an ERPG-3 level could result in a life-threatening health effect. For the postulated accident involving a chemical spill and fire, on-site personnel (worker) could be exposed to concentrations of hydrochloric acid, phosgene, sulfuric acid, and sodium hydroxide above ERPG-3 levels which indicates a potential for long-term health effects. However, no member of the general public located off-site would be expected to be exposed to levels above ERPG-3 except for Oak Ridge where sulfuric acid and sodium hydroxide concentrations could exceed ERPG-3. For the postulated accident involving a diesel fuel fire, on-site personnel could be exposed to concentrations of sulfur dioxide and oxides of nitrogen above ERPG-3 levels. No member of the general public located off-site would be expected to be exposed to levels above ERPG-3 except for Oak Ridge where sulfur dioxide and oxides of nitrogen concentrations could exceed ERPG-3 and one shipyard location (Norfolk) where nitric oxide concentrations could exceed ERPG-3 under severe meteorological conditions. However, for both postulated accidents, the accident analyses did not include evacuation of on-site or off-site personnel and it is expected that chemical exposures would be below ERPG-3 levels because actions such as evacuation would be used to reduce the effects on the public and workers.

Fugitive Dust Analysis

The FDM computer code was used to estimate the fugitive dust concentrations that could result from the construction of a water pool facility at the alternate locations. It was determined that the release of fugitive dust would not result in any adverse effects for any of the alternate locations.

Other Impacts

The radiological impact of accidents on the environs of a facility was determined by examining the area that could be contaminated following such an event. Calculations using average meteorological conditions were performed for each accident scenario. These calculations determined the extent of the contamination which causes only a small increase in background radiation from naturally occurring sources. For most facilities and most accidents, the contaminated area was confined to the boundaries of the site. For a few cases, the casualty scenarios did result in contaminated land outside the site boundaries; however, the total land contaminated for those scenarios (inside and outside the boundary) was no more than 207 acres. The impact of this contamination would be temporary while the area was isolated and remediation efforts completed.

F.1 RADIOLOGICAL ISSUES FROM NAVAL SPENT NUCLEAR FUEL

INSPECTIONS AND STORAGE

Naval spent nuclear fuel is currently examined and stored at the Naval Reactors Facility's Expended Core Facility (ECF) at the DOE Idaho National Engineering Laboratory (INEL). The INEL-ECF is a large laboratory facility used to receive, examine, and ship naval spent nuclear fuel and irradiated test specimen assemblies. Enclosed work areas at INEL-ECF include an array of interconnected reinforced concrete water pools which permit visual observation of naval spent nuclear fuel during handling and inspection while shielding workers from radiation. Adjacent to the water pools are shielded cells used for operations which must be performed dry. One of the water pools contains transfer canals that will link the water pools with a proposed Dry Cell Project, which would provide a location for preparation of spent fuel in a dry, enclosed environment.

The proposed Dry Cell Facility will consist of a shielded, radiologically controlled area built of structural steel and concrete with remotely operated equipment necessary to examine fuel modules.

The Organization for Economic Co-operation and Development (OECD) of the Nuclear Energy Agency (NEA) reported that extensive safety analysis has shown that pool storage of Zircaloy-clad fuel is a very safe option which can last for decades (NEA 1993). The external hazards, such as earthquakes and aircraft crashes, are potential threats for these facilities (loss of coolant) but appropriate siting, design, and additional shielding can cope with these hazards. Dry storage has not yet generally been carried out on a very large scale but it is anticipated that long-term storage in adequate canisters is a very safe practice even against earthquakes and aircraft crashes.

Several technologies are being used currently for the storage of spent fuel at reactor sites and at sites away from reactors. Both wet (pool) storage facilities and dry storage facilities (buildings and containers) are used on a commercial scale.

The safety of spent fuel storage has been extensively evaluated. The U.S. Nuclear Regulatory Commission (NRC) reported in the "Waste Confidence Decision" of 1984 that there is reasonable assurance that spent fuel can be stored safely and without significant environmental impact in reactor pools or in spent fuel storage installations (NUREG 1984). For both dry storage and wet storage, the NRC stated its belief that current storage technologies are capable of providing safe storage for at least 30 years beyond the active lifetime of the reactor facility. The NRC also concluded that the possibility of a major accident or sabotage at a spent fuel storage facility with radiological consequences for the public is extremely remote.

Considerable experience has been gained in the transport of spent fuel elements and in the consequent safety-related development of suitable transportation casks. This experience has made it possible to develop a concept for dry storage of spent fuel elements within transportation casks; dry storage containers generally have not been the transportation casks themselves.

The concept of a cask which could be used for both transportation and storage has been licensed in the United States in the framework of a policy of dry storage in Independent Spent Fuel

Storage Installations (CFR 1993). According to this policy, the reactor operators are entitled to store the spent fuel elements, which have cooled in a pool for at least one year after discharge from the reactor, in specially licensed containers under dry conditions for 20 years or more. A number of storage casks have received official approval for that purpose.

F.1.1 Normal Operations

Current practice for examination of naval spent nuclear fuel at ECF includes removal of upper and lower non-fuel bearing structures, visual examination, measurement of key dimensions, collection of specimens, and loading into a shipping cask. Temporary storage of spent fuel at INEL-ECF is required since fuel is, at times, received into the facility faster than it can be examined and shipped out of the facility. In addition, a small amount of spent fuel is selected for retention as library specimens for future reference and examination. Routine releases to the atmosphere were evaluated at all locations based on measured releases from INEL-ECF. Each location was evaluated using releases equivalent to those of INEL-ECF. Each location's specific population and meteorology were then used to produce estimated consequences.

F.1.1.1 Water Pool Storage. Wet storage is a highly developed technique and it is the standard

method used worldwide for storage of spent fuel. While in wet storage pools, temperatures, pressures, and radiation fluxes are lower than in the reactor, so there is no intrinsic driving force for the sudden release of a major fraction of the radioactive materials contained in the stored spent fuel.

The Zircaloy cladding of naval spent nuclear fuel is an efficient barrier against fission product release during handling and storage of spent fuel. Given adequate control of water purity, Zircaloy resists corrosion in water during the long-term storage conditions of fuel assemblies. At the end of its service life, the fuel is covered with a tightly adhering oxide layer formed at high temperatures which is a major factor that inhibits further corrosion during storage.

Direct exposure to radiation of persons working in storage facilities can occur during such activities as handling of fuel casks and fuel assemblies, handling of contaminated filters, and repair and maintenance work. Experience shows that, in common with other fuel cycle facilities, the risk of increased occupational exposure arises when any maintenance or unusual operations are carried out. Such increased exposures can, however, generally be minimized by good planning, adequate redundancy of critical components, paying particular attention to the design of those items that are liable to become contaminated from the point of view of repair and maintenance, and by the use of local shielding and equipment decontamination procedures. Systems and components that are important in this context include:

- pool water cooling and makeup systems;
- filter equipment for purification of pool water;
- ventilation systems;
- equipment for temperature, water level, and leakage measurement in the fuel pools;
- hoists and handling systems for fuel assemblies; and
- equipment for handling and storage of other wastes.

Shielding from radiation is normally assured by providing a minimum depth of water above the fuel elements in storage to reduce the exposure rates. Fuel transfer mechanisms have limit switches and mechanical stops to prevent the inadvertent raising of fuel to the water surface. A high-integrity pool structure is needed in order to guarantee adequate containment of the pool water, but a limited loss of water resulting in a substantial reduction of the shielding layer is unlikely to involve high risks of exposures to personnel above operational limits since adequate countermeasures can be taken in time.

Storage of naval spent nuclear fuel in water pools is an alternative being evaluated at all DOE and Navy shipyard locations discussed above. Source terms for all locations were based on actual releases reported by INEL-ECF in the past. Exposures due to downwind dispersion, water release, and direct radiation were calculated.

F.1.1.2 Dry Storage. Many thousands of spent fuel assemblies of different types have been stored for

periods of time ranging from a couple of years to over 30 years in more than 20 different dry storage facilities. In general, the spent fuel behavior during storage has been excellent and no detrimental effects of dry storage on the integrity of the spent fuel have been detected (NEA 1993).

The dry storage of spent fuel is being used to a limited extent in several countries. In the United States, fuel was stored in dry wells at the INEL. Dry wells were used for the storage of a small amount of fuel at the Nevada Test Site as part of a large dry storage demonstration program. Storage started at the Climax deep dry wells (600 meters below the surface in granite) in 1979. In 1983, one fuel assembly underwent extensive non-destructive and destructive characterization. No problems requiring process changes were identified (NEA 1993).

Designs of metal casks for use in spent fuel storage have been in existence since the late 1970s. The casks are generally equipped with a double-lid system to ensure safe containment of contents. These casks have been subjected to a variety of tests and demonstrations since the early 1980s using both intact and consolidated fuel.

The DOE sponsored the demonstration of the storage of fuel in metal casks at the Morris storage facility in 1984 and 1985. The DOE entered into a cooperative agreement with Virginia Power, a United States' utility, to demonstrate the use of three types of metal casks. The Virginia Power Surry Nuclear Power Station has been licensed by the NRC for storage of spent fuel in metal casks.

Results of demonstration activities have shown the following (NEA 1993):

- radiation and thermal levels resulting from metal cask storage have been acceptable;
- no fuel failure has occurred during demonstration storage;
- no secondary wastes have arisen from the storage operation.

Storage of naval spent nuclear fuel in storage or shipping containers is an alternative being evaluated at all locations. Since no airborne releases are expected from routine dry storage activity, only the biological effects of direct radiation exposure to the on-site personnel and the public were determined.

