1. INTRODUCTION

The U.S. Department of Energy (DOE) is evaluating its options for two separate but related sets of decisions pertinent to the management of the spent nuclear fuel (SNF) for which the DOE is responsible. As a result, this Environmental Impact Statement (EIS) is divided into two parts. Volume 1 involves programmatic (DOE-wide) approaches to the management of DOE's SNF; Volume 2 discusses site-specific approaches for environmental restoration and waste management activities at the Idaho National Engineering Laboratory, including SNF management. This EIS has been prepared in accordance with the National Environmental Policy Act and its applicable implementing regulations (40 CFR Parts 1500-1508 and 10 CFR Part 1021).

The DOE's proposed action for Volume 1 is to safely, efficiently, and responsibly manage existing and projected quantities of DOE's SNF through the year 2035, pending ultimate disposition. Volume 1 has been developed to support DOE's decisionmaking on the most appropriate location for implementing national strategies for managing DOE's SNF until its ultimate disposition is determined and implemented. For planning purposes, it has been assumed that decisions regarding ultimate disposition strategies may require as long as 40 years to implement. The general environmental consequences of managing SNF in a range of configurations at various sites are summarized in this volume.

Volume 1 is supported by site-specific appendices (under separate cover) that provide detailed information on the consequences of management activities under each alternative at the Hanford Site (Appendix A); Idaho National Engineering Laboratory (Appendix B); Savannah River Site (Appendix C); naval SNF management facilities, including management of naval SNF at DOE facilities (Appendix D); other generator/storage sites (Appendix E); and the Oak Ridge Reservation and the Nevada Test Site (Appendix F). This EIS does not select site-specific technical management options presented in Appendices A through F. The management options are representative of potential activities at each of the sites under consideration.

Volume 2 addresses the Environmental Restoration and Waste Management Programs at the Idaho National Engineering Laboratory. DOE objectives for the next 10 years are to mitigate the impacts of past operations through environmental restoration and to treat, store, or dispose of waste at the Idaho National Engineering Laboratory in a way that minimizes future adverse impacts.

Volume 3 summarizes the comments that DOE received on the Draft EIS during the public comment period and provides responses to those comments. Volume 3 also discusses the extent to which public comments resulted in changes to this EIS and describes how to find specific comment summaries and responses.

---

a. The Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement (SNF and INEL EIS)

1.1 Overview of Spent Nuclear Fuel in the DOE Complex

This section is an introduction to the nature, types, and quantities of DOE SNF; the historic generation and storage of SNF; and the current program structure as it existed in April 1995. This section also explains what SNF is not included in this EIS as DOE SNF.

1.1.1 What is Spent Nuclear Fuel

Nuclear reactors use a process called fission to generate heat to produce electricity and to generate power to propel Navy ships and submarines. Production reactors have been used to produce defense materials at DOE facilities and radioisotopes for industrial and medical use. Some colleges and universities, government facilities, and commercial establishments use nuclear reactors for research and educational purposes, as well. Fuel that has been withdrawn from a nuclear reactor following irradiation, the constituent elements of which have not been separated, is called spent nuclear fuel, or SNF. The EIS also evaluates uranium/neptunium target materials, blanket subassemblies, pieces of fuel, and debris. Contact-handled fuel/targets (that is, fuel/targets with radiation levels low enough to permit handling without shielding or remote operations), even though slightly irradiated, are not included. This material will be managed by DOE along with the other excess nuclear materials.

1.1.1.1 Configuration of Nuclear Fuel.

The fuel in a nuclear reactor consists of fuel assemblies that may range in number from one to several hundred, depending upon the reactor size and the design of the reactor and fuel assemblies. Fuel assemblies are constructed in many configurations, but they generally consist of the fuel matrix, cladding, and structural hardware.

The fuel matrix contains the fissionable material (typically uranium oxide or uranium metal). The matrix form is typically plates or cylindrical pellets. For gas-cooled reactors, the matrix may be small particles. The cladding is the encapsulation (typically zirconium, aluminum, or stainless steel) that surrounds the fuel, confining and protecting it. For gas-cooled reactors, this may be a ceramic coating over the fuel particles.

The structural parts of a fuel assembly hold fuel in the proper configuration and direct coolant flow (typically water) over the fuel. Structural hardware is generally nickel alloys, stainless steel, zirconium, or aluminum, or, for gas-cooled reactors, graphite. The size of a fuel assembly ranges from a weight of 1 kilogram (2.2 pounds) and a length of less than 1 meter (3 feet) to a weight of more than 450 kilograms (1,000 pounds) and a length of more than 3 meters (10 feet). Figure 1-1 illustrates a representative fuel element.

Figure 1-1. Representative reactor fuel assembly and element.

1.1.1.2 Properties of Spent Nuclear Fuel.

When it is initially removed from a reactor, SNF is highly radioactive. A fraction of the initial mass of fissionable material (uranium-235 or plutonium) has been converted into fission products, some of which are radioactive with half-lives ranging from a few seconds to thousands of years. At the time of withdrawal from the reactor, most of the radioactivity is associated with fission products with very short half-lives. The radioactivity from SNF decreases very rapidly over time after irradiation. After 1 year, the levels are about 1 percent of that at the time of removal. After 10 years, these levels have decreased by another factor of 10.

The radiation of most concern from SNF is gamma rays. Although the radiation levels can be very high, the gamma-ray intensities are readily reduced by shielding fuel elements with such materials as concrete, lead, steel, and water. The thickness of the required shielding is dependent on the energy of the radiation source, the desired protection level, and the density of the shielding material. Typically, shielding thicknesses for concrete or lead are much smaller than for water.

The radioactivity produces heat, and the assemblies must be cooled for a period of months to years following removal from the reactor to prevent excessive fuel temperatures from being reached. Typically, the SNF removed from reactors has been stored in water pools for a period of 3 to 18 months for cooling before transfer to other facilities for storage or processing. Storage systems are designed to prevent nuclear criticality (nuclear chain reaction).

Many fuel elements that are now SNF, particularly production reactor fuel, were designed to be easily dissolved in nitric acid for uranium-235 and plutonium recovery. Because the fuels were designed for only short-term storage, prolonged storage sometimes presents problems. For example, some fuels, such as aluminum-clad fuels, corrode during prolonged storage in water pools unless the water chemistry within the pool is carefully controlled. Corrosion can result in cladding failures and the release of small quantities of fission products, especially radioactive gases and readily soluble isotopes.

1.1.1.3 SNF Management Vulnerabilities.

Prolonged storage of some types of SNF has resulted in deterioration of the cladding, degradation of the fuel matrix, or other storage problems leading to significant environmental, safety, and health concerns. DOE reported its evaluation of these concerns in a Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and Other Reactor Irradiated Nuclear Materials and their Environmental, Safety and Health Vulnerabilities in November 1993 (DOE 1993a). This evaluation was followed by a Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities in February 1994, which identified three phases to resolve those vulnerabilities (DOE 1994a). This Phase I Action Plan, which addresses the most urgent activities, was issued immediately. The Phase II Action Plan was released April 1994 for public comment (DOE 1994b). The Phase III plan was issued in October 1994 (DOE 1994c). Phases I, II, and III corrective actions include activities at the main DOE SNF storage sites. Examples of corrective action projects include installing equipment to improve storage pool water quality at the Savannah River Site; transferring fuel from an old, inadequate water pool to a newer pool at the Idaho National Engineering Laboratory; removal of all fuel and sludge from the 105-K basins at the Hanford Site.

Some of the SNF Action Plan activities could potentially result in emission and effluents. These effects are not individually analyzed because their impacts are no greater than the impacts of normal SNF management activities reported and analyzed for each site in Volume 1 and the respective site appendices.
Successful completion of the corrective actions would reduce the potential for health and safety problems to the workers and public and minimize degradation to the environment.

In addition to the Spent Fuel Working Group report on vulnerabilities and the associated plans of action to resolve the identified vulnerabilities, the Defense Nuclear Facilities Safety Board issued Recommendation 94-1 (Conway 1994) calling for DOE to develop an expedited schedule for resolving identified vulnerabilities across the DOE complex. Recommendation 94-1 was critical of DOE's lack of urgency in correcting known SNF management deficiencies. Further, Recommendation 94-1 criticized DOE's lack of prioritization of corrective actions and lack of an integrated systems approach to resolving previously identified SNF management issues. DOE has developed a plan for implementing Recommendation 94-1 across the DOE complex. DOE's Implementation Plan (DOE 1995a) for Recommendation 94-1 was submitted to the Defense Nuclear Facilities Safety Board on February 28, 1995. The plan includes a prioritization of corrective actions to remedy known deficiencies utilizing a DOE complex-wide systems approach and considering limited budgets. The plan focuses on fulfilling outstanding commitments to other parties (for example, court-ordered milestones) and fully recognizes the urgency required to rectify long-standing SNF management issues.

1.1.2 DOE Spent Nuclear Fuel Management

For the purposes of this document, SNF is separated into two categories: commercial SNF and DOE-managed SNF. The management of commercial SNF (with a few special-case exceptions) is outside the scope of this SNF and INEL EIS and is not discussed further herein.

Since 1943, DOE and its predecessor agencies have generated more than 100,000 metric tons of heavy metal (MTHM) of SNF, of which about 2,700 metric tons remains. This SNF was generated in various programs in different types of reactors, including DOE defense production reactors, United States naval reactors, and DOE test and experimental reactors. In addition, DOE has accepted responsibility for SNF from non-DOE sources, including United States university research reactors, special-case commercial power reactors, and selected foreign research reactors.

In 1992, the Secretary of Energy directed the DOE to develop an integrated, long-term SNF management program. This program is assessing DOE's SNF and fuel storage facilities, integrating DOE's many existing SNF activities into one program, deciding the most appropriate and responsible means of facility operation, and ensuring that issues associated with SNF are resolved safely and cost effectively. Solutions to the storage questions may require changes in the management strategies for these fuels, including such options as the construction of new facilities and stabilization of certain fuels. The program has also established a programmatic objective to define a management path and proceed toward ultimate disposition of DOE-managed SNF, as outlined in DOE (1994d). A number of activities are currently in process to meet or address this objective. Appendix J, Spent Nuclear Fuel Management, provides an overview of technologies for SNF management.

---

a. The Atomic Energy Act of 1954, as amended, gives DOE the responsibility and ultimate title for the Nation's SNF. The Nuclear Waste Policy Act of 1982, as amended sets up the process for disposition of the Nation's commercial nuclear power reator SNF in a mined geologic repository and makes provisions for cost recovery for the ultimate disposition of that SNF. It also specifies the procedures for ultimate disposition of DOE's high-level waste and SNF.

b. Quantities of fresh nuclear fuel, SNF, and targets are traditionally expressed in terms of metric tons of heavy metal (typically uranium), without the inclusion of other materials, such as cladding, alloy materials, and structural materials. A metric ton equals approximately 2,200 pounds.

For various reasons, including the lack of characterization data on the interim storage behavior of certain SNF types and the fact that the acceptance criteria for ultimate disposition have not yet been defined, DOE cannot yet make all the decisions for the full 40-year period. Therefore, this EIS focuses on issues relating to deciding the locations of future SNF management activities.

DOE faces a number of major programmatic and site-specific decisions regarding SNF management over the next 40 years including

Where should DOE locate specific SNF management activities? Broadly, the alternatives include managing the SNF where it is and minimizing shipments; consolidating the SNF at a limited number of sites (the Decentralization, 1992/1993 Planning Basis, and Regionalization 4A and 4B alternatives); or consolidating the SNF at a central site.

What capabilities, facilities, and technologies are needed for SNF management? DOE has identified the need for SNF interim storage sites and must select appropriate means at each site for meeting these needs under each of the SNF siting alternatives.

What research and development activities should support the SNF management program?

1.1.2.1 Current and Projected Spent Nuclear Fuel Inventories.

Table 1-1 summarizes the current inventories of SNF at DOE and other facilities and those projected to be generated through the year 2035. These estimates are based on assumptions regarding reasonably foreseeable future reactor operations and the generation rates of SNF for which DOE is responsible. The principal SNF generators and storage sites for SNF are described below and in Appendices A through F. Figure 1-2 illustrates those locations, as well as representative points of entry for foreign fuels under consideration in this EIS.

1.1.2.2 DOE Facilities.

During the last four decades, DOE and its predecessor agencies have transported, received, reprocessed, and stored SNF at various facilities in the nationwide DOE complex. Three of the DOE facilities have primary responsibility for managing DOE SNF; several others have smaller roles in SNF management.

Table 1-1. Spent nuclear fuel inventory.[a]

Generator or storage site[b]	Existing (1995)		Future increases (through 2035)		Total (2035)	
Generator or storage site[b]	MTHM[c]	Percent	MTHM[c]	Percent	MTHM[c]	Percent
DOE Sites						
Hanford Site	2132.44	80.6	0.00	0.0	2132.44	77.8
Idaho National Engineering Laboratory	261.23	9.9	12.92	13.5	274.14	10.0
Savannah River Site	206.27	7.8	0.00	0.0	206.27	7.5
Oak Ridge Reservation	0.65	<0.1	1.13	1.2	1.78	<0.1
Other DOE Sites	0.78	<0.1	1.50	1.6	2.28	<0.1
Naval Nuclear Propulsion Reactors	0.00[d]	0.0	55.00	57.6	55.0	2.0
Foreign Research Reactor	0.00	0.0	21.70	22.7	21.70	0.8
Non-DOE Domestic						
Domestic Research and Test Reactors[e]	2.22	<0.1	3.28	3.4	5.50	0.2
Special-Case Commercial SNF at non-DOE locations[f]	42.69	1.6	0	0	42.69	1.6
Total[g,h]	2646.27		95.53		2741.80	
Percent of 2035 total	96.5		3.5		100.0	

---

a. Source: Wichmann (1995). Changes to the spent nuclear fuel (SNF) inventory contained in the Draft Environmental Impact Statement were made to reflect updated inventories at domestic research and test reactors and to remove materials that are contact-handled (i.e., materials unirradiated or slightly irradiated).

b. The Nevada Test Site does not currently store or generate SNF and is not expected to generate SNF through 2035.

c. MTHM = metric tons of heavy metal. One MTHM equals approximately 2,200 pounds.

d. Existing inventory of naval SNF (10.23 MTHM) is included in the Idaho National Engineering Laboratory totals.

e. Includes research reactors at commercial, university, and government facilities.

f. The total inventory of SNF from special-case commercial reactors is 186.41 MTHM. The 42.69 MTHM indicated here is just that stored at the Babcock & Wilcox Research Center, Fort St. Vrain Reactor, and West Valley Demonstration Project. The remaining special-case commercial SNF is stored at the Idaho National Engineering Laboratory, Oak Ridge Reservation, Hanford Site, and Savannah River Site and is included in the totals (in this table) for those sites.

g. Changes to the fuel inventory occurred due to recalculation of the Idaho National Engineering Laboratory inventory at the Experimental Breeder Reactor-II and Hot Fuel Examination Facility and the removal of contact-handled fuel.

h. Numbers may not sum due to rounding.

Figure 1-2. Locations of principal spent nuclear fuel generators and storage sites.

Hanford Site-The Hanford Site was dedicated to producing plutonium for more than 40 years, until production was halted in 1989. Hanford's production reactors (including the N Reactor and Single-Pass Reactor) have generated 2100 MTHM of the existing DOE SNF. The ongoing actions at Hanford are focused on improving worker health and safety and protecting the environment. SNF management activities include reducing water contamination levels, performing physical upgrades necessary to assure facility safety for near-term storage, characterizing SNF condition, and stabilization or repackaging for storage and/or ultimate disposition.