F.1.1.3 Dry Cell Operations. The handling of naval spent nuclear fuel for research and development

purposes in dry cells like the proposed Dry Cell Project was evaluated at selected DOE locations. The health effects due to routine airborne releases and direct radiation exposure were estimated.

F.1.2 Screening/Selection of Accidents for Detailed Examination

Accidents were considered for inclusion in detailed analyses if they were expected to contribute substantially to risk (defined as the product of the probability of occurrence of the accident times the consequence of the accident). Accidents were categorized into three types as either Abnormal Events, Design Basis Accidents, or Beyond Design Basis Accidents. These categories are characterized by their probability of occurrence as described further in Section F.1.3.7. Construction and industrial accidents are included in these categories.

In selecting accidents to include in detailed analyses, several considerations were utilized. Initiating events were reviewed including natural phenomena (earthquakes, volcanic activity, tornadoes, hurricanes and other natural events) and human initiated events (human error, equipment failures, fires, explosions, plane crashes, transportation accidents, and terrorism). Guiding principles were established, such as: the radioactive materials involved must be available in a dispersible form; there must be a mechanism available for release of such materials from the facility; and, there must be a mechanism available for off-site dispersion of the released materials. The pathways whereby members of the public can be affected from the nuclear aspects of spent fuel operations are direct exposure to radiation, inhalation of radioactive materials, or ingestion of radioactive materials. Recognizing these fundamental processes and pathways, accidents involving the following basic phenomena were identified:

- loss of shielding of radioactive materials,
- release of radioactive products to the environment due to overheating of fuel,
- release of radioactive products to the environment due to mechanical shock or damage or inadvertent breaching of fuel cladding or containment,
- an unplanned criticality,
- transportation accidents.

After the basic phenomena were identified, other references were consulted to ensure that all important accidents were considered. These included safety analysis reports, court decisions, other environmental impact statements, and summary documents such as the "Final Generic Environmental Impact Statement on Handling and Storage of Spent Light Water Reactor Power Reactor Fuel" (NUREG 1979a) and "The Safety of the Nuclear Fuel Cycle" (NEA 1993).

Examining the kinds of accidents which could result in release of radioactive material to the environment or an increase in radiation levels shows that they can only occur if an accident produces severe conditions. Some types of accidents, such as procedure violations, spills of small volumes of water containing radioactive particles, or most other types of common human error, may occur more frequently than the more severe accidents analyzed. However, they do not involve enough radioactive material or radiation to result in a significant release to the environment or a meaningful increase in radiation levels. Stated another way, the very low consequences associated with these events produce smaller risks than those for the accidents analyzed, even when combined with a higher probability of occurrence. Consequently, they have not been included in the results presented in this Environmental Impact Statement.

Acts of terrorism are expected to result in consequences which are bounded by the results of accidents which were evaluated. Naval spent nuclear fuel is not considered to be attractive to terrorists due to the bulk of the fuel and containers and due to the high radiation fields involved with unshielded spent nuclear fuel. However, terrorist attacks on naval spent nuclear fuel during shipment were evaluated. The massive structure of the shipping containers used for naval spent nuclear fuel makes them an unlikely target of a terrorist attack. No such attacks have occurred in the nearly 40 years of rail shipments which have now travelled about 2 million kilometers. Thus, the probability of a terrorist attack on a shipment is judged to be no more than the probability of a rail accident which is listed in Section A.7.1.2.1 of Attachment A to Appendix D of this Environmental Impact Statement. The consequences of a terrorist attack are also judged to be no more severe than those listed for transportation accidents. Therefore, the same conclusions reached for transportation accidents apply to the risk to the extremely rugged shipping containers from terrorist attack during a shipment. In addition, during shipment, all naval spent nuclear fuel containers are accompanied by escorts who remain in contact with headquarters. In the event of an emergency, state and federal resources would be quickly summoned to stabilize the situation.

For an act of war, sabotage, or terrorist attack, it is likely the risk would be lower than calculated for the airplane crash because it should be less probable that a force would exist to disperse radioactive products into the atmosphere from a weapon as compared to the motive force of the fire assumed in the case of an airplane crash. For example, attacks on containers using anti-tank weapons would be less severe than the accidents analyzed because: (a) anti-tank weapons would cause a self-sealing penetration in the metal of a container, unlike that which is assumed from the airplane crash (impact from a 50-inch diameter engine rotor); (b) there is no explosive material inside the container, so it will not "blow up" as a tank would if hit by such a weapon (in a tank attack, the tank shells inside the turret detonate); (c) there would be no fire to disperse the radioactivity that is released when the container is breached, unlike an aircraft crash where the jet fuel will burn creating such a fire. The rugged design of containers and the thick walls of water pools, combined with the shock-absorbing nature of water with a free surface, reduce the effects of other types of explosive charges. It is not credible that a terrorist attack would result in a criticality or meltdown of spent nuclear fuel; however, in Section F.1.4.2.1.2, the consequences of a hypothetical criticality accident are presented. The risks associated with an accidental criticality are less than those associated with a drained water pool or an airplane crash into dry storage containers.

The effect of a terrorist attack or an act of sabotage is expected to be conservatively bounded by the limiting accident discussed at each facility under each alternative. For example, the most limiting accident involving naval spent nuclear fuel is described in this attachment to be an airplane crash into a shipping container at the Pearl Harbor Naval Shipyard. This accident would lead to 26 latent fatal cancers over the next 50 years in the population within 50 miles of the shipyard. Since the probability of the event is one chance in 100,000 per year, the risk would be 0.00026 latent fatal cancer fatalities per year or, in other words, about one chance in 4,000 of a single latent fatal cancer fatality over a year. This risk is shared among the approximately 820,000 people residing within 50 miles of the shipyard who would be expected to have over 2,000 cancer fatalities from all causes every year. For an act of war, sabotage, or terrorist attack, it is likely the risk would be lower than calculated because it should be less probable that a force would exist to disperse radioactive products into the atmosphere from a weapon as compared to the motive force of the fire assumed in the case of an airplane crash.

Accidents initiated at nearby facilities, by other activities unrelated to spent nuclear fuel handling or storage, or during construction of an ECF or dry cell type of facility, would not produce effects more severe than the sequences of events described. This is because naval spent nuclear fuel undergoing examination or in storage under the conditions of the alternatives evaluated would not need special conditions or uninterrupted operator attention to prevent overheating, failure of containment, or loss of shielding. Therefore, evacuation in response to an accident at some other facility would not compromise safety. This inherent safety, combined with the distance between naval spent nuclear fuel facilities and any other activities which might suffer a catastrophic accident, means that the accidents analyzed in this document produce conditions at a naval spent nuclear fuel facility which would be more severe than those for any hypothetical synergistic combination of events resulting from accidents at other, unrelated facilities. Therefore, such analyses have not been included in this evaluation.

The existence of common cause accidents at a facility has been considered. In general, only one spent nuclear fuel facility is located at a particular Navy site. However, it is possible for natural phenomena, like an earthquake, to produce more than one accident at some sites causing a situation resulting in the release of radioactive material into the atmosphere or an increase in radiation levels due to loss of shielding. However, the probability of two or more accidents having maximum consequences occur concurrently is less than the probability of the individual events. For example, if an earthquake affected the Naval Reactors Facility at INEL, a crane might fail causing damage to stored spent fuel, the water pool might drain, and shielding for the Dry Cell might be damaged. The impacts for this could conservatively be estimated by summing the consequences. A combined total of 2.8 x 10-2 fatal cancers are estimated. Similarly, consequences from spent nuclear fuel facilities within a DOE site could be combined to conservatively estimate site wide impacts. But again, the probability of a common cause event resulting in this number of consequences is lower than the probability of the individual accidents because the severity of impact will vary between facilities due to separation distances.

Several accident scenarios were developed for the handling and storage of naval spent nuclear fuel. All potential accidents were not evaluated, but cases which are considered to be more severe than all other reasonable accidents were analyzed. Each of these accident scenarios was evaluated at several locations using identical source terms. Like the evaluations for normal operations, population and meteorology data specific to each site were used to estimate site specific health effects.

F.1.2.1 Water Pool Storage. Six hypothetical accident scenarios were evaluated for naval spent

nuclear fuel stored in water pools. These hypothetical sequences of events include a drainage of the water pool caused by an earthquake, an accidental criticality, mechanical damage due to operator error or crane failure, an airplane crash into the water pool facility, a fire in a high efficiency particulate air (HEPA) filter, and minor water pool leakage. Radiation exposure to on-site individuals, an individual at the site boundary, and the general population was estimated for airborne releases of radioactivity, water releases, and direct radiation exposure.

F.1.2.2 Dry Storage. Two hypothetical accident scenarios were evaluated for naval spent nuclear fuel

stored in shipping containers. The first scenario postulates that a wind-driven missile crashes into storage casks, with mechanical damage causing a release of corrosion products into the environment. The second hypothetical scenario is based on an airplane crash into the dry storage area. Once again, radiation exposure to on-site individuals, an individual at the site boundary, and the general population was estimated for airborne releases, water releases, and direct radiation exposure.

F.1.2.3 Dry Cell Operations. Three hypothetical accidents were evaluated for naval spent nuclear fuel

handled in dry cells at several locations. These scenarios include cutting into the fuel region or mechanical damage during examination work, partial loss of concrete shielding due to an earthquake, and an airplane crash into the dry cell facility. Once again, radiation exposure to on-site individuals, an individual at the site boundary, and the general population was estimated for airborne releases, water releases, and direct radiation exposure.

F.1.2.4 Shipboard Fire Involving Shipping Containers. Attachment A describes the historical

practice of shipping naval spent nuclear fuel from Pearl Harbor Naval Shipyard to Puget Sound Naval Shipyard by ship where the containers are then transported to ECF by rail. Since 1962, there have been 17 shipments containing a total of 20 shipping containers. Even though there have not been any accidents involving these shipments, hypothetical accidents were evaluated near the Pearl Harbor and Puget Sound shipyards. The scenario involves a collision of the spent nuclear fuel ship with another ship which results in a fire. The radiation exposure to nearby individuals and the general population was estimated for airborne and water releases.

F.1.3 Analysis Methods for Evaluation of Radiation Exposure

F.1.3.1 General. An evaluation of normal operations and hypothetical accidents at the existing and proposed sites was performed to assess the possible radiation exposure to individuals due to the release of radioactive materials. The analyses are based on the same operations carried out at the different potential locations and the same accidents at any of the sites evaluated. With this approach, it is possible to compare the incremental effect of the proposed alternative actions or the different impacts of the postulated accidents at the different sites. These locations include four naval shipyards (Portsmouth, Norfolk, Puget Sound, and Pearl Harbor), five Department of Energy facilities (INEL, Savannah River, Hanford, Nevada Test Site, and Oak Ridge), and the Kesselring Site.

F.1.3.2 Exposures to be Calculated. Radiation exposure to the following different individuals and the general population is calculated for normal operation of the spent fuel facility and for accident conditions:

- Worker (Worker). An individual located 100 meters (330 feet) from the radioactive material release point. (The impact of accidents on close-in workers is not calculated numerically but is discussed qualitatively for each accident in Section F.1.4.3 of this attachment.)

- Maximally exposed collocated worker (MCW). At DOE locations, a theoretical individual located at whichever is the greater of 0.4 mile from the facility area boundary or 75% of the distance to the nearest independent facility area. The MCW is not evaluated if the site boundary is closer than the MCW location. Thus, at shipyard locations and the Kesselring Site, the MCW is not specifically evaluated.

- Maximally exposed off-site individual (MOI). A theoretical individual living at the DOE site or shipyard boundary receiving the maximum exposure. At the Savannah River Site, two separate MOI locations were evaluated depending upon whether the spent fuel facility is constructed on the Savannah River Site or is located at the existing Barnwell Nuclear Fuel Plant (hereafter referred to as the Barnwell Plant) which is adjacent to the Savannah River Site. At Hanford, two separate MOI locations were also evaluated depending upon whether a new facility is constructed in the 200 Area or modifications are made to the Fuels and Materials Examination Facility (FMEF) which is located in the 400 Area.

- Nearest public access individual (NPA). At larger DOE sites, highways used by the public may cross the federal reservation which includes the facility where naval spent nuclear fuel operations could be conducted. Consequently, these analyses included evaluation of the exposure to a theoretical motorist who might be stranded on such a highway at the time of an accident. Based on experience from emergency exercises, emergency response teams would be able to evacuate such an individual within 2 hours, so this was the exposure time used in the calculations. At naval shipyard locations, no public access highways exist, but military personnel, civilian employees, or their family members, including some who reside on the base, may be located outside the controlled industrial area boundary but inside the confines of the military base. Such personnel might be at their homes, in buildings, or on the roadways of the base at the time of an accident or at any time throughout the year for the evaluation of normal operations. The base residents are used as the NPA individuals at these shipyards for analyses of normal operations. In the event of a severe accident they would be evacuated within 2 hours under military control of the base, so this time was used in accident calculations. No NPA value was calculated for the Kesselring Site and the Nevada Test Site because there are no public roads which cross these sites, there are no residents, and there are no other public accesses.

- Maximally exposed individual at nearby communities is evaluated for accidents.
- General population within a 50-mile radius of the facility.

Exposure is calculated to result from direct radiation from the facility and exposure to radioactive contamination released to the air. Normal releases directly to the water pathway occur only at shipyards which are located directly on bodies of water, and contamination of the water at all sites results from fallout of airborne contamination. The releases to the air might result in exposure through several pathways described as follows:

- External direct exposure from immersion in the airborne radioactive material (air immersion)
- External direct exposure from radioactive material deposited on the ground (ground surface)
- Internal exposure from inhalation of radioactive aerosols and suspended particles (inhalation)
- Internal exposure from ingestion of terrestrial food and animal products (ingestion)
- Exposure from contaminated water (water release).

The radiation exposure is calculated by the computer programs discussed in Section F.1.3.6 in a manner recommended by the International Commission on Radiological Protection (ICRP 1977; ICRP 1979). Weighting factors are used for various body organs to calculate a "committed effective dose equivalent" (CEDE) from radiation inside the body due to inhalation or ingestion. Committed dose equivalents (CDEs) are calculated for organs such as the lungs, stomach, small intestine, upper large intestine, lower large intestine, bone surface red bone marrow, testes, ovaries, muscle, thyroid, bladder, kidneys, liver etc. The CEDE value is the summation of the CDEs to the specific organ weighted by the relative risk to that organ compared to an equivalent whole-body exposure.

The programs also calculate an effective dose equivalent (EDE) for the external exposure pathways (immersion in the radioactive material, exposure to ground contamination) and a 50-year CEDE for the internal exposure pathways . The sum of the EDE from external pathways and the CEDE internal pathways is called the "total effective dose equivalent" (TEDE) in this Environmental Impact Statement (EIS) and is also calculated by the programs. The TEDE reported in the results section is the sum of the TEDE's from air, water, and direct radiation exposures.

The exposure from ingestion of terrestrial food and animal products is calculated on a yearly basis. However, it is expected that continued consumption of contaminated food products by the public would be suspended after a Protective Action Guideline is reached. In 1991, the Environmental Protection Agency recommended protective action guidelines in the range of 1 to 5 rem whole-body exposure. To ensure a consistent analysis basis, no reduction of exposure due to a Protective Action Guideline was accounted for in the analysis. This would result in a conservative approach which may slightly overestimate health effects within an exposed population, but allows for consistent comparisons between alternatives.

Table F.1.3.2-1 identifies selected nearby communities for each site for which hypothetical exposures for a maximally exposed individual were calculated. In all cases, the MOI exposure was greater than maximum exposure at any nearby community. Calculations were performed for these localities to evaluate exposures for areas representative of the range of communities within 50 miles of the sites analyzed. The selection of these communities was not intended to indicate that other localities were not important. Other communities of interest in the vicinity of the sites in addition to those evaluated include a number of communities in Maine and New Hampshire near the Portsmouth Naval Shipyard, including Portsmouth, Durham, Eliot, Greenland, Kittery, New Castle, North Hampton, Ogunquit, Rye, and South Berwick.

Table F.1.3.2-1. Nearby communities for each site.

INEL	Howe, Atomic City, Arco, Blackfoot, Idaho Falls
Savannah River	Snelling, Barnwell, Jackson, Aiken, Allendale, Augusta, Sylvania, Bamberg, Wrens
Hanford	Othello, Richland, Prosser, Pasco, Yakima, Umatilla
Nevada Test Site	Beatty, Pahrump, Las Vegas
Oak Ridge	Oak Ridge, Harriman, Rockwood, Knoxville, Jefferson City
Puget Sound	Seattle, Tacoma, Olympia, Port Angeles
Pearl Harbor	Pearl City, Aiea, Pacific Palisades, Ewa Beach, Honolulu, Ewa, Wahiawa
Norfolk	Newport News, Hampton, Suffolk, Virginia Beach, Williamsburg
Portsmouth	Dover, Exeter, Hampton Beach, Sanford, Nashua, Lowell, Concord, Portland, Boston
Kesselring	Ballston Spa, Saratoga Springs, Amsterdam, Schenectady, Corinth

Table F.1.3.2-2 presents an example of the detailed exposure calculation results which were performed. The table shows the possible exposure pathways and individuals analyzed.

F.1.3.3 Evaluation of Health Effects. Health effects are calculated from the exposure results. The risk factors used for calculations of health effects are taken from Publication 60 of the International Commission on Radiological Protection (ICRP 1991). Table F.1.3.3-1 lists the appropriate factors used in the analysis of both the normal operations and the hypothetical accident scenarios.

Cancer fatalities were used to summarize and compare the results in this Environmental Impact Statement since this effect was viewed to be of the greatest interest to most people. As shown in Table F.1.3.3-1, the number of total health effects (deaths, non-fatal cancers, genetic effects, and other impacts on human health) may be easily obtained by multiplying the latent cancer fatalities by the factor of 1.46, which is the ratio of 7.3/5.0.

The numerical estimates of cancer deaths and other health detriments presented were obtained by the practice of linear extrapolation from the nominal risk estimate for lifetime total cancer mortality at 10 rad. Other methods of extrapolation to the low-dose region could yield higher or lower numerical estimates of cancer deaths. Studies of human populations exposed at low doses are

Table F.1.3.2-2. Summary of exposure calculation results.

Location	Inhalation CEDE (rem)	Air Immersion EDE (rem)	Ground Surface EDE (rem)	Ingestion EDE (rem)	Total Airborne Release EDE (rem)	Water Release (rem)	Direct Radiation (rem)	Total EDE (rem)	Likelihood of Fatal Cancer
Worker	5.4×10^{-1}	6.5×10^{-4}	7.9×10^{-1}	N/A	1.3	N/A	8.8×10^{-5}	1.3	5.3×10^{-4}

									Number of Fatal Cancers
Exposure to Population within 50-mile Radius (person-rem)									
Population of 115690	1.1 x 10-1	6.1 x 10-5	1.5 x 10-1	4.5 x 10-2	3.0 x 10-1	3.8	5.3 x 10-6	4.1 10-1	2.1 x 10-3

Table F.1.3.3-1. Risk estimators for health effects from ionizing radiation.