The SNF at facilities associated with the Hanford Site include N-Reactor SNF, Single-Pass Reactor SNF, Shippingport Core II SNF, Fast Flux Test Facility SNF, and miscellaneous special-case commercial and experimental SNF. As shown in Table 1-1, the Hanford Site currently stores over 80 percent (by MTHM) of the current complex-wide SNF.

Idaho National Engineering Laboratory-The Idaho National Engineering Laboratory is one of the principal centers in the DOE complex for nuclear research and development. Ongoing activities include continued safe storage of SNF, continued reactor operations, and onsite fuel transfers to reduce identified vulnerabilities.

As a result of its historic mission, the Idaho National Engineering Laboratory has been safely managing SNF for over 40 years. This site is the home of the Expended Core Facility and the Naval Reactors Facility, which are central to the Navy's nuclear propulsion program. Currently, the site stores approximately 261 MTHM (about 10 percent) of DOE's SNF from a variety of DOE programs and a limited number of commercial and foreign sources.

Savannah River Site-The Savannah River Site was constructed in the early 1950s to produce the basic materials used in nuclear weapons-primarily plutonium and tritium.

Savannah River's production reactors have generated about 150 MTHM of the existing DOE SNF. Most of the SNF from Savannah River Site reactor operations is stored underwater in concrete, water-filled reactor storage basins. These reactor disassembly basins were originally intended for only short-term storage of production reactor SNF. Some of the SNF stored at Savannah River consists of uranium clad in stainless steel or zirconium alloy, which Savannah River Site cannot process without facility modifications. Ongoing activities include improving the use of existing storage facilities to provide for continued safe storage of the less corrosion-resistant aluminum-clad SNF. DOE currently manages approximately 206 MTHM (about 8 percent) of its SNF at the Savannah River Site.

Oak Ridge Reservation-The Oak Ridge Reservation was originally developed as part of the Manhattan Project-the effort to build the first nuclear weapons. The missions of Oak Ridge Reservation facilities include weapons dismantlement, storage of enriched uranium, maintaining production capability, technology research and development, and environmental management. Less than 1 MTHM (0.07 percent) of DOE's SNF is either in storage or being generated at several facilities at the Oak Ridge Reservation.

Other Department of Energy Sites-A number of other DOE sites also store SNF, principally from experimental and test reactors that have operated at many Department sites nationwide. Four of these DOE sites storing SNF are as follows:

Argonne National Laboratory-East has one reactor that is being decontaminated and decommissioned. This site currently manages 0.08 MTHM of SNF.

Brookhaven National Laboratory is generating and storing SNF at two facilities. The Brookhaven High Flux Beam Reactor and the Brookhaven Medical Research Reactor are both operating at the present time. This site currently manages 0.24 MTHM of the DOE's SNF.

Los Alamos National Laboratory has SNF at the Omega West Reactor, which has been shut down since December 1992. There is 0.014 MTHM of SNF in storage at Los Alamos.

Sandia National Laboratories have reactors that operate as needed. These reactors will generate small quantities (0.4 MTHM) of SNF when shut down and defueled.

1.1.2.3 Navy Nuclear Propulsion Program.

Naval SNF is removed from naval reactors at shipyards and prototype sites and placed in shielded shipping containers. Since 1957, the SNF removed from nuclear-powered naval vessels and prototypes has been transported from shipyards and prototype sites to the Naval Reactors Facility at the Idaho National Engineering Laboratory. The SNF is then removed from the shielded shipping containers and placed into a water pool at the Expended Core Facility. In the water pool, each naval fuel assembly receives, as a minimum, an internal and external visual examination to confirm that it performed as designed and to identify anomalies that would warrant more detailed examination. After examination, the SNF is loaded into shielded containers and transferred to the Idaho Chemical Processing Plant for storage.

Currently, four naval shipyards and one commercial shipyard (Norfolk, Puget Sound, Portsmouth, Pearl Harbor, and Newport News) and the Kesselring Site support the refueling of nuclear-powered ships and prototypes. Other naval shipyards that formerly supported defuelings and refuelings, such as Charleston and Mare Island, are being closed because of military base closure decisions. An existing water pool facility, constructed to support the refueling of nuclear-powered aircraft carriers, is located within the industrial zone of the Puget Sound Naval Shipyard. To date, the facility has been used for refueling equipment demonstrations and testing. The facility contains a radiologically controlled, high bay structure and a Personnel Support Building, which provides office and other nonradiological support functions. The high bay structure contains the water pool and general work areas. At Newport News, SNF is removed from naval vessels and temporarily stored near the removal site before transport.

1.1.2.4 Foreign Research Reactors.

In accordance with national nuclear nonproliferation goals, DOE has accepted (and is considering the renewal of the policy to accept) SNF that contains enriched uranium of United States origin that was used in foreign research reactors. In April 1994, DOE decided to accept up to 409 additional SNF elements from eight foreign research reactors in seven European countries for storage at the Savannah River Site. One hundred fifty-three of these elements were actually received before an order by the court in the case of South Carolina v. O'Leary, No. 3:94-2419-0 (District of South Carolina January 27, 1995) preventing the receipt of additional shipments. That order is currently on appeal to the United States Court of Appeal for the Fourth Circuit. The United States Government is currently considering the acceptance of SNF from approximately 40 nations. This foreign research reactor SNF is estimated to amount to 21.7 MTHM and is the subject of the Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel (see Section 1.2.5), due to be published in 1995.

1.1.2.5 Non-DOE Domestic.

This category includes non-DOE domestic, licensed facilities, including training, research, and test reactors at university, commercial establishments, and government-owned installations for which DOE has contractual obligations to accept SNF. Appendix E provides additional detail on these sites. These locations currently have less than 1 percent of the existing DOE SNF.

Domestic Research and Test Reactors-Fifty-seven domestic non-DOE facilities have been licensed by the U.S. Nuclear Regulatory Commission, 38 of which are expected to be small generators of DOE SNF during the next 40 years. These facilities include colleges, universities, government, and commercial establishments in the United States that use reactors for educational and research activities. The reactors are of several different types and are used for training, experimentation, and teaching in nuclear science and engineering. Some of these research sites have limited storage capacity compared with generation rates. Table 1-2 provides a summary of these locations, the SNF currently at these locations, and the amount of SNF they currently have stored plus projected generation through the year 2035.

Special-Case Commercial Power Reactors-DOE also has taken possession of SNF assemblies and complete or sectioned SNF rods from various commercial nuclear power reactors that were to be used to support DOE-sponsored research and development programs. By way of a three-party agreement among the Public Services Company of Colorado, General Atomics, and the Atomic Energy Commission, the DOE has agreed to provide dry storage at the Idaho National Engineering Laboratory for eight segments of Fort St. Vrain SNF (approximately 1,920 SNF elements). Three segments of this SNF have been transported to the Idaho National Engineering Laboratory; the other five are currently being stored at the Fort St. Vrain site. Other SNF in this category includes SNF from development reactors (Shippingport and Peach Bottom Unit 1); SNF used for destructive and nondestructive examination and testing; SNF remaining at the West Valley Demonstration Project; SNF from fuel performance testing at the Babcock & Wilcox Research Center; and special-case SNF debris (Three-Mile Island Unit 2).

Table 1-2. Summary of domestic research and test reactors.

Type	Number of locations	MTHM[a] (ROD[b])	MTHM[a] (2035)
Universities[c]	29	2.01	4.96
Government, non-DOE[c]	5	0.11	0.42
Commerical[c]	4	0.10	0.12
Total	38	2.22	5.50

---

a. MTHM = metric tons of heavy metal.
b. ROD = Record of Decision, June 1995.
c. See Appendix E of Volume 1 of this EIS for a discussion of these locations.

Table 1-3 summarizes the types and quantities of special-case commercial power reactor SNF in storage. This SNF currently is in storage at either the West Valley Demonstration Project in West Valley, New York, the Babcock & Wilcox Research Center in Lynchburg, Campbell County, Virginia, or the Fort St. Vrain facility in Colorado. Additionally, special-case commercial SNF (such as from Three-Mile Island, Peach Bottom, and Shippingport) is also stored at the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, and Oak Ridge Reservation.

1.1.3 Technologies for the Management of Spent Nuclear Fuel

DOE must safely manage SNF until its ultimate disposition. Some SNF, such as naval reactor fuel, was designed for long-term operation and to survive combat conditions; therefore, it is rugged enough to retain its integrity during prolonged storage. Commercial reactor fuel is also inherently stable and suitable for prolonged storage. The DOE will not select SNF technologies on the basis of Volume 1 of this EIS. These technology-based decisions are most appropriately dealt with on a fuel type-specific or site-specific basis.

Table 1-3. Special-case commercial power reactor spent nuclear fuel (SNF).

Storage location	Category	SNF in storage[a]	MTHM[b]
West Valley, NY	Light-water reactor fuel	125 elements	

			27
Lynchburg, VA	Light-water reactor partial fuel elements	3 full-length rods and 17 sectioned rods	0.044
Fort St. Vrain, CO	High-temperature gas-cooled reactor fuel	1,464 elements	16

---

a. No additions projected through 2035.
b. MTHM = metric tons of heavy metal. One MTHM equals approximately 2,200 pounds. (The approximate total of SNF currently at these locations is 43 MTHM.)

1.1.3.1 Storage.

Interim storage may be accomplished with either dry or wet storage technology. Wet storage normally involves the use of belowgrade water-filled pools. Dry storage places the SNF in a shielded container for aboveground storage. Dry storage technologies range from the use of casks, which hold only a few fuel elements, to vaults that are capable of holding a large quantity of fuel. Casks are normally constructed of steel or reinforced concrete, and vaults are normally constructed of concrete. For dry storage, a number of similar concepts have been used for commercial power reactor-type fuels and may be suitable for some of the DOE SNF. While both wet and dry storage are being evaluated for SNF management, dry storage has several unique advantages when heat dissipation is not a major concern. These advantages include lower emissions, simpler operation, lower cost, shorter times for design and construction, and capability for licensing by the U.S. Nuclear Regulatory Commission, if required.

1.1.3.2 Stabilization.

Stabilization may be necessary to provide safe interim storage of SNF. Stabilization technologies can be placed in three broad categories: containerization, processing without fissile material separation, and processing with fissile material separation. Containerization can involve processes such as canning, coating, and passivation. Canning involves placing the fuel in a sealed canister of durable construction (such as stainless steel). Coating involves depositing a protective film on the fuel to inhibit corrosion. Passivation involves treating the SNF to place exposed surfaces in a less reactive form when the SNF is stored in either water or air.

Processing without fissile material separation involves processes such as direct dissolving of the fuel elements or oxidation of the fuel elements. Oxidation involves separation of the fuel matrix from the cladding using oxygen at elevated temperatures [up to 800C (1,472F)]. The principal existing approach for processing with fissile material separation is aqueous processing. Aqueous processing involves breaking down the fuel through mechanical means (shearing, chopping, cutting) or chemical means (acid or electrolytic dissolution, combustion, hydrolysis) and then chemically separating the fuel constituents by solvent extraction. Aqueous processing would normally be followed by a vitrification process where the high-level waste is processed into a glass or ceramic form. The Savannah River Site currently has the capability to process aluminum-clad fuel.

Appendix J provides more details on fuel management technologies. Appendices A through F provide details on the storage and stabilization technologies evaluated for each of the potential SNF management sites. These technologies are representative of those discussed above. This EIS evaluates the environmental impact of these technologies to illustrate, at a programmatic level, the characteristic impacts from implementing each programmatic alternative.

The DOE will conduct additional National Environmental Policy Act reviews for research and development and characterization activities that help select technologies for placing the SNF in a form suitable for interim storage and ultimate disposition.

1.1.3.3 Transportation.

Depending on the SNF management options selected, some of the SNF may be moved one or more times before being transported. SNF is transported in massive, lead and steel shielded casks that can weigh above 100 tons. These casks must conform to both U.S. Nuclear Regulatory Commission and U.S. Department of Transportation regulations. Shipment by both rail cars and trucks is common, with the chief advantage of rail being the ability to transport heavier, more massive casks and, thus, transport more SNF per shipment.

The casks serve two functions: (a) providing gamma radiation shielding from the SNF so that the radiation level outside the casks meets regulatory requirements, and (b) providing protection to and containment of the SNF even in case of accidents. The casks are designed to withstand a wide range of very severe accidents. Because the SNF is generally metallic in form, most of the radionuclides stay within the metal fuel even in maximum foreseeable transportation accidents. The risks to both workers and the public have been evaluated many times, most recently in Appendix I of this EIS, and have been shown to be low.

1.1.3.4 Ultimate Disposition.

In the Nuclear Waste Policy Act, as amended, Congress established a national policy for disposal of high-level waste and commercial SNF in a geologic repository, and directed DOE to characterize the Yucca Mountain site in Nevada for suitability as the site of a first United States repository. That Act authorizes disposal of DOE SNF, as well as commercial spent fuel, in the first repository, subject to a limit on repository capacity and the payment of appropriate fees. For planning purposes, the DOE assumes that some or all of the SNF in its inventory that satisfies the repository's acceptance criteria could be placed in the first geologic repository developed under the Nuclear Waste Policy Act of 1982, as amended.

Although beyond the scope of this EIS, two broad strategies may at this point be envisioned for the ultimate disposition of DOE SNF. The DOE could (a) work toward direct disposal of SNF in a geologic repository, or (b) chemically dissolve the fuel and produce a waste form (such as vitrified glass) for repository disposal. Variations on these broad strategies are also possible, and both remain under consideration. It is possible that some of DOE's SNF could qualify for direct disposal. Aggressive characterization and, if appropriate, preparation programs would be necessary, and would need to be coordinated with plans to develop one or more repositories.

Sufficient quantity and quality of information is still not available to determine at this time whether the Yucca Mountain site is a suitable candidate for geologic disposal of SNF and high-level radioactive waste. The DOE, however, is in the early planning stages for a repository EIS, which will be prepared pursuant to the directives of the Nuclear Waste Policy Act of 1982, as amended. The DOE plans to issue in mid-1995 a formal notice of its intent to prepare this analysis. The repository EIS is being prepared to evaluate potential environmental impacts, based on the best available information and data, that would be associated with the repository's development and operation, and to support the Secretary of Energy's final recommendation to the President, as required by the Nuclear Waste Policy Act of 1982, as amended. The repository EIS will examine the site-specific environmental impacts from construction, operation, and eventual closure of the repository, including potential post-closure radiological effects to the environment. Until the repository EIS is complete, no final decision could be made concerning what DOE SNF would be accepted in a geologic repository.

As part of its SNF management program, DOE would (a) stabilize the SNF as needed to ensure safe interim storage, (b) characterize the existing SNF inventory to assess compliance with the repository acceptance criteria as they are developed, and (c) determine what processing, if any, is required to meet the criteria. Decisions regarding the actual disposition of DOE's SNF would follow appropriate review under the National Environmental Policy Act, and would be subject to licensing by the U.S. Nuclear Regulatory Commission. This "path forward" would be implemented so as to minimize impacts on the first repository schedule. The current planning assumption is that any DOE material (vitrified high-level waste and/or SNF) qualified and selected for emplacement in the first repository would be disposed beginning in the year 2015. Disposition of the remaining DOE SNF and vitrified high-level waste that is not emplaced in the first repository would not be decided until the DOE recommendation on the need for a second repository (which would consider such factors as the physical and statutory limits of the first repository). The Nuclear Waste Policy Act of 1982, as amended, requires DOE to make that recommendation between January 1, 2007, and January 1, 2010.