		Risk Factor (probability per rem)*	
Effect	Nuclide	Worker	General Population
Fatal cancer (all organs)	All	4.0 x 10-4	5.0 x 10-4
Weighted non-fatal cancer**	All	8.0 x 10-5	1.0 x 10-4
Weighted genetic effects**	All	8.0 x 10-5	1.3 x 10-4
Weighted total effects**	All	5.6 x 10-4	7.3 x 10-4

---

* For high individual exposures (y20 rem), the above risk factors are multiplied by a factor of two.
General population exposures were not modified because the large drop in exposure with increasing distances results in average exposure rates well below 20 rem.

** In determining a means of assessing health effects from radiation exposure, the ICRP has developed a weighting method for non-fatal cancers and genetic effects to obtain a total weighted effect, or "health detriment".

inadequate to demonstrate the actual level of risk. There is scientific uncertainty about cancer risk in the low-dose region below the range of epidemiologic observation, and the possibility of no risk cannot be excluded (CIRRPC 1992). In this appendix, the doses have been provided in all cases to allow independent evaluation using any relation between exposure and health effects.

F.1.3.4 Population. Population distributions specific to each site were used for the evaluations. The

population distributions were obtained from 1990 United States Census data. The population information was obtained in 16 compass directions and 5 equal radial distances from the likely location of a naval spent nuclear fuel site to a 50-mile total distance.

F.1.3.5 Meteorology. For the navy shipyards, Savannah River, and Kesselring Sites, the

meteorological data used in the analyses were obtained from the SCRAM bulletin board system. For the INEL, Hanford, Nevada Test Site, and Oak Ridge, site tower meteorological data were used. The SCRAM bulletin board is operated by the Support Center for Regulatory Air Models within the Environmental Protection Agency, Office of Air Quality Planning and Standards. The SCRAM surface meteorological data files are comprised of data acquired from the National Climatic Data Center. The SCRAM data for 4 or 5 years were used with programs from the bulletin board to develop meteorological data in the STability ARray (STAR) format which is a joint frequency distribution of 6 wind speed intervals, 16 wind directions, and 6 stability categories. The STAR data were reformatted into the format required by the GENII program, described below, for evaluation of normal operations.

The STAR data were also used to calculate the 50% and 95% meteorological conditions for the accident analyses. The 50% condition represents the average meteorological condition. This condition is defined as that for which more severe conditions with respect to accident consequences occur less than 50% of the time. The 95% condition represents the meteorological conditions which could produce the highest calculated exposures. This is defined as that condition which is not exceeded more than 5% of the time or is the worst combination of weather stability class and wind speed. Each of these conditions is evaluated for 16 wind directions.

For each location, the nearest available SCRAM data was used to represent the conditions at the site being evaluated. Table F.1.3.5-1 shows the pertinent data for the meteorological data application.

Table F.1.3.5-1. Meteorological data applicability.

Site	Data From	Data Years
Portsmouth	Portland ME Airport	1985-1989
Norfolk	Norfolk VA Airport	1985-1989
Puget Sound	SEATAC Airport	1985-1989
Pearl Harbor	Honolulu Airport	1985-1989
INEL	NRF Tower	1987-1991
Kesselring	Albany NY Airport	1985-1989
Savannah River	Augusta GA Airport	1984-1987
Hanford	200 Area Tower	1983-1990
Nevada Test Site	Desert Rock Tower	1990
Oak Ridge	Y-12 West Tower	1990

F.1.3.6 Computer Programs. Five computer programs were used to evaluate the radiation exposures

to the specified individuals and general population.

F.1.3.6.1 GENII. The code used for the environmental and transport and exposure assessment

calculations for normal operations was GENII (Napier et al. 1988). This code was developed at Pacific Northwest Laboratory by Battelle Memorial Institute to incorporate the internal dosimetry models recommended by the International Commission on Radiological Protection in Publication 26 (ICRP 1977) and Publication 30 (ICRP 1979) into environmental pathway analysis models in use at Pacific Northwest Laboratory.

Although GENII can be used to model both acute and chronic releases to the atmosphere, only the chronic option was used in the normal operations evaluation reflecting long-term average exposure to the released radioactive contaminants. For the chronic evaluations, the code also uses meteorological conditions averaged over each sector to reflect exposure to long-term average concentrations. The ingestion calculation used the modeling approach that exposed individuals within 50 miles of the site consumed 30% of milk products and 10% of all products grown locally where the people live.

F.1.3.6.2 RSAC-5. The computer code RSAC-5 was developed by Westinghouse Idaho

Nuclear Co, Inc., for the DOE-ID Operations Office and is in the public domain (Wenzel 1993). The code calculates the consequences of the release of radionuclides to the atmosphere. It allows the amount of each fission product nuclide from a nuclear event to be input individually or to be calculated internally by the code. RSAC-5 calculates potential radiation exposures to maximally exposed individuals or population groups via inhalation, ingestion, exposure to radionuclides deposited on the ground surface, immersion in airborne radioactive material, and radiation from a cloud of radioactive material. RSAC-5 meteorological capabilities include Gaussian plume dispersion for Pascal-Gifford conditions. RSAC-5 release scenario modeling allows reduction of nuclides by chemical group or element and calculates decay and buildup during transport through operations, facilities, and the environment. It also models the effect of filters or other cleanup systems. Population exposures are the product of the calculated individual exposure and the number of people in the affected population.

F.1.3.6.3 ORIGEN. ORIGEN (Croff 1980) is a computer code system for calculating the

buildup and decay of radioactive materials (fission products, actinides, and activation products). The code input was modeled to describe the naval nuclear fuel system and incorporates cross-section data that are distinct to naval fuels.

F.1.3.6.4 SPAN. SPAN (Wallace 1972) is the computer code which was used to calculate the

direct radiation levels. Attenuation from air was included in the calculated radiation levels. To determine the unit person exposure per sector, SPAN was used to integrate the radiation level over the sector. The radiation levels calculated at various distances were used as the source to represent the proper distance falloff in the sector, and a total radiation level for each sector was calculated. This total integrated radiation level for each sector was then divided by the sector volume, resulting in an "average" radiation exposure for any point within the sector.

F.1.3.6.5 WATER RELEASE. WATER RELEASE is an unpublished computer code used to

calculate exposures to humans arising from radionuclides which have been introduced into water in the vicinity of the proposed spent nuclear fuel storage and examination facilities. The following discussion provides a brief description of the key points associated with obtaining these estimates. All radionuclides which were considered to be introduced into the water at a site were postulated to be promptly distributed uniformly in the water in the immediate vicinity of the site during the time period in which the nuclides were introduced. There are two processes by which radionuclides might enter the water at each site: via liquid discharge or via airborne discharge. For liquid discharges, a fraction of the released radionuclides might enter the water accessed by humans each year by infiltrating the ground to the groundwater then traveling either to wells or surface water. For airborne discharges, some fraction of the released radionuclides might enter the water by deposition from the air. For both of these processes, the fraction of radionuclides that might enter the water used by humans has been postulated to enter the water immediately, except for NRF and the Nevada Test Site. For NRF and the Nevada Test Site, it has been postulated that 20 years pass before the nuclides might enter the water accessed by humans. This estimate is based upon the fact that water must percolate into the ground and reach groundwater resources. Further, contamination must travel with the water in the aquifer to a point where it can be used by humans, such as a well at Atomic City. An assessment of the infiltration rate of radionuclides beneath ICPP estimates that about 200 years are needed for them to pass into the aquifer (Smith 1994). Also, the water in the aquifer flows at a rate of 5 to 20 feet per day. Therefore, 20 years was used as the time for radionuclides to reach humans at INEL. Similarly, at the Nevada Test Site surface water is not present so water must reach aquifers which are more than 600 feet deep. Hence, 20 years was also used at this site.

Once the radionuclides have been introduced into the water at a site, they were calculated to be transported to locations where they might affect man either directly as via immersion (swimming) or indirectly as via ingestion of food. During this transport period, these radionuclides are subjected to various mechanisms which may reduce their concentration in the water such as radioactive decay, dilution in larger volumes of water, removal by sedimentation, etc. The pathways considered in this analysis by which radionuclides in the water at a site might reach man are immersion, exposure to surface deposits, boating and equipment exposure, and consumption of drinking water, fish, crustacea, molluscs, game animals, vegetables and fruits, root crops, milk and eggs, and domesticated animals. During the period when the radionuclides have left the water environment and are being transported through the pathways to man, they may be subjected to both concentration and removal mechanisms which will further modify their effect upon man. These mechanisms include concentration in the surface deposit, animal, and crop pathways; decay during periods between harvesting a crop and its ingestion by man; and removal of activity due to harvesting, handling, and cleaning of a foodstuff.

For each of the sites at which storage or examination of spent nuclear fuel is being considered, estimates were made for the exposures which the total population affected by releases from the site may receive and for the exposures which a maximally exposed individual may receive from these same releases. The exposures to the population affected at a given site were obtained by calculating the exposures received by an average individual in the vicinity of that site and multiplying that exposure by the number of people that are affected. The exposure to a maximally exposed individual used the maximum exposures and consumption rates which any individual at that site may experience regardless of the probabilities associated with just one individual actually following all the maximum pathways. The specific pathways which are applicable at a given site are dependent upon the site, since the exposure of an average or a maximum individual to each of the pathways is different for each of the sites. For example, exposures associated with the drinking water pathway are not considered for the shipyard sites since all radionuclides basically end up in salt water prior to their becoming available to man at these sites. On the other hand, the radionuclides introduced at the DOE and prototype sites can enter the drinking water pathway after a delay period. An initial delay occurs while the radionuclides seep through the ground soil before entering the aquifer. The delay continues while the radionuclides travel through the drinking water pathway and ultimately yield exposures to man. The total exposure to the population or to a maximally exposed individual at a given site is the resultant sum of the exposure commitments from the individual pathways applicable at that site.

F.1.3.7 Categorization of Accidents.

F.1.3.7.1 Abnormal Events. Abnormal Events are unplanned or improper events which result

in little or no consequence. Abnormal events include industrial accidents and accidents during normal operations such as skin contamination with radioactive materials, spills of radioactive liquids, or exposure to direct radiation due to improper placement of shielding. The occurrence of these unplanned events has been anticipated and mitigative procedures are in place which promptly detect and eliminate the events and limit the effects of these events on individuals. As a result, there is little hazard to the general population from these events. Such events are considered to occur in the probability range of 1 to 10-3 per year. The probability referred to here is the total probability of occurrence and includes the probability the event occurs (e.g., plane crash) times other probabilities required for the consequences. For accidents included in this range, results are presented for both the 50% meteorological condition (average meteorology) and the 95% meteorological condition.

F.1.3.7.2 Design Basis Accident Range. Accidents which have a probability of occurrence

in the range of 10-3 to 10-6 per year are included in the range called the Design Basis Accident Range. The terminology "design basis accident," which normally refers to facilities to be constructed, also includes the "evaluation" basis accident which applies to existing facilities. For accidents included in this range, results are presented for both the 50% meteorological condition (average meteorology) and the 95% meteorological condition. Risk calculations for accidents in this range utilize the consequences associated with 95% meteorological conditions.

F.1.3.7.3 Beyond Design Basis Accidents. This range includes accidents which are less

likely to occur than the design basis accidents but which may have very large or catastrophic consequences. Accidents included in this range typically have a total probability of occurrence in the range of 10-6 to 10-7 per year. Accidents which are less likely than 10-7 per year typically are not discussed since it is expected they do not contribute in any substantial way to the risk. For these beyond design basis accidents, consequences are presented for 50% and 95% meteorological conditions. Risk calculations for accidents in this range utilize the consequences associated with 95% meteorological conditions.

F.1.3.8 Evaluation of Impacted Area

The impacted area surrounding a facility following an accident was determined for each scenario evaluated. The impacted area was defined as that area in which the plume deposited radioactive material to such a degree that an individual standing on the boundary of the fallout area would receive approximately 0.01 mrem/hr of exposure. If this individual spends 24 hours a day at this location, that person would receive about 88 mrem per year from the ground surface shine. This is within the 100 mrem/year limit of 10CFR20.

To best characterize the affected areas for each casualty, a typical 50% meteorology was chosen (Pasquill-Gifford Class D, wind speed 10 mph) and applied to each accident scenario. The RSAC-5 results for ground surface dose were interpolated to determine the distance downwind where the centerline dose had dropped to approximately 88 mrem per year based on 24 hours per day exposure. For the wind class chosen, the plume remains within a singe 22.5-degree sector. The area affected by the plume is determined as the entire sector contaminated to the calculated downwind distance. Table F.1.3.8-1 lists each facility accident analyzed and the contaminated footprint associated with the accident.

F.1.3.8-1. Footprint estimates for facility accidents.

Accident Scenario	Footprint Length (miles)	Footprint Area* (acres)	Sites with Footprint Beyond Facility Boundary
Drained Water Pool	0.29	11	Norfolk, Oak Ridge, Portsmouth
Criticality	0.25	8	Norfolk, Oak Ridge, Portsmouth
Wet Storage Mechanical Damage	<0.06	<0.5	none
Wet Storage Airplane Crash	<0.06	<0.5	none
Dry Storage Mechanical Damage	<0.06	<0.5	none
Dry Storage Airplane Crash	0.91	106	Pearl Harbor, Norfolk, Oak Ridge, Portsmouth
Dry Cell Mechanical Damage	<0.06	<0.5	none
HEPA Filter Fire	<0.06	<0.5	none
Dry Cell Airplane Crash	1.27	207	Oak Ridge

*Based on contamination of a single sector.

Although the plume would be contained within a single sector, the direction of the wind is unknown. Therefore, each site was examined for impacts in all directions around the facility site out to a distance equal to the footprint length. Since the accidents do occur over a short duration of time, the acreage of the sector quoted is still an accurate indication of the total contaminated area. Identification of the potential impacts for each site is contained in Tables F.1.3.8-2 through -11.

Table F.1.3.8-2. Secondary impacts of facility accidents at Puget Sound Naval Shipyard.

Site	Significant Accidents in Decreasing Severity	Environmental Contamination	Endangered Species	Biotic Resources	Land Use	Water Resources	Treaty Rights	Economic Impacts	National Defense
Puget Sound Naval Shipyard	1. Dry Storage Plane Crash 2. Drained Water Pool	1. A total of approximately 106 acres might require clean-up. F.1.3.9 Emergency Preparedness and Mitigative Measures.

F.1.3.9.1 Emergency Preparedness Emergency plans are in effect at shipyards and

prototype sites to ensure that workers and the public would be properly protected in the event of an accident. In addition, emergency plans are in effect for accidents involving the transportation of radioactive materials. These response plans include the activation of emergency response teams provided by the site and a site emergency control center, as well as activation of a command and control network with Naval Reactors Headquarters and supporting laboratories. The long standing emergency planning program that exists within the Naval Nuclear Propulsion Program includes the ability to utilize the comprehensive and extensive emergency response resources of each naval site and provides for coordination with appropriate civil authorities. In addition to the Naval Nuclear Propulsion Program resources, extensive federal emergency response resources are available as needed to support State or local response.

Emergency response measures include provisions for immediate response to any emergency at the shipyard or prototype site, identification of the accident conditions, and communications with civil authorities providing radiological data and recommendations for any appropriate protective actions. In the event of an accident involving radioactive or toxic materials, workers in the vicinity of the accident would promptly evacuate the immediate area. This evacuation can typically be accomplished within minutes of the accident and would reduce the hazard to workers.

Regularly scheduled exercises are conducted periodically at each site in order to test each site's ability to respond to accidents. These exercises include realistic tests of people, equipment, and communications involved in all aspects of the plans, and the plans are regularly reviewed and modified to incorporate experience gained from the exercises. These exercises also periodically include steps to verify the adequacy of interactions with local hospitals and emergency personnel and state officials.

F.1.3.9.2 Mitigative Factors. For members of the general public residing at the site boundary

or beyond, no credit is taken for any preventive or mitigative actions that would limit their exposure. These individuals are calculated as being exposed to the entire contaminated plume as it travels downwind from the accident site. Similarly no action is taken to prevent these people from continuing their normal day-to-day routine and ingestion of terrestrial food and animal products continue on a yearly basis. As discussed in Section F.1.3, action would be taken to prevent the public from exceeding a Protective Action Guideline, if needed. No reduction of exposure due to these actions are accounted for in this analysis. The public is assumed to spend approximately 30% of the day within their homes or other buildings and the exposure to ground surface radiation is therefore reduced appropriately on a yearly basis.

Individuals that reside or work on site, or those that may be traversing the site in a vehicle would be evacuated from the affected area within 2 hours. This is based on the availability of security personnel at all locations to oversee the removal of residents, collocated workers, and travelers in a safe and efficient manner. Periodic training and evaluation of the security personnel is conducted to ensure that correct actions are taken during an actual casualty. Therefore, residents, collocated workers, and travelers would be exposed to the entire contaminated plume as it travels downwind for a period not to exceed 2 hours. Similarly, the radiation shine from the deposited radioactive materials would be limited to a 2-hour period. No ingestion of contamination is calculated for these individuals.

Facility workers all undergo training to take quick, decisive action during a casualty. These individuals quickly evacuate the area and move to previously defined "relocation" areas on the facility site. Workers could be exposed to a full 5 minutes of the radioactive plume as they move to the "relocation" centers. Once the immediate threat of the plume has moved off-site and downwind, the workers would be instructed to walk to vehicles waiting to evacuate them from the site. An additional 15 minutes would be required to evacuate the workers from the contaminated area and therefore the workers receive a total of 20 minutes of ground shine. No ingestion of contamination is calculated for these individuals.

The following summary provides the individual exposure times utilized in the accident analyses presented in Section F.1.4.2.

Estimated Time an Individual Might be Exposed

	Worker (100 m)	Collocated Worker (MCW) and Nearest Public Access (NPA)	Individual at Nearest Site Boundary (MOI)
To Plume	5 min.	100% of release time up to 120 min.	100% of release time

To Fallout on Ground Surface	20 min.	120 min.	0.7 yr
To Food	N/A	N/A	1 yr

F.1.3.10 Perspective on Calculations of Cancer Fatalities and Risk

The topics of human health effects caused by radiation and the risks associated with normal operations or postulated accidents associated with spent nuclear fuel management are discussed many times throughout this Environmental Impact Statement. It is important to understand these concepts and how they are used in order to understand the information presented in this document. It is also valuable to have some frame of reference or comparison for understanding how the risks compare to the risks of daily life.