Except perhaps for a need to develop them further, the technologies described above for stabilization and safe storage are available for the management of SNF and appear adequate to meet the needs of ultimate disposition. Disposal in a repository, for example, may require canning, canisterization, encapsulation, or processing the fuel to create a vitrified waste form. Resource recovery requires dissolving the fuel to separate the fissile material from the waste and producing a stable waste form. These required technologies have already been applied and are under continued development in several countries. Once the acceptance criteria are established, the appropriate technologies can be identified and finalized to ensure that the SNF can be put in an acceptable form for ultimate disposal.

1.2 Relationship to Other

National Environmental Policy Act Documents

DOE currently has a range of National Environmental Policy Act reviews planned or under way that are interrelated with or tier from this SNF management review. Because the scope of SNF management includes a wide variety of proposals, multiple National Environmental Policy Act reviews are, or will be, necessary. Related reviews are identified in Table 1-4. Figure 1-3 graphically presents the interrelationships of the various National Environmental Policy Act reviews. Discussion in the following subsections centers primarily on reviews with an interrelationship with this SNF management review. The remaining documents in Table 1-4 are site-specific reviews of SNF management, or individual project reviews that have a relationship to SNF management.

Table 1-4. Major National Environmental Policy Act (NEPA) reviews related to Volume 1 of this Environmental Impact Statement (EIS) as of March 1995.

Site	Type of NEPA Review	Subject	Status
DOE		Waste Management Programmatic EIS	

(Headquarters)	EIS		In preparation
	EIS	Programmatic EIS for Tritium Supply and Recycling[a]	In preparation
	EIS	Stockpile Stewardship and Management EIS	Future
	EIS	EIS for a potential repository at Yucca Mountain for disposal of high-level radioactive waste	Future
	EIS	EIS on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel	In preparation
	EIS	Storage and Disposition of Weapons-Usable Fissile Materials	In preparation
	EIS	Fabrication and Deployment of a Multi-Purpose Canister-Based System for the Management of Civilian Spent Nuclear Fuel	In preparation
U.S. Navy	EA/FONSI[b]	Short-Term Storage of Naval Spent Nuclear Fuel (SNF)	Issued
West Valley Demonstration Project	EA	Management of SNF in Storage at the West Valley Demonstration Project (interim onsite dry storage)	In preparation
	EIS	West Valley Demonstration Project Completion and Site Closure	In preparation
Savannah River	EA/FONSI	Urgent-Relief Acceptance of Foreign Research Reactor SNF[c]	Issued
	EIS	Interim Management of Nuclear Materials at Savannah River Site	In preparation
Oak Ridge Reservation	EA/FONSI	High Flux Isotope Reactor SNF storage reracking	Issued
	EA	High Flux Isotope Reactor Dry Storage Pad	Future
Idaho National Engineering Laboratory	EIS	Programmatic SNF and Idaho National Engineering Laboratory Environmental Restoration and Waste Management, Volume 2	In preparation
	EA/FONSI[d]	Fort St. Vrain Fuel Shipments to the Idaho Chemical Processing Plant	Issued
	EA	Test Area North Pool Stabilization Project (also known as Dry Cask Storage Project)	In preparation
Nevada Test Site	EIS	Nevada Test Site and Other Off-Site Test Locations Within the State of Nevada Site-Wide EIS	In preparation
Hanford Site	EA/FONSI	105-KE and 105-KW Basins Fuel Encapsulation and Repackaging, 100-K Area	Issued
	EA	Transfer of Plutonium Uranium Extraction Plant and N-Reactor Irradiated Fuel for Encapsulation and Storage at the K-Basins	In preparation
	EA	Shutdown of the Fast Flux Test Facility	In preparation
	EA	Relocating TRIGA[e] Reactor Fuel from 308 Building (covers SNF, lightly irradiated fuel, and unirradiated fuel)	In preparation
	EA	Characterization of Stored Defense Production SNF and Associated Materials at Hanford Site, Richland, Washington	In preparation
	EIS	Hanford SNF Management EIS	Future
	EIS	Preparation of an EIS for Management of SNF from the K-basins at the Hanford Site, Richland, Washington	In preparation

---

a. The Nuclear Weapons Complex Reconfiguration Study was replaced by two separate National Environmental Policy Act reviews: the

Programmatic EIS for Tritium Supply and Recycling and the Stockpile Stewardship and Management Programmatic EIS.

b. Environmental Assessment (EA): A concise public document provided by a Federal agency that presents evidence and analysis for determining whether to prepare an EIS or a Finding of No Significant Impact (FONSI).

c. After the FONSI was issued, one shipment of foreign research reactor fuel was actually received in the U.S. A lawsuit by the State of South Carolina resulted in an order preventing the receipt of additional shipments (South Carolina v. O'Leary, No. 3:94-2419-0 (D.S.C. January 27, 1995). That order is currently on appeal to the United States Court of Appeal for the Fourth District.

d. The EA and FONSI were determined by the District Court to be inadequate. Volumes 1 and 2 of this EIS address shipments of Fort St. Vrain fuel.

e. TRIGA: Training, research, and isotope reactors built by General Atomics.

Figure 1-3. Interrelationships of National Environmental Policy Act reviews related to SNF management. Volume 1 of this EIS provides the overall programmatic National Environmental Policy Act review of the management of DOE SNF. This review and the Record of Decision will be summarized and incorporated in the DOE Waste Management Programmatic EIS, currently in development. Programmatic reviews for nuclear weapons disposition and weapons-usable fissile materials will also provide input to the DOE Waste Management Programmatic EIS. This SNF EIS will provide input to the EIS for the management of SNF from foreign research reactors. Except for special-case commercial reactors, commercial SNF is not evaluated in this SNF EIS. DOE is also preparing an EIS for a multipurpose canister system. Additional National Environmental Policy Act reviews for DOE and commercial SNF will be prepared as needed.

Table 1-4 and Figure 1-3 also identify site- or project-specific National Environmental Policy Act reviews currently planned or underway. This Volume 1 is a DOE-wide programmatic EIS covering a full range of strategic alternatives for the management of SNF. As such, this document is an upper tier EIS, intended to provide National Environmental Policy Act review of related and potential actions. By tiering National Environmental Policy Act documentation, DOE is able to look at the overall potential impact of a group of connected actions. Lower-tier reviews provide more specific and detailed analyses on specific sites and projects that stem from the programmatic decisions. The tiering of National Environmental Policy Act reviews as they relate to this SNF management review is shown schematically in Figure 1-3. This programmatic EIS does not replace site-specific or project-specific National Environmental Policy Act documentation, except where adequate coverage is provided in this EIS to evaluate reasonably foreseeable impacts. For the Idaho National Engineering Laboratory, the site-specific documentation is provided by Volume 2 of this EIS.

1.2.1 Waste Management Programmatic Environmental Impact Statement

DOE is currently analyzing nationwide and site-specific alternative strategies to maximize efficiency for DOE's waste management program. The nationwide analyses will be part of the DOE Waste Management Programmatic Environmental Impact Statement (PEIS) (previously known as the Environmental Management Programmatic Environmental Impact Statement). This PEIS evaluates proposed DOE actions regarding the

Type, size, and number of waste storage, treatment, and disposal facilities needed and where to build them, including the transportation network

Proposed action formulating and implementing an integrated Waste Management Program

Alternative configurations for each waste type (except hazardous waste) to provide a framework for siting future facilities at specific locations.

The alternatives are structured to ensure analysis of the impacts of the mixed waste configuration that will be defined in the site treatment plans developed pursuant to the Federal Facility Compliance Act.

The Draft Waste Management PEIS is scheduled to be available for public and agency review and comment by mid-1995. Although the DOE Waste Management PEIS was originally intended to provide the programmatic analyses of alternatives for SNF management, these analyses are also presented in this volume. The Waste Management PEIS is expected to summarize and consider, as part of its analysis of cumulative environmental consequences, the impacts of the SNF alternatives identified in this EIS.

1.2.2 Programmatic Environmental Impact Statement for Tritium Supply and Recycling

The Nuclear Weapons Complex Reconfiguration Program has evolved considerably since its original Notice of Intent to prepare a Nuclear Weapons Complex Reconfiguration PEIS was issued in February 1991. DOE has now separated the Nuclear Weapons Complex Reconfiguration EIS into two programmatic EISs: (a) a PEIS for Tritium Supply and Recycling (expected completion in November 1995) and (b) a Stockpile Stewardship and Management PEIS. In the original Notice of Intent, DOE proposed to reconfigure the Nation's nuclear weapons complex to be smaller, less diverse, and less expensive to operate. This proposal offered the advantage of enabling the closure and remediation of the Mound and Rocky Flats Plants. At that time, no new plutonium or highly enriched uranium storage facilities were envisioned, and a new tritium production facility was being planned as part of a separate New Production Reactor Program. Later, the New Production Reactor Program was incorporated into the Reconfiguration PEIS. DOE's needs have evolved since then for many reasons, but primary among them is the end of the Cold War. The tangible effects of this include the significant reduction in the size of the Nation's stockpile of nuclear weapons and reduced requirements for production of tritium.

Accordingly, the Tritium Supply and Recycling PEIS addresses alternatives associated with new tritium production and the recycling of tritium recovered from weapons being retired from the stockpile. Alternative technologies for producing tritium are planned to be analyzed at five candidate sites (Savannah River Site, Oak Ridge Reservation, the Pantex Plant, the Idaho National Engineering Laboratory, and the Nevada Test Site). The PEIS was issued in draft form February 28, 1995.

1.2.3 Stockpile Stewardship and Management Environmental Impact Statement

The Stockpile Stewardship and Management Environmental Impact Statement was originally part of the Nuclear Weapons Complex Reconfiguration Programmatic Environmental Impact Statement (see Section 1.2.2). DOE expects to begin the scoping process for the Stockpile Stewardship and Management PEIS in 1995. Stockpile stewardship includes activities required to maintain a high level of confidence in the safety, reliability, and performance of nuclear weapons in the absence of underground testing, and to be prepared to test weapons if directed by the President. Stockpile management activities include maintenance, evaluation, repair, or replacement of weapons in the existing stockpile. The review will take into account the latest information on current and projected future stockpile requirements.

1.2.4 Storage and Disposition of Weapons-Usable Fissile Materials Programmatic

Environmental Impact Statement

In response to the President's Nonproliferation and Export Control Policy issued on January 24, 1994, the Department created a separate Department-wide project for developing recommendations and for directing implementation of decisions concerning disposition of excess nuclear materials. Through this PEIS, DOE proposes to develop a comprehensive national policy for the management and disposition of fissile materials (primarily separated plutonium and highly enriched uranium, but also other excess nuclear materials including neptunium, americium, and uranium-233) that are no longer required for military purposes.

1.2.5 Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research

Reactor Spent Nuclear Fuel Environmental Impact Statement

DOE proposes to adopt and implement a policy concerning management of SNF containing enriched uranium that originated in the United States and was used by foreign research reactors. Under the proposed policy, the United States may manage approximately 22,750 elements (19.2 MTHM) of high-enriched uranium or low-enriched uranium SNF during a 10-year period from foreign research reactors in approximately 40 nations. Alternative methods of implementing the proposed action and the No Action alternative are being analyzed in an EIS. DOE will not make a final decision on the acceptance of SNF from these foreign research reactors until after the EIS for the Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor SNF and this programmatic SNF EIS are both completed. Both of these EISs are scheduled to be completed in 1995.

The proposed action would support the nuclear nonproliferation policy of the United States by removing the highly enriched uranium from these reactors from international commerce. The implementation of this policy could result in the receipt of foreign research reactor SNF at one or more United States points of entry and overland transport to one or more DOE sites for storage and/or processing.

1.2.6 Fabrication and Deployment of a Multipurpose Canister-Based System for the

Management of Civilian Spent Nuclear Fuel Environmental Impact Statement

This environmental impact statement is addressing the potential environmental impacts associated with alternative systems for storage and transport of SNF assemblies for civilian and naval SNF. The review will analyze the following: (a) manufacturing of multipurpose canister system components, (b) packaging and handling of SNF as it is transferred to canisters or casks, (c) canister transfer and loading operations, (d) storage of SNF in canisters and casks at the reactor sites, (e) SNF transport from the reactor sites to a hypothetical monitored retrievable storage facility and/or repository, (f) handling and storage of SNF at a hypothetical monitored retrievable storage facility, and (g) surface activities involving the handling and disposal of SNF at a repository.

The multipurpose canister-based technology may have application for DOE and Navy SNF.

1.2.7 Environmental Impact Statement for a Potential Repository at Yucca Mountain for

Disposal of High-Level Radioactive Waste

Under the Nuclear Waste Policy Act of 1982, as amended, DOE is investigating the suitability of the Yucca Mountain, Nevada, site as the nation's first licensed geologic repository for SNF and high-level radioactive waste. The Nuclear Waste Policy Act of 1982, as amended, requires that DOE's recommendation of a repository site to the President must be accompanied by an EIS. DOE has tentatively scheduled the Notice of Intent for the repository EIS for 1995 and the Record of Decision for 2000. Yucca Mountain is a potential disposal site for DOE SNF.

1.3 Scope of this Volume

1.3.1 Scoping Process

On October 22, 1990, DOE published a Notice of Intent in the Federal Register announcing its intent to prepare a PEIS addressing environmental restoration and waste management (including SNF management) activities across the entire DOE complex. DOE then invited the public to submit written comments on the scope of the PEIS, held 23 scoping meetings across the country, and issued a draft Implementation Plan in January 1992 reflecting the comments provided. DOE held six regional public workshops on the draft Implementation Plan and recorded public comments given at these workshops. The Implementation Plan for the PEIS was issued in January 1994 and addressed the comments received from scoping and the regional workshops.

On October 5, 1992, DOE published a Notice of Intent to prepare an EIS for Environmental Restoration and Waste Management at the Idaho National Engineering Laboratory in the Federal Register. The notice invited Government agencies and the public to participate in five scoping meetings throughout Idaho and to provide written comments. Oral testimony from the meetings was transcribed and made available at DOE public reading rooms. The comment period lasted from October 5, 1992, to December 4, 1992.

On September 3, 1993, DOE published a Notice of Opportunity to Comment in the Federal Register proposing to expand the scope of the Idaho National Engineering Laboratory Environmental Restoration and Waste Management EIS to include impacts related to transportation, receipt, processing, and storage of DOE SNF at locations other than the Idaho National Engineering Laboratory. This comment period started on September 3, 1993, and ended on October 4, 1993. Government agencies and the public were invited to provide comments on the DOE Programmatic SNF and the Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs EIS. A toll-free telephone number was provided for questions, requests for documents or other information, and for the public to provide oral comments that were transcribed for DOE's consideration. The Implementation Plan (issued October 29, 1993, and amended on May 9, 1994) for this EIS summarizes these comments and DOE's responses.

As existing large-scale SNF management operations, the Hanford Site at Richland, Washington; the Idaho National Engineering Laboratory in southeastern Idaho; and the Savannah River Site near Aiken, South Carolina, were logically identified as reasonable site alternatives for SNF management in the October 29, 1993, Implementation Plan. In addition, four Navy shipyards and the Kesselring Site (in West Milton, New York) with years of SNF handling experience were identified for consideration in the EIS for activities limited to naval SNF. The four Navy shipyards are the Norfolk Naval Shipyard, Portsmouth, Virginia; the Portsmouth Naval Shipyard, Kittery, Maine; the Pearl Harbor Naval Shipyard, Honolulu, Hawaii; and the Puget Sound Naval Shipyard, Bremerton, Washington.

In response to public scoping comments, DOE committed to consider other sites for SNF management in an effort to broaden the range of reasonable alternatives for locations at which SNF management activities could be conducted. DOE developed a screening process, which resulted in selection of the Oak Ridge Reservation, near Oak Ridge, Tennessee, and Nevada Test Site, near Mercury, Nevada, as additional site alternatives for regionalized or centralized SNF management (DOE-ID 1994). The EIS Implementation Plan was amended on May 9, 1994, to reflect this addition.

1.3.2 Scope

1.3.2.1 Programmatic Spent Nuclear Fuel Disposition.

The DOE will not analyze the ultimate disposition of SNF in this EIS. The focus of this Volume 1 of the EIS is the management of SNF in a safe and environmentally sound manner until decisions regarding its ultimate disposition are made and implemented. Decisions regarding the actual disposition of DOE's SNF will follow appropriate review under separate National Environmental Policy Act documentation. Congress has mandated that the Federal Government pursue the development of mined geologic repositories for the permanent disposal of SNF and high-level waste, and has directed DOE to study the Yucca Mountain, Nevada, site to determine whether it is a suitable site. Ultimate disposition of DOE SNF, however, is outside the scope of this programmatic SNF EIS.

1.3.2.2 Programmatic Spent Nuclear Fuel Stabilization.

DOE is phasing out reprocessing activities because of decreased demand for the recovery and reuse of certain nuclear materials. Fuel stabilization activities potentially required for safe interim storage and management of SNF, such as canning of some degraded fuels or processing as necessary, are relevant to the safe storage of SNF and within the scope of this EIS. Worker safety, public health, and potential environmental impacts associated with SNF stabilization, research and development of technologies, and pilot programs are topics of importance in analyzing the appropriate alternatives for interim storage of SNF and are included in this EIS.

In April 1992, the Secretary of Energy directed that DOE phase out defense-related chemical separations activities due to a reduction in the demand for new material for nuclear weapons (Claytor 1992). DOE no longer produces plutonium-239 and highly enriched uranium, and, in December 1994, DOE committed to prohibit the use of plutonium-239 and highly enriched uranium separated and/or stabilized during the phaseout, shutdown, and cleanout of weapons complex facilities for nuclear explosives purposes (Reis and Grumbly 1994). However, the use of chemical separations or other processing technologies is a reasonable site-specific option to assure the safe interim management of some types of SNF (or its constituents). Selection of chemical processing as a potential management option will be made after detailed analyses in site-specific National Environmental Policy Act reviews tiered from this EIS. Specific technologies for managing SNF are described in Volume 1, Appendix J. The potential impacts from a representative processing technology have been evaluated to aid in the analysis of reasonable technology options for interim storage of SNF and are included in this EIS. The DOE selected chemical separations for stabilization of degrading SNF as the technology for evaluation. The DOE believes the impacts from this activity are representative of the overall potential impacts of other similar technologies. This EIS assesses the impacts of processing only at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site because DOE determined it would require significant resources to consider undertaking such processing activities at sites with no facilities or infrastructure to support these processes. Processing operations that modify the SNF form to create new forms suitable for interim storage are much more complex than the activities associated with either dry storage or wet storage of intact SNF. For example, processing by chemical separation requires large-scale facilities for: SNF storage, SNF dissolution and chemical element separation operations, liquid high-level waste storage, storage for special nuclear material, and facilities to process the liquid high-level waste into a stable form, for example, vitrification, for storage. Additionally, all these facilities must be supported by a complex infrastructure of services and utilities. The Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site have some or all these facilities and all of the infrastructure for these types of operations. The other sites (that is, Nevada Test Site and Oak Ridge Reservation) lack this level of plant facilities or high-level waste infrastructure. The cost alone to create this level of capability makes evaluating the other sites less than desirable. Construction of the necessary high-level waste infrastructure is estimated to be several billion dollars.

1.3.2.3 Programmatic Spent Nuclear Fuel Storage.

Current and projected DOE SNF inventories are considered in this EIS. Existing storage facilities are identified, and their status, capacities, and accident histories are described. SNF container design, integrity, corrosion and corrosion byproducts, storage technologies, and storage facility design life are factored into the EIS analysis for each alternative. Storage options at the site of generation and other storage options are analyzed. The analysis of the storage options for each alternative includes the estimated type and size of representative storage facilities potentially needed at each site.

1.3.2.4 Programmatic Spent Nuclear Fuel Transportation.

The EIS includes an analysis of the potential impacts of SNF transportation, including safety and emergency preparedness requirements. A review of the safety record for past SNF transportation activity is included, along with an analysis of potential transportation impacts from normal transport and from transportation accidents.

Transportation modes and routes deemed reasonable for SNF shipment have been analyzed to estimate potential risks to worker safety, public health, and the environment. Federal and state regulations that place restrictions on certain aspects of SNF shipment and limits on shipment size, types of containers, and number of shipments have been accounted for in the analyses. Hazardous materials manifests, required for each shipment of SNF, include information on the carrier, the materials involved and their characteristics, and the containers.

The potential impacts of transporting nuclear fuel for ultimate disposition will be included in the appropriate National Environmental Policy Act documentation. Therefore, an alternative to transport SNF directly to a repository is not considered in this EIS.

1.3.2.5 Special-Case Commercial Fuels.

This EIS addresses the management of certain small quantities of special-case commercial SNF for which DOE has responsibility. Some of this SNF is currently being managed at DOE facilities; some is being managed at non-DOE facilities.

1.3.2.6 Naval Spent Nuclear Fuel.

This EIS addresses the impacts of and alternatives to transporting, receiving, and storing SNF from naval reactors (Navy warships and reactor prototypes) at a number of sites across the country, including sites near the point of refueling or defueling. The analysis includes alternative sites for naval fuel examination, as well as the possibility of phasing out this examination. This EIS addresses existing naval SNF inventories and fuel to be generated from future refuelings and defuelings.

1.4 Response to Public Comments

Volume 3, Response to Public Comments, was added to this EIS to fully address and respond to public comments. In addition, DOE considered public comments, along with other factors such as programmatic need, technical feasibility, and cost, in arriving at DOE's preferred alternatives. During the public comment period for the Draft EIS, more than 1,430 individuals, agencies, and organizations provided DOE with comments. A broad spectrum of private citizens; businesses; local, state, and Federal officials; Native American tribes; and public interest groups are represented within this volume of comments. Comments were received from all affected DOE and shipyard communities.

Volume 3 summarizes the comments on the EIS received by DOE during the public comment period and provides responses to those comments. In addition, Volume 3 explains how public comments influenced the selection of the preferred alternatives, discusses the extent to which public comments resulted in changes to the EIS, and describes how to find specific comment summaries and responses in this volume.

Responses to comments consist of two parts. The first part summarizes the comment(s), and the second part responds to the comment(s). Identical or similar comment(s) were frequently provided by more than one commentor and, in such cases, DOE grouped the comments and prepared a single response for each group. This summarization was also appropriate due to the large volume of comments received.

In compliance with National Environmental Policy Act and Council on Environmental Quality regulations, public comments on the Draft EIS were assessed and considered both individually and collectively by DOE and the Navy. Some comments resulted in modifications in the EIS or explanations of why comments did not warrant further response. Most comments not requiring a change to the EIS resulted in a response to correct factual misinterpretations, to explain or communicate government policy, to clarify the scope of the EIS, to explain the relationship of the EIS to other related policy, to clarify the scope of the EIS, to explain the relationship of the EIS to other related National Environmental Policy Act documentation, to refer commentors to information in the EIS, to answer technical questions, or to further explain technical issues. The Record of Decision will include the decision made by the Secretary of Energy, which will consider public comments on the Draft EIS.

1.4.1 How DOE Considered Public Comments in the National Environmental Policy Act Process

As required in the Council on Environmental Quality regulations [40 CFR 1502.14(e)], DOE's preferred alternatives are identified in the Final EIS. The preferred alternatives for Volumes 1 and 2 were identified based on the consideration of environmental impacts, regulatory compliance, DOE and SNF programmatic missions, public issues and concerns, national security and defense, cost, and DOE policy. Public input considered in the decisionmaking and preferred alternatives selection process included concerns, desires, and opinions regarding the activities addressed in the EIS and expectations of DOE in making the management decisions on complex-wide programmatic SNF management and environmental restoration and waste management programs at the Idaho National Engineering Laboratory. Public input contributed to the development of performance factors, defined as desirable attributes or characteristics that measure the relative acceptability of alternatives, which were used to select candidate preferred alternatives. The candidate preferred alternatives were then evaluated against a number of technical and nontechnical sensitivities, including public perception of environmental impact, indicated stakeholder preferences, implementation flexibility, regulatory risk, SNF processing potential, environmental justice, potential resistance to implementation, and fairness. DOE's preferred alternative reflects DOE consensus that SNF should be actively managed in preparation for ultimate disposition. In addition, DOE's preferred alternative supports the implementation of a path forward for the ultimate disposition of SNF, a significant issue raised by the public. The EIS, including its preferred alternatives, will be considered by the Secretary of Energy, along with other factors, in arriving at a decision to be documented in a formal Record of Decision.

1.4.2 Changes to the Environmental Impact Statement Resulting from Public Comment

A major purpose of the National Environmental Policy Act is to promote efforts that will prevent or eliminate damage to the environment by ensuring informed decisionmaking on major Federal actions significantly affecting the quality of the human environment. Consideration of public comments on the Draft EIS helps to ensure that the EIS is an adequate decisionmaking tool; accordingly, this EIS has been enhanced, as appropriate, in response to public comments. While a number of specific issues and concerns were raised by commentors, none of the issues or concerns identified new reasonable alternatives requiring assessment or resulted in significant change in the results of the analysis of the potential environmental consequences.

Based on review of public comments, coupled with the consultations held with commenting agencies as well as State and tribal governments, the main EIS enhancements include the following:

Seismic and water resources discussions were reviewed, clarified, and enhanced for all alternative sites, and current data and analyses were added to Volumes 1 and 2, as appropriate.

A discussion of potential accidents caused by a common initiator was added. The option of stabilizing some of DOE's SNF (specifically from the N Reactor) by processing it at available facilities located overseas was added, thus enhancing the processing options discussed in the EIS. An analysis of barge transportation was added to the EIS, with respect to the option of transporting N-Reactor fuel to a shipping point for overseas processing, as well as to support the potential transport of Brookhaven National Laboratory SNF to another site, as appropriate.

In addition, an analysis of shipboard fires was added, primarily in response to comments related to receiving SNF containing uranium of U.S. origin from foreign research reactors.

In Volume 2 of the EIS, the air quality analysis was revised to upgrade the existing baseline conditions and impacts of alternatives in terms of the amount of Prevention of Significant Deterioration (PSD) increment consumed, thus updating the baseline conditions presented for the Idaho National Engineering Laboratory. Additionally, the Waste Experimental Reduction Facility project summary was enhanced and clarified. This EIS was also revised to reflect current projections of employment, including the projected downsizing of the Idaho National Engineering Laboratory due to contractor consolidation.

In response to public comments, a brief summary of the results of a separate evaluation of the costs of the various alternatives was added to the EIS, although the cost evaluation was performed independently of the EIS for additional purposes. The discussion of the options regarding the management of Fort St. Vrain SNF currently stored in Colorado has been expanded. As committed to in the Draft EIS, the evaluation and discussion of environmental justice has been expanded in both Volumes 1 and 2 of the EIS. This analysis was based on interim DOE guidance in the absence of interagency policy in this regard and reflects limited public comments received regarding environmental justice. Consultation with the commenting Native American tribes is reflected in the environmental justice analysis, as well as in the various sections of the EIS, as appropriate.

Other enhancements include a clarification that potential shipment of SNF containing uranium of U.S. origin from foreign research reactors consists of a bounding estimate of 22 MTHM.

In addition, as a result of public comments, Volume 1 of the EIS was enhanced to clarify the relationship between current DOE National Environmental Policy Act actions and this EIS. Likewise, the relationship between the EIS and the Spent Fuel Vulnerability Action Plans was clarified in this EIS. With respect to the naval SNF, Appendix D of Volume 1 was modified to more fully explain the import of naval SNF and to discuss potential effects of terrorist attacks at naval shipyards.

2. PURPOSE AND NEED FOR AGENCY ACTION

DOE, according to the Atomic Energy Act of 1954, as amended, is responsible for developing and maintaining a capability to manage nuclear materials [Atomic Energy Act Sections 11(z), 11(aa), and 11(e)]. During the last four decades, DOE and its predecessor agencies have transported, received, stored, and reprocessed approximately 100,000 MTHM of SNF from various sources, including DOE production reactors; the Naval Nuclear Propulsion Program; DOE, university, and other research and test reactors; special case commercial power reactors; and certain foreign research reactors. Approximately 2,700 MTHM of SNF was not reprocessed and is stored at various locations in the United States and overseas. Approximately 100 MTHM of additional SNF is projected to be received in the next 40 years. This SNF is in a wide range of enrichments, types, and conditions.

The end of the Cold War led DOE to reevaluate the scale of its weapons production, nuclear propulsion, and research missions. In April 1992, the Secretary of Energy directed DOE to phase out reprocessing of SNF for recovery and recycling of plutonium and highly enriched uranium to support the nuclear weapons stockpile. In 1993, a DOE report[a] documented current and potential environmental, safety, and health vulnerabilities regarding existing DOE SNF storage facilities. The report identified locations with degraded fuel cladding integrity and other problems that require action to ensure continued safe storage. As a result of the Secretary's directive and the information in the DOE report, the proposed action is to safely, efficiently, and responsibly manage existing and projected quantities of spent nuclear fuel through the year 2035, pending ultimate disposition.

As part of establishing an effective SNF Management Program, DOE needs to make complex-wide strategic decisions for the management of SNF for the next 40 years, including (a) where to conduct SNF management activities, after evaluating existing and potential locations, (b) the appropriate capabilities, facilities, and technologies for SNF management, and (c) the research and development activities to support the SNF Management Program.

Volume 1 of this EIS focuses on strategies for where to conduct SNF management activities as in (a) above. Decisions on the site-specific and technical implementation of the program, as in (b) and (c) above, would be made after subsequent, tiered National Environmental Policy Act reviews, as appropriate.

---

[a] Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and Other Reactor Irradiated Nuclear Materials and Their Environmental, Safety and Health Vulnerabilities (DOE 1993b.)

3. ALTERNATIVES

Chapter 3 describes a range of programmatic alternatives for managing the DOE SNF currently stored within the DOE complex and at non-DOE generator sites. These alternatives also address SNF that is projected to be generated through the year 2035. Figure 1-2, given in Chapter 1, identifies locations within the United States where DOE SNF is being generated and stored.

The five alternatives analyzed in Volume 1 of this EIS are summarized in the box to the right. These alternatives, which are consistent with the alternatives under consideration for the DOE Waste Management Programmatic EIS, present a range of programmatic approaches for managing existing and projected SNF inventories. The alternatives involve varying amounts of SNF shipments, levels of fuel stabilization, numbers and types of storage facilities, and the scope of research and development efforts for SNF management technologies.

Summary of Alternatives for the Management of DOE Spent Nuclear Fuel

No Action

Take minimum actions required for safe and secure management of SNF at or close to the generation site or current storage location.

Decentralization

Store most SNF at or close to the generation site or current storage location, with limited shipments to DOE facilities.

1992/1993 Planning Basis

Transport and store newly generated SNF at the Idaho National Engineering Laboratory or Savannah River Site. Consolidate some existing fuels at the Idaho National Engineering Laboratory or at the Savannah River Site.