The method used to calculate the risk of any impact is fundamental to all of the evaluations presented and follows standard accepted practices. The first step is to determine the probability that a specific event will occur. For example, the probability that a routine task, such as operating a crane, will be performed sometime during a year of normal operations at a facility would be 1. That means that the action would certainly occur. The probability that an accident might occur is less than 1.0. This is true because accidents occur only occasionally and some of the more severe accidents, such as a catastrophic earthquake, might occur at any location only once in hundreds, thousands, or millions of years.

Once the probability of an event has been determined, the next step is to predict what the consequences of the event being considered might be. One important measure of consequences chosen for this EIS is the number of human fatalities from cancer induced by radiation. This was chosen because this document deals with radioactive materials. The number of cancer fatalities that might be caused by any routine operation or any postulated accident can be calculated using a standard technique based on the amount of radiation exposure that might occur from all conceivable pathways and the number of people who might be affected (refer to Section F.1.3.3).

A couple of examples should serve to illustrate the calculation of risk. In the first, the lifetime risk of dying in a motor vehicle accident can be computed from the likelihood of an individual being in an automobile accident and the consequences or number of fatalities per accident. There were 10,000,000 motor vehicle accidents during 1992 in the United States resulting in about 40,000 deaths (NSC 1993). Thus, the probability of a person being in an automobile accident is 10,000,000 accidents divided by approximately 250,000,000 persons in the United States, or 0.04 per year. The number of fatalities per accident, 0.004 (40,000 deaths divided by 10,000,000 accidents), is less than 1 since many accidents do not cause fatalities. Multiplying the probability of the accident (0.04 per year) by the consequences of the accident (0.004 deaths per accident) by the number of years the person is exposed to the risk (72 years is considered to be an average lifetime) gives the risk for any individual being killed in an automobile accident. From this calculation, the overall risk of someone dying in a motor vehicle accident is about 1 chance in 87 over their lifetime.

A second example illustrates the calculation of risk for another event which occurs daily. Fossil fuels, such as natural gas or coal, contain naturally occurring radioactive material that is released into the air during combustion. This radioactivity in the air finds its way into our bodies through our food and the air we breathe. This radioactivity has been estimated to produce about 0.5 millirem of radiation dose to the average American each year (NCRP 1987). The probability of this happening is essentially 1.0 since these fuels are burned every day all over the country. The number of fatal cancers from exposure to 0.5

millirem per year is calculated by taking 0.5 millirem per year times the 72 years considered to be an average lifetime times the 0.0005 fatal cancers estimated to be caused by each rem (0.5 millirem per year x 72 years x 0.0005 fatal cancers per rem = 0.000018 fatal cancers per individual lifetime). The risk is the probability (1.0) times the consequences (0.000018 cancer fatalities) which equals about 1 chance in 55,000 of death from this cause over a lifetime.

These risks and others from everyday life can be used to gain a perspective on the risks associated with the alternatives in this EIS. As illustrated, the risk of death from cancer from the radioactivity released daily from combustion of fossil fuels is about 1 chance in 55,000 for the average American. As a further comparison, the naturally occurring radioactive materials in agricultural fertilizer contribute about 1 to 2 millirem per year to an average American's exposure to radiation (NCRP 1987). A calculation similar to the one in the preceding paragraph shows that the use of fertilizer to produce food crops in the United States results in a risk of death from cancer between 1 chance in 12,500 and 1 chance in 25,000. Finally, the average American's risk of dying from cancer from all causes is 1 chance in 5 over his or her lifetime. These risks can be compared, for example, to the average individual risk of less than 1 chance in 1 billion for a resident in the vicinity of the INEL developing a fatal cancer due to normal operations at the Expended Core Facility (see the data in Section F.1.4.1).

A frame of reference for the risks from accidents associated with spent nuclear fuel management alternatives can be developed in the same way. For an average resident in the vicinity of the INEL, the individual risk of death from cancer caused by the water leaking from the Expended Core Facility after a large earthquake would be approximately 1 chance in 9 billion. This individual risk was determined by dividing the risk value to the population within 50 miles (1.7 x 10-7 fatalities per year per accident from Table F-3) by the total population of 115,690 and multiplying by an average life span of 72 years. This risk can be compared to the risks of death from other accidental causes to gain a perspective. For example, the risk of death in a motor vehicle accident was calculated earlier to be about 1 chance in 87. Similarly, the risk of death for the average American from fires is approximately 1 chance in 500, and for death from accidental poisoning the risk is about 1 chance in 1000 (Crouch 1982).

F.1.4 Analysis Results

F.1.4.1 Normal Operations. The purpose of this analysis is to determine the hypothetical health effects on workers and the public due to routine handling of naval spent nuclear fuel. Radioactive releases from facilities involved in routine handling of naval spent nuclear fuel are small and less than those of comparable DOE and commercial nuclear facilities. Records of routine releases due to operations at ECF were used as source terms for all locations to estimate what effects these types of releases have on workers and the public. Site-specific meteorological and population data were used at each of the locations analyzed. For normal operations at the Naval Reactors Facility (NRF and Oak Ridge), exposure to the nearest public access (NPA) individual is not estimated due to the short period of time that such an individual would spend on-site while driving on the public access road. At Hanford, the NPA is located at the Washington Public Power Supply System Plant, and at Savannah River at the U.S. Forestry Service Office. The NPA at shipyard locations is defined in Section F.1.3.2.

F.1.4.1.1 Water Pool Examination and Storage Source Terms. The evaluation of normal water pool operations was performed using two different source terms. In one analysis, a source term was utilized which included both the incremental release of radioactive materials due to the alternative spent nuclear fuel storage actions and the release from other ongoing Naval Reactors activities. Identical source terms were used for the evaluation of radiation exposure due to the release of radioactive materials during normal operations of wet storage and spent fuel examinations. The 1991 annual airborne release from the INEL-ECF was used to evaluate these operations. Since the INEL-ECF releases are extremely low, this upper limit approach is not unduly conservative for the wet storage option which is expected to have a lower release. Table F.1.4.1.1-1 shows the 1991 INEL-ECF release rate, the current release rate at Kesselring and NRF (including both INEL-ECF and prototypes), and the release rate representing Naval Reactors operations at naval shipyards. The release rate representing naval shipyards is based on upper bound data from Navy operations contained in Naval Nuclear Propulsion Program (NNPP) Report NT-94-1 (NNPP 1994). With no current Naval Reactors facilities at Savannah River, Hanford, Oak Ridge, or the Nevada Test Site, the current release for each of these sites is zero for this analysis.

Table F.1.4.1.1-1. Airborne releases from current Naval Reactors operations.

Location	Annual Releases (Ci/year)	
INEL-ECF	H-3 9.35 x 10-2	Y-90 5.5 x 10-6

	Kr-85m 2.4 x 10-2	Xe-135 2.5 x 10-1
	Kr-85 1.0 x 10-3	

The evaluation of continuing Naval Reactors activities combined with the proposed alternatives for naval spent nuclear fuel is based on the combined airborne release source terms shown in Table F.1.4.1.1-2. This table presents a summation of the INEL-ECF source term and the current Naval Reactors operations source terms from Table F.1.4.1.1-1 for each location. Beginning in 1995, with the shutdown of the S5G prototype, the NRF releases will only result from the INEL-ECF, and this condition is shown in the table.

The other analysis utilized the same source term at all locations. The INEL-ECF source term of Table F.1.4.1.1-1 was used to compare the incremental health effects due to providing water pool storage or examination facilities at each location.

Both analyses also considered the impact on health effects of direct radiation levels from a water pool facility and the deposition of radionuclides onto the ground and into water supplies as discussed in Sections F.1.3.6.4 and F.1.3.6.5.

Table F.1.4.1.1-2. Airborne releases used in the analysis of water pool activities plus ongoing Naval Reactors operations.

	Kr-87 5.0 x 10-2	Xe-135 2.5 x 10-1

F.1.4.1.2 Dry Storage Source Terms. Another operation analyzed was the storage of naval

spent nuclear fuel in shipping containers or storage casks in a safe array at NRF, the naval shipyards, and Kesselring locations. It is postulated that shielding and physical boundaries are established in accordance with existing regulations to protect facility workers. There are expected to be no routine airborne or water releases from the dry storage activity. The source will consist of an array of filled storage containers. Supplementary shielding would be provided as needed to ensure that there would be no measurable increase in radiation levels at the perimeter of the industrial area and that radiation levels within the industrial area but outside the storage area would not require occupational radiation exposure monitoring for workers. Each location analyzed would have a different number of storage casks. As containers are received over time, shielding will be provided to limit radiation exposure rates as discussed above. Distance falloff for radiation levels was determined using SPAN computer calculations as discussed in Section F.1.3.6.4.

F.1.4.1.3 Dry Cell Facility Source Terms. The normal airborne release source terms

utilized for the dry cell facility analyses are identical to the INEL-ECF releases in Table F.1.4.1-1. It is expected that these values bound the actual releases from the proposed facility. A source term different from the water pool analysis was utilized for the direct radiation calculations. This source term is based on the proposed facility design, expected fuel examination capacity, and shielding calculations. Like the airborne releases, source terms for water deposition were identical to those utilized in the water pool analysis.

F.1.4.1.4 Water Pool Storage. This section presents tabulated radiation exposure results for

the wet storage option. The following summary provides an indication of the incremental change at each location due to the addition of an ECF-type facility.