Regionalization

Distribute existing and projected SNF among DOE sites based primarily on fuel type (Regionalization 4A) or geographic location (Regionalization 4B).

Centralization

Manage all existing and projected SNF inventories at one site until ultimate disposition.

The programmatic action that DOE ultimately selects is not necessarily limited to one of the alternatives presented. A hybrid alternative could, for example, be developed that would incorporate actions from one or more of the five alternatives analyzed. Moreover, the programmatic decisions will not identify all site-specific SNF management options. If appropriate, the decisions would be made after additional site-specific National Environmental Policy Act evaluations.

In developing the alternatives, the need to comply with applicable regulations, permits, and DOE orders was assumed. Under some of the alternatives (for example, No Action and Decentralization), DOE would be required to renegotiate existing commitments to accept SNF from utilities (for example, Fort St. Vrain), domestic research reactor SNF, and potential agreements to accept foreign research reactor SNF.

Under all alternatives, actions to resolve outstanding SNF management deficiencies identified and prioritized according to the Defense Nuclear Facilities Safety Board Recommendation 94-1 Implementation Plan would be implemented as appropriate. The Defense Nuclear Facilities Safety Board 94-1 Implementation Plan will be balanced with other factors such as budgetary constraints and public comments. Under all alternatives, DOE would consider ways to reduce costs for the management of SNF.

Some of the alternatives include references to transition periods. These can be defined as the periods of time needed to fully implement the alternative, if selected. Transition periods vary from 3 to 20 years depending on the time required to plan, design, procure, or construct equipment and facilities needed to fully implement the alternative. Activities taking place during transition periods would be similar to anticipated activities associated with one or more of the defined alternatives. Therefore, environmental impacts of transition period activities are bounded by the impacts assessment for the defined alternatives.

The DOE SNF Management Program is intended to (a) provide interim storage and management for SNF at specified locations until ultimate disposition, (b) stabilize the fuel as required for environmentally safe storage and protection of human health (for both workers and the public), (c) increase safe storage capacity, replacing facilities that cannot meet current standards and provide additional capacity for newly generated SNF, (d) conduct research and development initiatives to support safe storage and safe disposal, and (e) examine SNF generated by the Naval Nuclear Propulsion Program. The possible need to convert SNF into a form that meets the acceptance criteria of geologic repositories is beyond the scope of this EIS and will be the subject of future National Environmental Policy Act review.

The planning period for this EIS is 40 years, beginning with the issuance of the Record of Decision (that is, baseline conditions in June 1995) and extending through the year 2035. The 40-year timeframe may be required to make and implement decisions on the ultimate disposition of SNF. Detailed impact analyses are performed for the time period from 1995 to 2005. Normal operation impacts are then projected for the remaining 30 years.

Decisions as a result of this EIS apply to actions taken by DOE and the Navy from the date of the Record of Decision through the interim storage period. At the present time, intersite shipments of DOE SNF have been curtailed. However, limited shipments of SNF from Navy shipyards have occurred during the preparation of the EIS. Shipments from sources such as universities and foreign research reactors needing urgent relief have also occurred. These shipments are in accordance with existing court orders, Federal facility compliance agreements, and Council on Environmental Quality regulations. If the No Action alternative is selected in the Record of Decision, all such shipments would cease after an appropriate transition period.

After considering a number of elements, DOE has identified Regionalization 4A (management by fuel type) as the preferred alternative. DOE arrived at its preferred alternative through a formal decision management process, which included developing screening and performance criteria. Screening criteria are requirements that an alternative must satisfy to be further evaluated; performance criteria are desirable attributes or characteristics that help distinguish the relative merit of each alternative that satisfies the screening criteria. After applying the screening criteria, additional management considerations (technical and nontechnical), discussed below, were used to arrive at the final preferred alternative.

The screening and performance criteria were developed considering the following factors: (a) environmental impact, (b) environmental regulatory compliance, (c) DOE and SNF programmatic missions, (d) public comments, (e) national security mission, (f) cost, and (g) DOE policy.

Each alternative was first evaluated based on the following screening criteria:

Resolving vulnerabilities consistent with DOE's Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities (DOE 1994a, b, c)

Complying with all applicable Federal and state environmental laws and regulations, consent orders, and Federal facility agreements

Maintaining backup capabilities for SNF management to limit interruptions of vital SNF program activities

Providing the capability for 100 percent examination of naval SNF

Providing technology development for SNF treatment, storage, and ultimate disposition.

Those alternatives that did not satisfy all of the screening criteria were not considered further, and these were No Action, Decentralization A and B, and Centralization. The remaining alternatives, 1992-93 Planning Basis, Decentralization C, and Regionalization 4A and 4B, met all of the screening criteria. These alternatives were then evaluated based on optimizing overall performance relative to the following performance criteria:

Minimizing transport of SNF

Minimizing environmental impact

Assuring lowest cost consistent with mission accomplishment

Maximizing support for DOE's National SNF Program to achieve safe storage and preparation for final disposition

Maximizing DOE's ability to honor new and historical commitments and contracts.

Applying these performance criteria, two of the four remaining alternatives, 1992-93 Planning Basis and Regionalization 4A, rated the highest, so they were determined to be candidates for the preferred alternative. These candidate alternatives were then evaluated against a number of technical and nontechnical considerations, including environmental impact perception, indicated stakeholder preferences, implementation factors, regulatory risk, SNF processing potential, environmental justice, and fairness. This final evaluation resulted in Regionalization 4A being identified as the preferred alternative, because Regionalization 4A better supports a path forward for ultimate disposition of the SNF. Additional information on this alternative can be found in Section 3.1.4.

While the Nevada Test Site is analyzed in this EIS as an alternative site for SNF management activities, DOE did not consider it to be a preferred site for the management of SNF because of the State of Nevada's current role as the host site for the Yucca Mountain Site Characterization Project and the Nevada Test Site's lack of SNF management facilities and high-level waste infrastructure.

The DOE's preferred alternative is consistent with the Navy's preferred alternative to continue to conduct refueling and defueling of nuclear-powered vessels and prototypes, and to transport SNF to the Idaho National Engineering Laboratory for full examination and interim storage, using the same practices as in the past. Details and analyses supporting the Navy's preferred alternative can be found in Appendix D of Volume 1.

The remainder of this chapter is comprised of three sections. Section 3.1 summarizes the alternatives and the implications for each site. Section 3.2 discusses the alternatives eliminated from further evaluation. Section 3.3 provides a brief comparison of the potential environmental impacts associated with each alternative.

3.1 Overview of Alternatives Considered

Section 3.1 and Tables 3-1 through 3-5 discuss the potential actions at each site as a result of implementing each of the alternatives.

Table 3-1. Summary of the No Action alternativeTable 3-2. Summary of the Decentralization alternative.Table 3-3. Summary of the 1992/1993 Planning Basis alternativeTable 3-4. Summary of the Regionalization alternative.Table 3-4. Summary of the Regionalization alternative (cont.).Table 3-5. Summary of the Centralization alternative.Table 3-5. Summary of the Centralization alterantive (cont.).

No Action Alternative

Take minimum actions required for safe and secure management of SNF at or close to the generation site or current storage location.

After an approximate 3-year transition period, no transport of SNF to or from DOE facilities would occur.

Stabilization activities would be limited to the minimum actions required to safely store SNF.
Naval reactor SNF would be stored at naval sites.
Facility upgrade/replacement and onsite fuel transfers would be limited to those necessary for safe interim storage.
Existing research and development activities would continue.

3.1.1 No Action

The No Action alternative is an alternative required under the Council on Environmental Quality regulations for implementing the National Environmental Policy Act of 1969. Under the No Action alternative, DOE would limit actions to the minimum necessary for safe and secure management of SNF at the generation site or current storage location. Under this alternative, small and large DOE sites, naval sites, university and other non-DOE domestic reactors, and foreign research reactors would all independently manage their SNF onsite. Generally, after an appropriate transition period SNF shipments between sites for management purposes would be discontinued, including those SNF shipments currently allowed by court orders and Federal facility compliance agreements. Figure 3-1 indicates SNF inventories. The technology development activities related to SNF management, limited to activities already approved, would continue within DOE. Figure 3-1 also shows the distribution of fuel from 1995 through 2035.

The following subsections highlight actions associated with the No Action alternative at the sites being considered for SNF management.

3.1.1.1 Hanford Site.

Under the No Action alternative at the Hanford Site, only those actions deemed necessary for the continued safe and secure management of the SNF would be carried out. Thus, the existing SNF would be maintained close to its current storage locations and there would be minimal facility upgrades. Activities required to safely store SNF would continue.

Specific actions proposed for the near term include proceeding with the characterization of defense production reactor fuel to establish safe interim storage limits, containerizing the fuel in the 105-KE reactor basin by 1998, procuring the first 10 dry storage casks for the Fast Flux Test Facility, transferring SNF to dry cask storage if required for safety reasons (with emphasis on Fast Flux Test Facility fuel now stored in liquid sodium), and possibly consolidating SNF from defense production at the 105-KW reactor basin.

Figure 3-1. Spent nuclear fuel distribution, location, and inventory for the No Action alternative.

No new facilities are planned under the No Action alternative.

3.1.1.2 Idaho National Engineering Laboratory.

For the No Action alternative, DOE would maintain SNF close to defueling or current storage locations with minimal facility upgrades or replacements. The Idaho National Engineering Laboratory would neither receive nor transport SNF except for naval SNF during a transition period of about 3 years (see Section 3.1.1.6). After the transition period, naval SNF would not be transferred to the Idaho National Engineering Laboratory, and the Expended Core Facility at the Idaho

National Engineering Laboratory would be shut down. DOE would continue to transfer onsite SNF to the Idaho Chemical Processing Plant until the existing storage capacity is used.

DOE would continue operating existing SNF-related facilities at the Idaho National Engineering Laboratory. Because of the deteriorated condition of some of the fuel stored underwater in the CPP-603 Underwater Fuel Storage Facility, additional characterization and canning capabilities would be necessary to stabilize the fuel for safe transport and subsequent storage. DOE has scheduled the installation and operation of new fuel characterization and canning equipment in the Irradiated Fuel Storage Facility by late 1995 to provide these capabilities. DOE would perform other required stabilization of SNF at the Idaho National Engineering Laboratory in either the Remote Analytical Laboratory or the Fluorinel Dissolution Process Hot Cell. DOE would not start any new projects to increase SNF interim storage capacity.

SNF research and development would be limited. Existing SNF management research and development projects would continue, but the development of technology for the ultimate disposition of SNF would cease. Existing facilities, such as the Process Improvement Facility, the Remote Analytical Laboratory, and the Pilot Plant Facility, would support continuing research and development work.

3.1.1.3 Savannah River Site.

For the No Action alternative, DOE would use the existing Savannah River Site facilities for extended wet storage of its current SNF inventories. The Savannah River Site would not transport any SNF offsite and would not receive any SNF. Only onsite consolidation and rearrangement would take place. DOE would temporarily move fuel currently on the Savannah River Site among facilities to accommodate facility upgrades.

Six Savannah River Site facilities are used for the storage of SNF: the Receiving Basin for Offsite Fuel, K-Reactor Disassembly Basin, L-Reactor Disassembly Basin, P-Reactor Disassembly Basin, F-Canyon, and H-Canyon. Most of the fuel is located in the Receiving Basin for Offsite Fuel, the L-Reactor Disassembly Basin, and the F-Canyon. DOE would accomplish onsite transfers as required to ensure the safety of aluminum-clad fuel. The Receiving Basin for Offsite Fuels and an upgraded reactor basin would be utilized for continued storage of this fuel. Additionally, DOE would place the aluminum-clad fuel, which is degrading because of corrosion, in containers to minimize the spread of radioactive material in the pools in case the cladding is breached. DOE would continue existing SNF-related research and development.

3.1.1.4 Oak Ridge Reservation.

Under the No Action alternative, the Oak Ridge National Laboratory, which is on the Oak Ridge Reservation, would generate and store SNF as a result of reactor research activities. No SNF would be transported to the Oak Ridge Reservation, and no SNF would be transported offsite. SNF would be stabilized, as necessary, to ensure safe storage. Oak Ridge Reservation research and development activities would continue as planned except that the alternative could lead to the shutdown of the High Flux Isotope Reactor as a result of filling the existing SNF storage capacity. Additional SNF management planning is not expected to be required for the Bulk Shielding Reactor or the Oak Ridge Research Reactor through the year 2035. It is anticipated that the fuel now stored in the Tower Shielding Reactor No. II core would be moved to the Y-12 area at the Oak Ridge Reservation for interim storage. If this is not possible, additional storage space or cessation of reactor operations may be required after 2005. If the Advanced Neutron Source becomes operational in 2005, additional SNF interim storage space may be required.

3.1.1.5 Nevada Test Site.

The Nevada Test Site does not generate or store any SNF and would not receive any SNF under the No Action alternative. Therefore, this alternative does not affect the Nevada Test Site.

3.1.1.6 Naval Nuclear Propulsion Program.

Under the No Action alternative, naval reactors would continue to be defueled and refueled as planned. In accordance with normal practices, the spent fuel would be removed from the ships (or prototypes) and placed into shipping containers. No action would be needed to prepare the naval SNF for storage because of its corrosion resistance, high integrity, and strength. The SNF would be stored in this condition at a location near the defueling site. Naval SNF from ships defueled or refueled at Newport News Shipbuilding, a private shipyard located in Newport News, Virginia, would be transported to the Norfolk Naval Shipyard, in Portsmouth, Virginia, which is the nearest naval site.

Under this alternative, examination of naval SNF would ultimately cease. A transition period of approximately 3 years would be required to procure sufficient shipping containers to store naval SNF being removed by ongoing defueling or refueling. During this period, naval SNF would continue to be transported to the Idaho National Engineering Laboratory for detailed examination and storage. After the transition period, naval SNF would no longer be transported to the Idaho National Engineering Laboratory for examination and subsequent storage; the SNF removed from naval reactors would remain for storage at the naval sites. In addition, the Expended Core Facility at the Idaho National Engineering Laboratory would be shut down.

3.1.1.7 Other Generator/Storage Locations.

Under the No Action alternative, the SNF generated and/or stored at DOE research and non-DOE research reactors and other locations would not be transported offsite. For the purposes of this analysis, it is assumed that SNF from foreign research reactors would not be transported to the United States under this alternative. DOE research reactors with adequate storage capacity could continue operating as planned. If the onsite storage capacity is inadequate or cannot be expanded, new plans would have to be considered, including potential cessation of reactor operations after storage capacity limits are reached.

The No Action alternative would also affect the management of SNF from nuclear power plants that DOE is obligated to store. For this alternative, the SNF would remain at these sites. Stabilization would be performed, as necessary, to ensure safe storage. Loss of access to the Idaho National Engineering Laboratory for storage of its SNF has already resulted in the construction of new onsite SNF storage at Fort St. Vrain. Therefore, implementation of the No Action alternative would have no additional impact on the management of SNF at Fort St. Vrain.

3.1.2 Decentralization

Decentralization Alternative
Store most SNF at or close to the generation site or current storage location, with limited shipments to DOE facilities.

DOE SNF shipments would be limited to the following:
- SNF stored or generated at universities and non-DOE facilities
- Potential foreign research reactor fuel.

SNF processing might need to be conducted. Other forms of stabilization might occur to provide for safe storage and/or transport.
Some facilities would be upgraded/replaced and additional storage capacity required by the alternative would be constructed.
Onsite fuel transfers would occur for improved safe storage.

Research and development activities would be undertaken for SNF management, including stabilization technology.
Three options for naval fuel
- No inspection fuel remains close to refueling/defueling site
- Limited inspection at Puget Sound Naval Shipyard
- Full inspection at the Idaho National Engineering Laboratory followed by storage close to refueling/defueling site.

Under the Decentralization alternative, DOE would (a) maintain existing SNF in storage at current locations, and (b) store new SNF at or near the site of generation, thereby reducing the amount of fuel transported before a decision on ultimate disposition. This alternative differs from the No Action alternative by slightly increasing shipments to DOE sites and developing or upgrading facilities. Table 3-2 summarizes the basic actions at each site under this alternative. Actions that would improve management of SNF would be undertaken. SNF processing and research and development would be performed. Fuel may be transported for safety or research and development purposes. Figure 3-2 identifies the movement of fuel from 1995 through 2035 under this alternative. SNF from non-DOE locations would be transported to one of the major existing sites for management. SNF managed by DOE would remain at its current location until a decision on final disposition is made. The Navy has evaluated three options for SNF management under this alternative, based on the amount of examination that would be performed on the SNF. In general, naval SNF would be stored at the defueling site. SNF from Newport News Shipbuilding would be transferred to the Norfolk Naval Shipyard.

3.1.2.1 Hanford Site.

Under the Decentralization alternative, the near-term activities at the Hanford Site include those activities identified under the No Action alternative, as well as substantial facility development and upgrades, and SNF processing research and development. In addition to the three principal activities identified for the No Action alternative (that is, fuel characterization, fuel canning, and cask procurement for Fast Flux Test Facility fuel), the following general activities would also occur: evaluating wet and dry storage methods for defense production N-Reactor and Single-Pass Reactor fuel; evaluating dry storage methods for other fuels (Shippingport Core II, Fast Flux Test Facility, miscellaneous); conducting extensive research and development on defense production SNF stabilization techniques; and constructing and using wet and/or dry storage facilities and possibly a stabilization facility. In response to public comment, this alternative also includes the option to process defense production SNF at an overseas facility. A discussion of this option is provided in Volume 1, Appendix A, Attachment B.

Figure 3-2. Spent nuclear fuel distribution, location, and inventory for the Decentralization alternative.

The Hanford Site would not transport SNF to or receive SNF from offsite locations, unless the option to process defense production SNF at an overseas facility is selected. Local transport of fuel would occur to support safety requirements, improved SNF management, and research and development activities.

Combinations of wet and dry storage would be considered. Either a new wet storage facility or dry casks or vault-type dry storage would be needed to replace existing facilities. Dry storage of defense production SNF would require a new stabilization facility. Because of substantial chemical and physical differences between defense production fuels and the nondefense fuels, it is possible that separate storage facilities would be built. Additional National Environmental Policy Act documentation would be prepared before selecting this option.

3.1.2.2 Idaho National Engineering Laboratory.

Under the Decentralization alternative, the Idaho National Engineering Laboratory would accept limited shipments of SNF for storage, including SNF from some domestic research reactors and some foreign research reactors. Some onsite transfers would also be conducted. DOE would manage the existing SNF at the Idaho National Engineering Laboratory, such as the naval SNF at the Naval Reactors Facility and the SNF in underwater pools, to accomplish safe and secure interim storage until ultimate disposition.

DOE would use the characterization and canning equipment described for the No Action alternative to stabilize SNF removed from the CPP-603 Underwater Fuel Storage Facility for interim SNF storage. DOE would transfer the SNF in the CPP-603 Underwater Fuel Storage Facility to the Fuel Storage Area by the year 2000. DOE would continue to use the Underground Storage Facility and the Irradiated Fuel Storage Facility for existing SNF inventory and transfers of other SNF based on safety analyses. DOE would upgrade or increase fuel storage capacity at the Idaho National Engineering Laboratory, as required.

The Idaho National Engineering Laboratory would conduct various research and development activities, including laboratory and pilot-plant testing, continued repository performance assessments and acceptance criteria development, and the characterization of SNF.

The Idaho National Engineering Laboratory would examine different amounts of naval SNF, depending on the option selected for the Navy Nuclear Propulsion Program (see Section 3.1.2.6). Under two of the three options, the Expended Core Facility would ultimately be shut down. As with the No Action alternative, each of the options for naval fuel would require a transition period. During this transition period, SNF would be transported in shipping containers to the Expended Core Facility for examination and then to the Idaho Chemical Processing Plant for storage.

3.1.2.3 Savannah River Site.

The near-term fuel transfer and consolidation activities at the Savannah River Site for the Decentralization alternative would be similar to those under the No Action alternative, except that the site would receive limited SNF shipments from other locations. The Savannah River Site would receive research and test reactor fuel from some domestic and perhaps some foreign research reactors. This SNF would consist primarily of aluminum-clad fuel elements and some stainless steel and zircaloy fuel elements.

Fuel would continue to be stored in the Receiving Basin for Offsite Fuels and in an upgraded reactor basin until it is either canned, placed in wet or dry storage, or is processed. The processing option represented for evaluation in the EIS consists of processing existing Savannah River Site aluminum-clad fuel using existing chemical separations facilities (that is, F- and H-Canyons) and storing the current inventory of stainless-steel-clad and zirconium-clad fuel as well as future receipts of aluminum-clad SNF.

This option is analyzed because DOE has data from past processing that can be used for analyses. The impacts from this technology are representative of other processing technology options that may be considered in the future. Other processing options, such as processing all SNF or processing coupled with vitrification, are also feasible and would be analyzed as part of the site-specific National Environmental Policy Act documentation needed to implement any option for this alternative.

The Decentralization alternative would require a new fuel characterization facility, a new wet or dry canning facility, and a new wet or dry storage facility. The Savannah River Site would evaluate wet and dry storage and processing options because (as in the No Action alternative) interim wet storage of the fuel elements without canning could cause corrosion and cladding failures. The Savannah River Site would initiate projects to design characterization, canning, and dry storage facilities for aluminum-clad fuels. Ongoing SNF research would continue at the site.

3.1.2.4 Oak Ridge Reservation.

Under the Decentralization alternative, the Oak Ridge National Laboratory would generate and store SNF from reactor research activities. No SNF would be transported to the Oak Ridge Reservation except for small amounts associated with research and development activities (for example, from Sandia National Laboratories). No SNF would be transported offsite. SNF would be stabilized, as necessary, to provide safe storage. Research and development activities at the Oak Ridge Reservation would continue as planned. Because the interim storage capacity for SNF at the Oak Ridge Reservation is limited, new interim storage capacity would be added. The amount of SNF in interim storage would not increase substantially.

3.1.2.5 Nevada Test Site.

Under the Decentralization alternative, the Nevada Test Site would not generate or store any SNF and would not receive any SNF. Therefore, this alternative is not applicable to the Nevada Test Site.

3.1.2.6 Naval Nuclear Propulsion Program.

The Decentralization alternative at the naval sites is similar to the No Action alternative because naval reactors would continue to be defueled and refueled as planned, and the fuel would generally be stored at or near the defueling site. No action would be needed to prepare the naval SNF for storage because of its corrosion resistance, high integrity, and strength. A transition period would be required while the necessary interim storage capabilities could be procured and developed at the naval sites. During this period, naval SNF would continue to be transported to the Expended Core Facility for examination and subsequent interim storage at the Idaho National Engineering Laboratory. The principal difference from the No Action alternative is that the options for interim storage would be selected from shipping containers, dry storage casks, and wet storage in water pools. Another important difference is that examination of naval fuel would be possible.

Under this alternative, the Navy has three options, which vary by the amount of detailed examination that could be performed on the naval SNF:

Option A, No Examination-Interim storage of naval SNF at the naval site of origin without any detailed examination, except during the 3-year transition period when naval SNF would continue to be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for detailed examination and preparation for storage at the Idaho Chemical Processing Plant.

Option B, Limited Examination-Transport approximately 10 percent of the naval SNF to the Puget Sound Naval Shipyard where the existing water pool, designed to support aircraft carrier refuelings, would be modified to enable limited examination of certain high-priority SNF. Use of this water pool for examination would preclude the performance of aircraft carrier refueling work at the shipyard.

Option C, Full Examination-Transport naval SNF to the Expended Core Facility for full examination and then return the fuel to the naval or DOE facility near the site of origin for storage.

For Option A, the Expended Core Facility at the Idaho National Engineering Laboratory would be shut down after the transition period. For Option B, the water pool facility at the Puget Sound Naval Shipyard would be modified to support SNF examinations and, upon completion, the Expended Core Facility would be shut down. It would not be possible to perform aircraft carrier refuelings at the Puget Sound Naval Shipyard if this option were selected. Under Options A and B, examinations of SNF would be either terminated or severely decreased. Under Option C, the Expended Core Facility would continue to operate, and planned Expended Core Facility improvements, including construction of the dry cell, would be completed.

3.1.2.7 Other Generator/Storage Locations.

The Decentralization alternative for other generators and storage locations is similar to the No Action alternative because offsite transport of SNF would be allowed in limited amounts for continued operation. Thus, both DOE and non-DOE research reactors would be allowed to transport SNF offsite, as necessary. Additional SNF interim storage facilities at domestic research reactors would not be required. For this alternative, SNF currently stored at the West Valley Demonstration Project, Babcock & Wilcox Research Center, and the Fort St. Vrain power plant would remain at these sites. As identified in the No Action alternative, loss of access to the Idaho National Engineering Laboratory for storage of its SNF has already resulted in the construction of new onsite SNF storage at Fort St. Vrain. Therefore, implementation of the Decentralization alternative would have no additional impact on the management of SNF at Fort St. Vrain.

3.1.3 1992/1993 Planning Basis

1992/1993 Planning Basis Alternative

Transport to and store newly generated SNF at the Idaho National Engineering Laboratory or Savannah River Site. Consolidate some existing fuels at the Idaho National Engineering Laboratory or the Savannah River Site.

Fuel would be transported as follows:

- TRIGA fuel from the Hanford Site to the Idaho National Engineering Laboratory; Hanford Site receives limited fuel for research of storage and dispositioning technologies
- Naval fuel to the Idaho National Engineering Laboratory for examination and storage
- West Valley Demonstration Project and Fort St. Vrain fuel to the Idaho National Engineering Laboratory
- Oak Ridge Reservation fuel to the Savannah River Site
- Domestic research fuel, and foreign research reactor fuel as may yet be determined, divided between the Savannah River

Site and the Idaho National Engineering Laboratory.

Facilities upgrades and replacements that were planned would proceed, including increased storage capacity.
Research and development for SNF management would be undertaken, including stabilization technology.
SNF processing might need to be conducted. Other forms of stabilization might occur to provide for safe storage and/or transport.

The 1992/1993 Planning Basis alternative represents DOE's 1992/1993 plans for management of its SNF. Under this alternative, existing SNF located at major DOE sites would remain at those sites. This results in less intersite transportation of SNF compared with the other alternatives, except for the No Action alternative. Table 3-3 summarizes the basic actions at each site under this alternative.

Under this alternative, DOE would transport and store newly generated SNF at the Idaho National Engineering Laboratory or Savannah River Site. Some existing SNF currently at other sites would be consolidated at the Idaho National Engineering Laboratory or the Savannah River Site. Specifically, the Idaho National Engineering Laboratory would receive TRIGA fuel from the Hanford Site, SNF from naval sites, some test reactor SNF, SNF from the West Valley Demonstration Project and Fort St. Vrain, and some SNF from university and perhaps from foreign research reactors. The Savannah River Site would also receive some test reactor SNF and some SNF from university and perhaps from foreign research reactors. DOE sites would generally upgrade facilities and construct new facilities for the management of SNF.

Continued SNF transportation, receipt, processing, and storage are assumed for this alternative. The construction and operation of any new facilities required to accommodate current and project-specific SNF interim storage requirements would be implemented. Figure 3-3 identifies the movement of fuel from 1995 through 2035 under this alternative. Activities related to SNF processing would include research and development and pilot programs to support future decisions on the ultimate disposition of SNF.

Figure 3-3. Spent nuclear fuel distribution, location, and inventory for the 1992/1993 Planning Basis alternative.

Naval SNF would continue to be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for examination. After examination, the SNF would be transferred to the Idaho Chemical Processing Plant for interim storage, pending ultimate disposition.

3.1.3.1 Hanford Site.

The activities at the Hanford Site for the 1992/1993 Planning Basis alternative are the same as those identified for the Decentralization alternative, except that 191 TRIGA SNF elements currently stored in the 308 Building and the 200 Area low-level burial grounds would be transported to the Idaho National Engineering Laboratory. No new SNF would be transported to the Hanford Site except for limited quantities of materials for research in support of interim storage technologies for ultimate disposition. Thus, the overall inventory at the Hanford Site would decrease slightly.

3.1.3.2 Idaho National Engineering Laboratory.

Under the 1992/1993 Planning Basis alternative, DOE would continue the maintenance and operation of existing SNF-related facilities in a manner similar to the No Action alternative; however, some consolidation of Idaho National Engineering Laboratory facilities could occur. Newly generated SNF would, with minor exceptions, be transported to either the Idaho National Engineering Laboratory or the Savannah River Site.

DOE would complete a new characterization and canning facility with appropriate inspection, conditioning, and packaging equipment to stabilize any new receipts of SNF and to prepare fuel currently in underwater storage for dry storage. DOE would upgrade or increase dry fuel storage capacity at the Idaho National Engineering Laboratory, as required.

SNF research and development, with the construction of a Technology Development Facility, would continue as planned. The Electrometallurgical Process Demonstration Project would continue at the Argonne National Laboratory-West Fuel Cycle Facility. The Dry Fuels Storage Facility would be used to demonstrate technology for the dry storage of selected DOE highly enriched uranium fuels.

Naval SNF would continue to be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for examination. After examination, the SNF would be transferred to the Idaho Chemical Processing Plant for interim storage, pending ultimate disposition.

3.1.3.3 Savannah River Site.

The implementation of the 1992/1993 Planning Basis alternative at the Savannah River Site would involve the same actions and options as the Decentralization alternative, except that DOE would transfer about half of the newly generated domestic and foreign aluminum-clad research reactor SNF to the Savannah River Site.

The stabilization activities and options would be the same as those for the Decentralization alternative. The Savannah River Site would place the nonaluminum fuels and offsite aluminum-clad fuel receipts in interim storage and either process the aluminum-clad fuels currently at the Savannah River Site or place them in interim storage. The storage options and new facility requirements would also be the same as those for the Decentralization alternative. The Savannah River Site would undertake the same types of research and development programs as those described for the Decentralization alternative. Current ongoing activities would continue. The Savannah River Site would also conduct research and pilot-scale studies to determine the best technology for ultimate disposition of the aluminum-clad fuels.

3.1.3.4 Oak Ridge Reservation.

Under the 1992/1993 Planning Basis alternative, the Oak Ridge Reservation would transport excess SNF to other DOE locations as necessary to permit continued operations of Oak Ridge reactors. The option for acquiring dry storage facilities would support continued High Flux Isotope Reactor operation during the transition period. The amount of SNF stored at the Oak Ridge Reservation would not increase. Research and development activities would continue, and SNF interim storage capacity would not increase.

3.1.3.5 Nevada Test Site.

Under the 1992/1993 Planning Basis alternative, the Nevada Test Site would not generate or store any SNF and would not receive any SNF. Therefore, this alternative is not applicable to the Nevada Test Site.