Summary of Exposure Calculation Results
For Normal Operations - Water Pool Examination or Storage only
At All Sites

	INEL/NRF	Savannah River	Hanford	Puget Sound	Pearl Harbor
Worker EDE (rem)	7.1 x 10-5	9.1 x 10-5	8.9 x 10-5	9.4 x 10-5	1.1 x 10-4
MOI EDE (rem)	2.5 x 10-7	4.8 x 10-7 3.8 x 10-6*	2.4 x 10-7 4.4 x 10-7**	8.7 x 10-5	2.0 x 10-5
NPA EDE (rem)	N/A	2.1 x 10-8	1.3 x 10-8	6.2 x 10-4	5.2 x 10-4
Total EDE (person-rem)	1.7 x 10-3	3.6 x 10-2	8.0 x 10-3	1.3 x 10-1	1.4 x 10-1
Number of Fatal Cancers	8.5 x 10-7	1.8 x 10-5	4.0 x 10-6	6.5 x 10-5	7.0 x 10-5

* MOI (Barnwell Plant)
** MOI (FMEF)

	Norfolk	Portsmouth	Kesselring	Nevada Test Site	Oak Ridge
Worker EDE (rem)	6.9 x 10-5	7.7 x 10-5	8.5 x 10-5	4.6 x 10-5	1.2 x 10-4
MOI EDE (rem)	1.1 x 10-4	4.4 x 10-5	6.8 x 10-6	3.4 x 10-7	1.0 x 10-4
NPA EDE (rem)	6.8 x 10-5	3.3 x 10-4	N/A	N/A	N/A
Total EDE (person-rem)	2.8 x 10-1	4.5 x 10-2	8.2 x 10-2	1.8 x 10-4	1.0 x 10-1
Number of Fatal Cancers	1.4 x 10-4	2.3 x 10-5	4.1 x 10-5	9.0 x 10-8	5.0 x 10-5

Evaluations of environmental impacts at DOE sites are presented in Volume 1, Appendices A, B, C, and F. The radiological impacts at these sites are quite low in that fatal cancer projections to the population within 50 miles from normal operations are well below 1.0. Further, impacts at naval shipyards and prototype sites are addressed in Appendix D and also are well below 1.0. Hence, the addition of the above small values to those which already exist at a site result in total values which are also quite small.

The following summary provides the exposure calculation results for water pool storage or examination plus all ongoing Naval Reactors operations at each site.

Summary of Exposure Calculation Results
For Normal Operations - Water Pool Examination or Storage
plus all ongoing Naval Reactors operations
At all sites

	INEL/NRF	Savannah River	Hanford	Puget Sound	Pearl Harbor
Worker EDE (rem)	7.1 x 10-5	9.1 x 10-5	8.9 x 10-5	1.2 x 10-4	1.4 x 10-4
MOI EDE (rem)	2.5 x 10-7	4.8 x 10-7 3.8 x 10-6*	2.4 x 10-7 4.4 x 10-7**	1.0 x 10-4	2.3 x 10-5
NPA EDE (rem)	N/A	2.1 x 10-8	1.3 x 10-8	7.2 x 10-4	5.8 x 10-4
Total EDE (person-rem)	1.7 x 10-3	3.6 x 10-2	8.0 x 10-3	1.5 x 10-1	1.7 x 10-1

F.1.4.1.5 Dry Storage. This section presents tabulated radiation exposure results for the dry storage option at INEL, Navy shipyard sites, and the Kesselring Site. Dry storage at Hanford, Savannah River, the Nevada Test Site, and Oak Ridge is not included in this section as it is discussed in EIS Volume 1, Appendices A, C, and F, respectively. The following summary provides an indication of the incremental change at each location due to the addition of dry storage areas. The health effect due to dry storage of spent fuel is largest at the Navy shipyards and is extremely small at all DOE locations.

Summary of Exposure Calculation Results
For Normal Operations - Dry Storage only
At all sites

	INEL	Puget Sound	Pearl Harbor	Norfolk	Portsmouth	Kesselring
Worker EDE (rem)	1.1 x 10-2	5.4 x 10-3	2.1 x 10-3	5.8 x 10-3	2.7 x 10-3	6.1 x 10-4

Population of 1,148,587	5.7 x 10-2	2.9 x 10-5

F.1.4.1.6 Dry Cell Operations. This section presents tabulated radiation exposure results for the dry cell operations option. Since a facility like the proposed dry cell would only be constructed for the alternatives which include examination of all naval spent fuel, this analysis was only performed for the INEL, Savannah River, Hanford, the Nevada Test Site, and Oak Ridge locations. The following summary provides an indication of the incremental change at each location due to the addition of a dry cell facility.

The calculated health effect to the general population is roughly proportional to the surrounding population with Oak Ridge being the worst and Nevada Test Site being the best.

Summary of Exposure Calculation Results
For Normal Operations - Dry Cell Operations
At all sites

	INEL/NRF	Savannah River	Hanford	Nevada Test Site	Oak Ridge
Worker EDE (rem)	6.3 x 10-5	8.3 x 10-5	8.1 x 10-5	3.5 x 10-5	1.1 x 10-4

Exposure to Population within 50-mile Radius (person-rem)		Number of Fatal Cancers
Population of 871,531	1.0 x 10-1	5.0 x 10-5

F.1.4.2 Accident Evaluation. The analysis of airborne releases from hypothetical accidents is

evaluated with RSAC-5. Unless stated otherwise, the following conditions were used when performing calculations with RSAC-5. In most cases, these conditions are taken directly as defaults from the code.

Meteorological Data

- Wind speed, direction, and Pasquill stability are taken from 50% and 95% meteorology. See Section F.1.3.5 for a discussion of meteorological conditions.
- The release is calculated as occurring at ground level (0 m).
- Mixing layer height is 400 meters (1320 feet). Airborne materials freely diffuse in the atmosphere near ground level in what is known as the mixing depth. A stable layer exists above the mixing depth which restricts vertical diffusion.
- Wet deposition is zero (no rain occurs to accelerate deposition and reduce the area affected).
- Dry deposition of the cloud is modeled. During movement of the radioactive plume, a fraction of the plume is deposited on the ground due to gravitational forces and becomes available for exposure by ground surface radiation and ingestion.
- The quantity of deposited radioactive material is proportional to the material size and speed. The following dry deposition velocities (m/s) were used:
  solids = 0.001 halogens = 0.01 noble gases = 0.0
  cesium = 0.001 ruthenium = 0.001.
- If radioactive releases occur through a stack, then additional plume dispersion can be accounted for by calculating a jet plume rise. In this analysis, jet plume rise is ignored.
- When released gases have a heat content, the plume can disperse more quickly. In this calculation, buoyant plume effects are ignored.

Inhalation Data

- Breathing rate is 3.33 x 10-4 cubic meters per second (cu m/s) for worker, MCW, and NPA; 2.66 x 10-4 cu m/s for people at site boundary and beyond.
- Particle size is 1.0 micron.
- The internal exposure period is 50 years for individual organs and tissues which have radionuclides committed.
- Exposure to the entire plume for the general public. The worker, MCW, and NPA are exposed as discussed in Section F.1.3.9.
- Inhalation exposure factors based on ICRP 30.

Ground Surface Exposure

- Exposed to contaminated soil for 1 year for the general public. See Section F.1.3.9 for additional details.
- Building shielding factor is 0.7 which exposes the individual to contaminated soil for 16 hours a day.

Ingestion Data

- Ingestion numbers will be reduced by a factor of 10 to account for only 10% of the food consumed being grown locally (such as in a person's garden).
- The following changes from RSAC-5 defaults were used:

  Annual Dietary Consumption Rates:

  177 Kg/yr Stored Vegetables (produce)
  18.3 Kg/yr Fresh Vegetables (leafy)
  94 Kg/yr Meat
  112 L/yr Milk.

F.1.4.2.1 Water Pool Storage. In the analysis of a spent fuel storage pool, a number of possible disturbances and minor accidents have been postulated. A prerequisite for a large release of radioactive material to the environment under more severe accident conditions is the damage of the cladding of a fairly large amount of stored fuel, with an accompanying release of gaseous and airborne particles of radioactive material from the fuel. Several conceivable mechanisms which might lead to this situation are the possibility that the fuel overheats so that the fuel cladding loses its integrity or there is a massive mechanical impact on the stored fuel.

The only way for the fuel to overheat would be to lose enough pool water such that cooling of the stored fuel ceases and the fuel temperature increases to fission product release temperatures due to decay heat. The pool water could be lost by leakage at a rate in excess of the makeup system capability. Unless a catastrophic event like an earthquake causes severe damage to the structure of the water pool, loss of water from the pool structure would be a slow phenomenon with only gradually increasing severity for which corrective measures can be taken in due time. Additionally, a thermal analysis was conducted to demonstrate that fuel overheating is not possible in the event of a drained water pool.

The circumstances in which an event could lead to severe mechanical loading of the fuel have been identified as:

- accidents during handling of heavy items, such as a lifting device failure
- external events (earthquake, tornado, flood, aircraft crash, etc.) which could cause structural failure.

Prevention of inadvertent, uncontrolled nuclear chain reactions is generally assured by the design of the racks for the fuel, primarily by diminishing the chances for a chain reaction by spacing the fuel element bundles far enough apart to eliminate the possibility. Special attention is given to the risk of accidental criticality which might be experienced in fuel transport and handling operations.

Uncontrolled nuclear reaction is prevented during fuel handling by applying the principle of transferring one fuel element, module, or container at a time. In addition, fuel handling rules are developed to ensure that criticality cannot occur. The double accident criterion is applied to ensure that criticality would not occur following two severe, concurrent, unrelated accidents. Thus, three fuel handling accidents are required to reach an uncontrolled nuclear chain reaction.

F.1.4.2.1.1 Drained Water Pool.