3.1.3.6 Naval Nuclear Propulsion Program.

Under this alternative, naval reactors would continue to be defueled and refueled as planned. Upon removal from the ship, the SNF would be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for examination. After examination, the fuel would be transported to the Idaho Chemical Processing Plant for interim storage, pending ultimate disposition. No action to prepare the SNF for storage would be necessary because of its corrosion resistance, high integrity, and strength. Planned improvements for the Expended Core Facility, including construction of the dry cell facility, would be completed.

3.1.3.7 Other Generator/Storage Locations.

Under this alternative, SNF would continue to be transported to designated DOE sites. At Brookhaven National Laboratory, implementation of this alternative could require a transition period of several years and construction of temporary SNF storage facilities or acquisition of dry storage containers. DOE assumes that no additional SNF interim storage facilities would be constructed at the other generator/storage sites. For this alternative, SNF currently stored at the West Valley Demonstration Project, Babcock & Wilcox Research Center, and the Fort St. Vrain power plant would be transported to the Idaho National Engineering Laboratory.

3.1.4 Regionalization

The Regionalization alternative comprises Regionalization 4A, which would assign existing and projected SNF among DOE sites based primarily on fuel type, and Regionalization 4B, which would assign fuels geographically. This subsection briefly defines each one, provides a boxed summary, and discusses the implications of both on each site.

Table 3-4 summarizes actions at the sites being considered for the Regionalization alternative.

Regionalization 4A Preferred Alternative

Distribute existing and projected SNF among DOE sites based primarily on fuel type.

Naval fuel would be transported to, examined, and stored at the Idaho National Engineering Laboratory.

Aluminum-clad fuel would be transported to the Savannah River Site; TRIGA and nonaluminum fuel would be transported to the Idaho National Engineering Laboratory; defense production fuel would be retained at the Hanford Site.

SNF processing might need to be conducted. Other forms of stabilization might occur to provide for safe storage and/or transport.

Facilities required to support SNF management would be upgraded or built as necessary.

Research and development for SNF management would be undertaken, including stabilization technology.

Regionalization 4A is the management of SNF based on the specific fuel type. The DOE has identified Regionalization 4A as its preferred alternative (see Section 3.0). All SNF would be transported to and stored at either the Idaho National Engineering Laboratory or the Savannah River Site, depending upon the fuel type, with the exception of defense production fuel that would be retained at the Hanford Site. Regionalization 4A is similar to the 1992/1993 Planning Basis alternative but involves more intersite transportation of SNF to the sites, depending on the existing capabilities of the sites to manage the specific fuel types with respect to cladding material, physical and chemical composition, fuel condition, and adequate facilities to handle the increased quantity. Actions for this alternative would assign all but defense production SNF to either the Idaho National Engineering Laboratory or the Savannah River Site, depending on the fuel type.

Figure 3-4 shows the movement of SNF from 1995 through 2035 under Regionalization 4A. Facility upgrades, replacements, and additions would be undertaken to the extent required by this alternative. Activities related to the management of SNF, including research and development activities, would be included.

Figure 3-4. Spent nuclear fuel distribution, location, and inventory for Regionalization 4A (by fuel type).

Regionalization 4B

Distribute existing and projected SNF between an Eastern Regional Site (either Oak Ridge Reservation or Savannah River Site) and a Western Regional Site (either Hanford Site, Idaho National Engineering Laboratory, or Nevada Test Site).

The Eastern Regional Site would receive fuel from east of the Mississippi River and the Western Regional Site would receive fuel from west of the Mississippi River.

Naval fuel would be transported to, examined, and stored at either the Western Regional Site or the Eastern Regional Site.

SNF processing might need to be conducted. Other forms of stabilization might occur to provide for safe storage and/or transport.

Facilities required to support SNF management would be upgraded or built as necessary.

Research and development would be undertaken for SNF management, including stabilization technology.

Regionalization 4B is the management of SNF based on geography. In general, SNF from eastern locations (east of the Mississippi River) would be consolidated at the Eastern Regional Site (either the Oak Ridge Reservation or the Savannah River Site); SNF from western locations (west of the Mississippi River) would be consolidated at the Western Regional Site (either the Hanford Site, the Idaho National Engineering Laboratory, or the Nevada Test Site). All naval SNF would be transported to, examined, and stored at either the Eastern or the Western Regional Site. Regionalization 4B has 10 options, based on the combination of sites selected as the Eastern and Western Regional Site and the placement of the expended core facility at either the Eastern or the Western Regional Site. There are three potential Western and two potential Eastern Regional Sites that could be paired, with either supporting the expended core facility. Neither of the two possible combinations that include the Idaho National Engineering Laboratory as the Western Regional Site would consider constructing another expended core facility at the Eastern Site because of the estimated $1 billion cost to construct the expended core facility. Figure 3-5 shows the movement of SNF from 1995 through 2035 under Regionalization 4B with the Idaho National Engineering Laboratory as the Western Regional Site and the Savannah River Site as the Eastern Regional Site. Facility upgrades, replacements, and additions would be undertaken to the extent required by Regionalization 4B. Activities related to the management of

SNF, including research and development, would be included.

3.1.4.1 Hanford Site.

Regionalization 4A-Under Regionalization 4A, activities at the Hanford Site would be intermediate to those of the Decentralization and the 1992/1993 Planning Basis alternatives. Hanford would continue to store its defense production fuel. The Hanford Site would not receive any shipments of SNF and would transport commercial remnants and stainless steel and nondefense production zircaloy-clad fuels to the Idaho National Engineering Laboratory. Facility upgrades, replacements, and additions associated with defense production fuel would occur as for the Decentralization and 1992/1993 Planning Basis alternatives. Minor facility additions required to consolidate and prepare other onsite SNF for transport offsite would also occur.

Figure 3-5. Spent nuclear fuel distribution, location, and inventory for Regionalization 4B (by geography).

Regionalization 4B-If the Hanford Site were selected as the Western Regional Site for implementation of Regionalization 4B, DOE SNF located or generated in the western United States and possibly naval SNF nationwide would be sent to the Hanford Site. This would require the completion of upgrades, increases, and replacements of storage capacity identified for the existing inventory under the Decentralization alternative, as well as additional capacity to accommodate DOE SNF and naval SNF within the existing or new facilities. A new stabilization facility may be required to accomplish safe interim storage of SNF.

New facilities would also be required to receive, handle, and store offsite fuel. In addition, a new facility for research and development and pilot programs would be required to support ultimate disposition. An expended core facility would be built on the Hanford Site, if the naval SNF were sent to the Hanford Site.

Implementation of Regionalization 4B at a site other than the Hanford Site would require the Hanford Site to consolidate and prepare onsite SNF for transport to the Western Regional Site. Because of the potential chemical reactivity of the defense production fuel at Hanford, it would require stabilization before offsite transport, which would require a new facility similar to the one described in the Decentralization alternative. Additional casks and associated handling equipment compatible with the receiving capabilities at the regional site may also be required. After the SNF is transported, related facilities at the Hanford Site would be closed.

3.1.4.2 Idaho National Engineering Laboratory.

Regionalization 4A-Under Regionalization A, stainless-steel- and zircaloy-clad, TRIGA, and naval SNF would be transported to the Idaho National Engineering Laboratory. The Idaho National Engineering Laboratory would transport aluminum-clad fuel to the Savannah River Site. Dry interim storage capacity would be increased and facility upgrades similar to those described for the 1992/1993 Planning Basis alternative would be undertaken, with replacements and additions as appropriate.

Regionalization 4B-If the Idaho National Engineering Laboratory were selected as the Western Regional Site for implementation of Regionalization 4B, SNF from western locations would be transported to the Idaho National Engineering Laboratory. The western facilities would characterize, stabilize, and can the SNF in containers compatible with dry storage at the Idaho Chemical Processing Plant at the Idaho National Engineering Laboratory. Naval SNF removed from naval reactors would be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for examination. Following examination, the SNF would be transferred to the Idaho Chemical Processing Plant for interim storage.

DOE would complete an expanded Dry Fuels Storage Facility, which would include a new characterization and canning facility similar to the one described for the 1992/1993 Planning Basis alternative. In addition, the same new facility projects described for the 1992/1993 Planning Basis alternative would be initiated.

DOE would conduct SNF research and development. Similar to the 1992/1993 Planning Basis alternative, the Electrometallurgical Process Demonstration Project would continue at Argonne National Laboratory-West.

If implementation of Regionalization 4B were to occur at a different site, DOE would construct a characterization and canning facility at the Idaho Chemical Processing Plant to assist in stabilizing the different types of Idaho National Engineering Laboratory SNF before placement in various shipping casks and storage containers before transport to the selected Western Regional Site.

Similar to the No Action alternative, DOE would complete the transfer of the CPP-603 Underwater Fuel Storage Facility pool inventory to existing dry storage facilities by the year 2000. DOE would not build the Dry Fuels Storage Facility. DOE would then close all SNF-related facilities at the Idaho National Engineering Laboratory, except for operating reactor support facilities, such as the Advanced Test Reactor canal or the Argonne National Laboratory-West Hot Fuel Examination Facility and Fuel Cycle Facility.

The SNF-related research and development activities would be phased out, although the Electrometallurgical Process Demonstration Project would continue at Argonne National Laboratory-West (but would only test processes for SNF currently on the site). Similar to the No Action alternative, shipments of naval SNF to the Idaho National Engineering Laboratory would cease, and the Expended Core Facility would be phased out.

3.1.4.3 Savannah River Site.

Regionalization 4A-Under Regionalization 4A, DOE would transport aluminum-clad fuels to the Savannah River Site. The same actions and options as the Decentralization alternative would be required. The Savannah River Site would transport nonaluminum-clad fuels to the Idaho National Engineering Laboratory.

The stabilization activities and options would be similar to those described for the Decentralization alternative. The principal differences are that, under this alternative, the Savannah River Site would can and store more aluminum-clad fuel and would not manage nonaluminum-clad fuels. The amount of fuel processed would remain the same. The storage options and new facility requirements would be similar to those described for the Decentralization alternative, except that storage space for stainless-steel-clad and zirconium-alloy-clad fuels would not be necessary. The Savannah River Site would undertake similar types of research and development programs as those described for the 1992/1993 Planning Basis alternative. The principal difference would be that nonaluminum-clad fuels would not be included under this alternative.

Regionalization 4B-If the Savannah River Site were selected as the Eastern Regional Site for implementation of Regionalization 4B, eastern locations would transport aluminum-clad and nonaluminum-clad fuels to the site. In addition, naval SNF might be transported to the Savannah River Site, if the Eastern Regional Site were selected for naval fuels. The stabilization activities and options required would be similar to those for the Decentralization alternative. The Savannah River Site would store the nonaluminum fuels and either store or process the aluminum-clad fuels. The storage options and new facility requirements would also be the same as those for the Decentralization alternative. The Savannah River Site would undertake the same types of research and development programs as those described for the Decentralization alternative. Current ongoing activities would continue. The Savannah River Site would also conduct research and pilot-scale studies to determine the best technology for ultimate disposition of aluminum-clad fuels.

If the Savannah River Site were not selected as the Eastern Regional Site, DOE would transport SNF to the Oak Ridge Reservation. Some fuel would have to be stabilized before transport.

3.1.4.4 Oak Ridge Reservation.

Regionalization 4A-Under Regionalization 4A , the Oak Ridge Reservation would not receive SNF and would transport its aluminum-clad SNF to the Savannah River Site. All other SNF would be transported to the Idaho National Engineering Laboratory.

Regionalization 4B-If the Oak Ridge Reservation were selected as the Eastern Regional Site for implementation of Regionalization 4B, the eastern locations would transport SNF to the Oak Ridge Reservation for storage. In addition, naval SNF might be transported to the Oak Ridge Reservation if the Eastern Regional Site were selected for naval fuel. SNF currently stored at other DOE facilities would arrive at the Oak Ridge Reservation fully stabilized. New non-DOE domestic, foreign research reactor, and naval SNF would arrive in a condition necessary for safe transportation but uncanned. This fuel would be stabilized, prepared, and canned at the Oak Ridge Reservation to assure safe interim storage. Research and development activities at the Oak Ridge Reservation would increase from current levels. A new SNF management complex would be built, including (a) a SNF receiving and canning facility, (b) a technology development facility, (c) an interim dry storage area, and (d) an expended core facility similar to the one at the Idaho National Engineering Laboratory.

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before dry storage. The technology development facility would be used to investigate the applicability of dry storage technologies and pilot-scale technology development for disposition of the various types of SNF. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. Naval SNF would be examined at the new expended core facility at Oak Ridge before interim storage.

A small quantity of Molten Salt SNF is stored in tanks at the Oak Ridge Reservation. Currently, technology to stabilize this SNF for transport does not exist. Under this alternative, if the Oak Ridge Reservation were to transport SNF to the Savannah River Site, this Molten Salt SNF would continue to be stored at the Oak Ridge Reservation until it could be stabilized for safe transport.

If the Oak Ridge Reservation were not selected as the Eastern Regional Site, almost all SNF at the Oak Ridge Reservation would be transported to the Savannah River Site. Some SNF might not be transported until a stabilization process is developed because of the current inability to stabilize some SNF for transport. The option for acquiring dry storage facilities would support continued High Flux Isotope Reactor operation during the transition period.

3.1.4.5 Nevada Test Site.

Regionalization 4A would not affect the Nevada Test Site because fuel is not currently stored onsite and fuel would not be transported to the site.

If the Nevada Test Site were selected as the Western Regional Site for implementation of Regionalization 4B, SNF from western locations would be transported to the Nevada Test Site for storage. In addition, naval SNF might be transported to the Nevada Test Site if the Western Site were selected for naval fuel. SNF currently stored at other DOE facilities would arrive at the Nevada Test Site fully stabilized. New non-DOE domestic, foreign research reactor, and naval SNF would arrive in a state necessary for safe transportation but uncanned. This fuel would be stabilized, prepared, and canned at the Nevada Test Site to ensure safe interim storage. A new SNF management complex would be built including (a) an SNF receiving and canning facility, (b) a technology development facility, (c) an interim dry storage area, and (d) an expended core facility similar to the one at the Idaho National Engineering Laboratory (if Nevada Test Site were selected for receipt of naval fuel).

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF, as necessary, before dry storage. The technology development facility would be used to investigate the applicability of dry storage technologies and pilot-scale technology development for disposal of the various types of SNF. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. Naval fuel would be examined at the new expended core facility at the Nevada Test Site before interim storage (if Nevada Test Site were selected for receipt of naval fuel).

If the Nevada Test Site were not selected as the Western Regional Site, then Regionalization 4B would not be applicable to the Nevada Test Site because it does not generate or store SNF.

3.1.4.6 Naval Nuclear Propulsion Program.

Regionalization 4A-Under Regionalization 4A, the management of naval SNF would be the same as for the 1992/1993 Planning Basis alternative. Naval SNF removed from naval reactors would continue to be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for examination. Following examination, the SNF would be transferred to the Idaho Chemical Processing Plant for interim storage. Planned improvements for the Expended Core Facility, including additions to the Dry Cell Facility, would be completed.

Regionalization 4B-Under Regionalization 4B, naval reactors would continue to be defueled and refueled, and the SNF would be sent to either the Western or the Eastern Regional Site for examination and storage.

If the Idaho National Engineering Laboratory were selected as the Western Regional Site, then naval SNF would continue to be transported to the Expended Core Facility for examination. After examination, the SNF would be transferred to the Idaho Chemical Processing Plant for storage. If another site were chosen for storage, naval SNF would continue to be transported to the Expended Core Facility at the Idaho National Engineering Laboratory for examination until construction of a new nuclear fuel examination facility or modification of an existing facility to perform the examinations at the selected site. The new facility would provide capabilities equivalent to the Expended Core Facility at the Idaho National Engineering Laboratory.