F.1.4.2.1.1.1 Description of Conditions. In this hypothetical accident scenario, a

catastrophic event, like an earthquake, causes severe damage to the structure of the water pool, resulting in a complete loss of pool water. A thermal analysis of spent fuel in a water pool was conducted to demonstrate that clad failure or fuel melting is not possible in the event of an accidentally drained water pool. Air circulation through the fuel racks and fuel units was shown to be sufficient to prevent clad failure in the unlikely event of complete loss of pool water. However, the loss of water could result in increased direct radiation and a release of corrosion products.

F.1.4.2.1.1.2 Source Term. Conditions used in developing the source term are as follows:

- 300 naval fuel units would be in the water pool.
- The thermal analysis demonstrates that no fission product release would occur during the accident.
- The amount of corrosion products on the fuel units is based on best estimate values.
- The release to the environment would occur at a constant rate over a 15-minute period.
- One percent of the original corrosion products from the fuel units might be released to the atmosphere due to thermal air currents. Additionally, 10% of the corrosion products could be released to the environment with the pool water.
- The following amounts of corrosion product nuclides might be released to the atmosphere. As noted above, the release to the water environment is 10 times these values. This listing includes nuclides that result in at least 99% of the exposure.
- No filtration by High Efficiency Particulate Air (HEPA) filters is assumed.

Nuclide	Curies
Co-60	3.6
Fe-55	6.6
Co-58	1.3
Mn-54	2.2 x 10-1
Fe-59	1.9 x 10-2

F.1.4.2.1.1.3 Results. The following table summarizes the public health risk to the general

population that might result from the hypothetical drained water pool accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. The results are presented for the design basis accident with 50% and 95% meteorology. For INEL, the evaluation basis earthquake results in a 0.24 g peak ground acceleration at the ECF (Rizzo 1994). This is based on the event being initiated at the Howe earthquake epicenter and involving a surface rupture length of 34 kilometers. Using the medium response spectra, which is appropriate for a risk oriented analysis, the analyses of the structures at the INEL-ECF indicate that damage sufficient to cause the pool to drain would not occur if the pool is filled, but that, if several sections of the water pool were empty, a crack could develop in the area between the wall and floor of some of the older sections of the water pool. However, the INEL-ECF water pools are nearly always filled. Sections of the pool are only drained if maintenance work is necessary within the pools. Taking into account the probability of the initiating seismic event (1 x 10-4 per year to 4 x 10-4 per year) and the probability the earthquake will occur with a section of the pool drained, the total probability of occurrence of an event leading to draining of the pool is estimated to be in the range of 10-5 to 10-6 per year. A value of 10-5 was used to develop the risk results in the table.

A beyond design basis seismic event was also considered. For INEL, this beyond design basis earthquake is based on a scenario that results in a peak ground acceleration at the INEL-ECF of 0.40 g (Rizzo 1994). Analysis of this event has shown that some cracks could develop. The probability of this beyond design basis event is estimated to be in the range of 10-6 to 10-7 per year based on the probability of the initiating seismic event (2 x 10-5 to 6 x 10-5), and the probability of failure of the mitigative actions that would be taken to prevent the pool from draining. A value of 10-6 was selected to calculate risk for this beyond design basis event. Any cracks developed as a result of either a design basis or a beyond design basis seismic event are expected to be small and mitigative actions could be taken to stop the pool from draining. Analysis has shown that air cooling is sufficient to maintain fuel integrity if the pool was drained. No overheating of fuel would occur; hence, no fission products would be released even if the pool were completely drained. The consequences calculated stem from the release of radioactive corrosion products within the pool water and would be the same for the design basis and beyond design basis seismic events. Since the consequences are the same, the following table uses the accident probability for the design basis seismic event since that results in the larger risk.

For locations other than INEL, water pools might need to be constructed. For these locations, it was expected that the design approaches would be similar to or better than were used in the construction of the INEL-ECF. Therefore, a probability value of 10-5 per year was also used at these locations for the total probability that a design basis seismic event would lead to draining of a water pool. Consequences were based on site specific population data and meteorology.

Drained Water Pool Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancers if accident occurs	Risk per year
INEL	1.7 x 10-2	1.7 x 10-2	1.7 x 10-7
Savannah River	1.6 x 10-2	1.1 x 10-1	1.1 x 10-6
Hanford	6.3 x 10-3	4.7 x 10-2	4.7 x 10-7
Puget Sound	1.4	5.1 x 10-1	5.1 x 10-6
Pearl Harbor	7.9 x 10-1	1.1	1.1 x 10-5
Norfolk	3.0	6.0 x 10-1	6.0 x 10-6
Portsmouth	1.6	3.4 x 10-1	3.4 x 10-6
Kesselring	2.9 x 10-1	2.5 x 10-1	2.5 x 10-6
Nevada Test Site	3.3 x 10-2	1.9 x 10-3	1.9 x 10-8
Oak Ridge	5.2	1.8 x 10-1	1.8 x 10-6

The risk for this hypothetical accident is generally more severe at Navy shipyards than at the DOE sites. At all sites, this accident results in the highest risk of the wet storage accidents evaluated.

For the hypothetical drained water pool scenario, the radioactive plume might result in contamination of the ground to a downwind distance of 0.29 mile. This would yield a total area impacted by the accident of approximately 11 acres. The calculated downwind distance would be contained within the boundaries of all sites under evaluation with the exception of Oak Ridge and Norfolk.

F.1.4.2.1.2 Accidental Criticality.

F.1.4.2.1.2.1 Description of Conditions.

In this hypothetical accident scenario, an accidental uncontrolled chain reaction producing 1 x 1019 fissions is postulated. The criticality occurs in the water pool which is not emptied by the event and does not subsequently empty. Release of fission products includes those specified in Regulatory Guide 3.34 (NUREG 1979b) from the criticality, plus fission products remaining in the fuel as a result of the original use. Removal of fission products by the pool water is included.

F.1.4.2.1.2.2 Source Term.

Conditions used in developing the source term are as follows:

- The fraction of the fission products released to the building is 100% of the noble gases, 25% of the halogens, 0.1% of the ruthenium (Elder et al. 1986), and 0.05% of the cesium and remaining solids.
- The original inventory of fission products from two naval fuel units are available for release in addition to those created by the criticality event.
- A High Efficiency Particulate Air (HEPA) filter removes 99.9% of the solid fission products from the plume.
- The release to the environment occurs at a constant rate over a 15-minute period. This is conservative as compared to the 8-hour release allowed in Regulatory Guide 3.34.
- The following amounts of radionuclides are released to the environment. This listing includes nuclides that result in at least 99% of the possible exposure.

Nuclide	Curies	Nuclide	Curies
Te-133	3.4 x 103	I-132	1.7 x 100
I-134	3.5 x 102	Sr-90	1.94 x 10-2
I-135	1.2 x 102	Y-91m	4.3 x 10-8
Cs-138	1.6 x 10-4	Rb-88	1.7 x 10-5
Rb-89	6.05 x 10-4	Y-91	1.1 x 10-2

Rb-90	2.2 x 10-2		

F.1.4.2.1.2.3 Results. The following table summarizes the public health risk to the general population that would result from the hypothetical criticality accident at each location. The number of fatal cancers would be expected to occur over a 50-year period. "Risk" is defined as the number of fatal cancers times the probability of occurrence. An accidental criticality during spent nuclear fuel handling operations is extremely unlikely. There are no known events of this type which have occurred during handling of fuel modules either in or out of water. Due to the need for a neutron moderator, extremely large quantities of naval fuels would be required to achieve criticality in a dry state. Fuel handling procedures in water in conjunction with required physical barriers ensure that a double accident criterion is met. This criterion specifies that the fuel will not attain a critical condition even if any two unlikely and unrelated accidents occur at the same time. The DOE criticality control requirement is a double contingency criterion which specifies that a second unlikely and unrelated accident would be required for a critical condition to result. To satisfy the NNPP double accident criterion, naval fuel handling operations are conducted in the following manner:

- No more than one module is to be handled in one area at a time.
- If two modules are capable of achieving a critical condition, separation must be maintained by a positive barrier between them which is locked in place.
- If three modules are required to achieve criticality, a physical barrier which does not need to be locked is required to be placed between them.
- If four or more modules are needed to achieve criticality, no barriers are required, but modules are to remain separated.

Based on the above requirements, at least three distinct errors are needed to achieve accidental criticality. For example, bringing two or more modules in close proximity is always prohibited. Failure to maintain separation constitutes an error. Secondly, failure to recognize and use physical barriers when required also constitutes an error. A human error rate of 10-3 per operation (Swain and Guttman 1983) is taken as the probability of error for trained personnel. Further, because all fuel handling operations must be checked by an independent verifier, an additional factor of 10-1 may be taken for a probability of 10-4 for each independent error. For naval fuel handling, an error in which two modules are brought together is a violation of a fundamental requirement. Compliance with this requirement alone ensures that a subcritical state is maintained. Therefore, the bringing of two or more modules together error is considered separate and independent of all other errors. Because a second error must occur to cause accidental criticality, an additional reduction in the probability is warranted. For example, failure to recognize the need to install a barrier when required is such an error. Because this mistake is independent of the first error and has been checked, a second value of 10-4 is appropriate for a total value of 10-8 per year. This probability is taken as the likelihood of a criticality for movement of a single module. Based on an estimated 1,000 fuel handling operations a year, a value of 10-5 per year has been used in the risk assessment of accidental criticality.

Accidental Criticality Summary

Site	Maximally exposed off-site individual (MOI) (rem)	No. of fatal cancer if accident occurs	Risk per year
INEL	9.2 x 10-3	6.4 x 10-3	6.4 x 10-8