3.1.4.7 Other Generator/Storage Locations.

Under Regionalization 4A, the activities at the other generator and storage locations are the same as indicated for the 1992/1993 Planning Basis alternative. The exact destination of SNF transported would vary depending on the fuel type under Regionalization 4A and on the generation/storage location under Regionalization 4B.

3.1.5 Centralization

Centralization Alternative

Manage all existing and projected SNF inventories at one site until ultimate disposition.

- Existing SNF would be transported to the centralized site.
- Naval fuel would be transported to, examined, and stored at the centralized site.
- Projected SNF receipts would be transported to the centralized site.
- SNF processing might need to be conducted. Other forms of

stabilization might occur to provide for safe storage and/or transport.
Facility upgrade/replacement and new storage capacity would be provided at the centralized site; stabilization facilities would be provided at the transporting sites.
Research and development would be undertaken for SNF management, including stabilization technology.

Under the Centralization alternative, the SNF that DOE is obligated to manage would be transported to a single location for management. Potential sites include the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site. Table 3-5 summarizes the basic actions at each site under this alternative. Consequently, this alternative has five options (Options A through E)-centralization at each of the five potential sites. For the five sites designated under the Centralization alternative, the following discussion comprises two parts. The first part addresses the implications for the site if it were selected as the receiving site (that is, the centralization site). The second part presents the implications to the site if it were not selected as the centralization site, but currently managed SNF would be transported to the centralized site.

Regardless of the option selected, new facilities would be built at the selected site to accommodate the increased inventories. Some SNF would require stabilization, such as canning, before transport. SNF facilities at the transporting sites would then be closed. Activities related to the processing of SNF, including research and development and pilot programs, would also be centralized. Figure 3-6 shows the movement of fuel from 1995 through 2035 under this alternative.

For consolidation at sites other than the Idaho National Engineering Laboratory, a new expended core facility with capabilities comparable to the one in Idaho would be constructed, and the Idaho facility would be closed. Naval SNF would continue to be transported to the Expended Core Facility at the Idaho National Engineering Laboratory during a transition period, pending construction of storage and examination facilities at the central site.

3.1.5.1 Hanford Site.

Under the Centralization alternative, Option A, DOE-controlled and naval reactor SNF would be transported to the Hanford Site. This would require the completion of

Figure 3-6. Spent nuclear fuel distribution, location, and inventory for the Centralization alternative.

the upgrades, increases, and replacements of storage capacity identified for the existing inventory under the Decentralization alternative, as well as of the additional capacity within those facilities or new facilities to accommodate the SNF from the other sites and possibly a stabilization facility.

New facilities would also be required to receive, handle, and store offsite fuel. In addition, a new facility for research and development and pilot programs would be required to support ultimate disposition. An expended core facility would also be built at the Hanford Site.

If the Hanford Site were not selected for storage, Hanford would have to consolidate and prepare onsite SNF for transport to the central site. Some of the SNF would require stabilization before offsite transport, which would require a new facility similar to the one described in the Decentralization alternative. Additional casks and associated handling equipment compatible with the receiving capabilities at the central site might also be required. After transport of the SNF, related facilities at the Hanford Site would be closed.

3.1.5.2 Idaho National Engineering Laboratory.

If Option B were selected under the Centralization alternative, the Hanford Site, the Savannah River Site, and other DOE facilities would characterize, stabilize, and can the SNF in containers compatible with dry storage at the Idaho Chemical Processing Plant. Naval SNF removed from naval reactors would be transported to the Expended Core Facility at the Idaho National Engineering Laboratory.

Projects and activities for storage of SNF would be similar to those described for the 1992/1993 Planning Basis alternative, except that accelerated schedules for the Increased Rack Capacity and Additional Increased Rack Capacity projects would be necessary to accommodate the increased fuel receipts. In addition, the schedule for the Dry Fuel Storage Facility project would have to be accelerated and its scope expanded.

DOE would conduct maximum SNF research and development. Similar to the Regionalization alternative, the Electrometallurgical Process Demonstration Project would continue at Argonne National Laboratory-West.

If the Idaho National Engineering Laboratory were not selected as the storage site, a canning and characterization facility would be constructed at the Idaho Chemical Processing Plant to stabilize the different types of Idaho National Engineering Laboratory SNF in various shipping casks and storage containers before transport to the selected DOE facility.

Like the No Action alternative, the CPP-603 Underwater Fuel Storage Facility pool inventory would be transferred to existing dry storage facilities until it is transported offsite. The dry fuels storage facility would not be built. SNF-related facilities at the Idaho National Engineering Laboratory would be closed, except for facilities directly supporting operating reactors, such as the Advanced Test Reactor canal or the Argonne National Laboratory-West Fuel Cycle Facility.

SNF-related research and development activities would be phased out, although the Electrometallurgical Process Demonstration Project would continue at the Argonne National Laboratory-West Fuel Cycle Facility (but would process only SNF currently on the site). Similar to the No Action alternative, naval SNF would not be transported to the Idaho National Engineering Laboratory, and the Expended Core Facility would be shut down.

3.1.5.3 Savannah River Site.

If Option C were selected under the Centralization alternative, the Savannah River Site would receive all DOE and naval SNF. Major new facilities, including an expended core facility for naval fuels, would have to be constructed. Near-term actions and options would be similar to those described for the Decentralization alternative.

The activities and options for management of the aluminum-clad fuel would be similar to those described for the Decentralization alternative. Fuels received from other sites would be stored.

The Receiving Basin for Offsite Fuels and reactor disassembly basins would be used to meet near-term storage requirements for the current inventory of Savannah River Site SNF in the same manner as described for the Decentralization alternative. The Savannah River Site would build large-capacity wet or dry storage facilities for the SNF received. In addition, SNF receiving, characterization, and canning facilities would be necessary, and an expended core facility would be built onsite for examination of naval SNF.

Projects would be initiated to design characterization, canning, and storage facilities for the fuel types that the Savannah River Site would manage. Additional research would be conducted to develop requirements for the ultimate disposition of the SNF.

If the Savannah River Site were not selected as the centralized storage site, it would have to transport onsite SNF to the central site after stabilizing any fuel that is not safe for transport. No new storage facilities would be necessary because the Savannah River Site would maintain the SNF in the existing pools (as described for the Decentralization alternative) until moving it to the characterization facility before transport. The Savannah River Site would construct new characterization and canning facilities to prepare the SNF for transport. In addition, research would be conducted on stabilization and transport of aluminum-clad fuel that is heavily corroded.

3.1.5.4 Oak Ridge Reservation.

If Option D were selected under the Centralization alternative, the Oak Ridge Reservation would receive DOE SNF stabilized and canned to the extent necessary for safe transportation. The SNF might need to be uncanned, stabilized, prepared, and recanned at the Oak Ridge Reservation, however, to ensure safe interim storage. New non-DOE domestic, foreign research reactor, and naval SNF would arrive in a form suitable for safe transportation. If necessary, this fuel would be stabilized, prepared, and canned at the Oak Ridge Reservation to ensure safe interim storage. Research and development activities would increase from current levels. A new SNF management complex would be built, including (a) an SNF receiving and canning facility, (b) a technology development facility, (c) an interim dry storage area, and (d) an expended core facility similar to the one currently at the Idaho National Engineering Laboratory.

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before it is placed into dry storage, as necessary. The applicability of dry storage technologies and pilot-scale technology development for ultimate disposition of the various types of SNF would be investigated in the technology development facility. The interim dry storage area would consist of passive storage modules designed to safely store the SNF. Naval SNF would be examined at the expended core facility before storage.

A small quantity of Molten Salt SNF is stored in tanks at the Oak Ridge Reservation. Currently, technology to stabilize this SNF for transport does not exist. Under this alternative, if the Oak Ridge Reservation were to transport SNF to the Savannah River Site, this Molten Salt SNF would continue to be stored at the Oak Ridge Reservation until it could be stabilized for safe transport.

If the Oak Ridge Reservation were not selected as the centralization site, then almost all SNF at the Oak Ridge Reservation would be transported to the centralization site. The option for acquiring dry storage facilities would support continued High Flux Isotope Reactor operation during the transition period.

3.1.5.5 Nevada Test Site.

If Option E were selected under the Centralization alternative, the Nevada Test Site would receive DOE SNF stabilized and canned to the extent necessary for safe transportation. (However, the SNF might need to be uncanned, stabilized, prepared, and recanned at the Nevada Test Site to ensure safe interim storage.) New non-DOE domestic, foreign research reactor, and naval SNF would arrive in a state necessary for safe transportation but uncanned. This fuel would be stabilized, prepared, and canned at the Nevada Test Site to ensure safe interim storage. A new SNF management complex would be built, including (a) an SNF receiving and canning facility, (b) a technology development facility, (c) an interim dry storage area, and (d) an expended core facility similar to the one currently at the Idaho National Engineering Laboratory.

The SNF receiving and canning facility would receive SNF cask shipments from offsite and prepare the SNF for dry storage. A pool storage area would be included in this facility for cooling SNF before it is placed into dry storage, as necessary. The applicability of dry storage technologies and pilot-scale technology development for disposal of the various types of SNF would be investigated in the technology development facility. The interim dry storage area would consist of passive storage modules designed to safely store the SNF for 40 years. Naval SNF would be examined at the expended core facility before interim storage.

If the Nevada Test Site were not selected as the centralization site, then this alternative would not be applicable to the Nevada Test Site because it neither generates nor stores SNF.

3.1.5.6 Naval Nuclear Propulsion Program.

Under the Centralization alternative, naval SNF would be transported to the selected site for examination and storage. If a site other than the Idaho National Engineering Laboratory were selected, then a transition period would be required, during which naval SNF would be transported to the Expended Core Facility at the Idaho National Engineering Laboratory and a new expended core facility at the central site would be constructed. No actions would be needed to prepare the naval SNF for storage because of its corrosion resistance, high integrity, and strength.

3.1.5.7 Other Generator/Storage Locations.

Under the Centralization alternative, SNF would be transferred from the other generator and storage locations to the central storage site. Although the shipment destination may vary, the impacts from SNF operations at these locations would be the same as those identified in the 1992/1993 Planning Basis alternative.

3.2 Alternatives Eliminated from Detailed Analysis

In the process of evaluating management alternatives available to the DOE, several other management concepts and technologies have been considered for incorporation into the programmatic alternatives described in Section 3.1. The following section describes the concepts and technologies considered and not carried forward and identifies why they have been eliminated from detailed analysis.

3.2.1 Examine or Store Spent Nuclear Fuel in Foreign Facilities

The design and operating characteristics of the fuel for naval reactors and certain portions of other SNF are classified. As such, they are not releasable to foreign interests without going through a complex procedure prescribed in the Atomic Energy Act and strict U.S. Nuclear Regulatory Commission licensing requirements. Some of these classified design details and characteristics are obvious from the physical form of the fuel, and others could be learned from detailed examination or analyses. The United States Nuclear Weapons Nonproliferation Policy is summarized in the White House Fact Sheet on Nonproliferation and Export Control Policy, dated September 27, 1993 (White House 1993). Under its nuclear nonproliferation policy, the United States seeks to reduce or eliminate, where possible, the accumulation of stockpiles of highly enriched uranium or plutonium. These factors, along with others such as the security required for foreign transport and storage, make this alternative impractical. Based on these considerations, this alternative was eliminated from detailed analysis.

3.2.2 Leave Naval Spent Nuclear Fuel in Nuclear-Powered Ships

It is physically possible to retain SNF in the reactors in nuclear-powered vessels and moor the ships at shipyards until a decision on the ultimate disposition of the SNF is determined and implemented, and the fuel could then be removed from the ships.

Implementing this alternative would require extensive modifications to facilities at shipyards, including increasing the number of piers and the availability of waterfront utilities to support the ships at their moorings. Other shipyard facilities also might have to be modified or replaced in order to moor the numbers of ships involved during the 40-year period. The construction of piers and other needed facilities would cause impacts on the waterfronts and harbors and could affect the local ecology. Shipyard facilities would become overloaded with the requirement to moor vessels retaining their SNF onboard and skilled shipyard staff would be unable to continue to work on the operational fleet.

In addition, the costs and impacts on national security resulting from such an approach would be large; it would affect the ability of the U.S. Navy to carry out its mission. The costs of maintaining the ships with SNF remaining installed under Navy operating procedures and of providing the additional piers, waterfront services, and utilities would be large, both for ships that are to be decommissioned and for ships that would normally be refueled and returned to duty. (Failure to remove the SNF from Navy ships that are still needed for service would result in these ships being unavailable once their currently installed reactor fuel reaches the end of useful life.)

3.2.3 Alternate Sites for the Management of Spent Nuclear Fuel

An alternative SNF site selection process was undertaken to identify alternatives to the three major DOE sites-Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The candidate sites evaluated, site selection screening process, and results are presented in the Alternate Site Selection Decision Process Report (DOE-ID 1994). This study concluded that the uncertainties regarding Department of Defense sites together with their lack of SNF facilities and expertise made these additional Department of Defense sites less attractive as site alternatives. The alternative SNF site selection process resulted in the addition of the Nevada Test Site and Oak Ridge Reservation as potential regionalization and centralization sites for SNF management. The Oak Ridge Reservation represented a reasonable alternative site to the Savannah River Site for regionalization of Eastern-based SNF and the Nevada Test Site represented a reasonable alternative site to the Idaho National Engineering Laboratory or Hanford sites for regionalization of Western-based SNF. These two sites also represented options for centralization of all SNF management activities. However, the DOE did not consider the Nevada Test Site to be a preferred site for the management of SNF because of the State of Nevada's current role as the host site for the Yucca Mountain Site Characterization Project and the Nevada Test Site's lack of SNF management facilities and high-level waste infrastructure. For purposes of conducting a thorough National Environmental Policy Act analysis, the Nevada Test Site provides a contrast to other potential sites because it represents a site that has no existing SNF infrastructure. Non-DOE sites were eliminated from further analysis.

3.2.4 Chemical Separation/Processing of Spent Nuclear Fuel

Three potential technical management options were evaluated for chemical separation/processing of DOE SNF. However, DOE will not select SNF technical management options on the basis of Volume 1 of this EIS. These technology-based decisions are most appropriately made after detailed analysis on a fuel type-specific or site-specific basis. The three options include (a) chemical separation/processing in DOE facilities at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site; (b) chemical separation/processing in foreign commercial facilities; and, (c) chemical separation/processing in domestic commercial facilities.

Chemical separation/processing at DOE sites was evaluated under certain alternatives as a reasonably foreseeable activity as a SNF stabilization technology. This activity is discussed in Section 3.1 of this EIS. However, the evaluation was limited to certain alternatives and certain fuel types based largely on historical technologies and capabilities. Future technology-based SNF management decisions would be made only after further National Environmental Policy Act reviews were completed.

Several foreign commercial facilities exist that have the capability to process certain types of DOE SNF. An analysis of processing DOE SNF at those facilities would have to consider United States nuclear nonproliferation policy (with regard to highly enriched uranium and plutonium), national security concerns (with regard to the classified nature of naval fuel), and other technical considerations (with regard to transportation of wet fuel, processing capability in foreign facilities, possible fuel instability, etc.). There are certain fuel types addressed in this EIS for which management by processing in a foreign facility may be considered appropriate. In such instances, final decisions on technology-based options would be made based on further analysis in other site-specific or fuel type-specific National Environmental Policy Act reviews tiered from this EIS. For example, in a separate EIS on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel, DOE addresses foreign processing of the foreign research reactor SNF included in this EIS as a potential management alternative.

In response to public comment, Appendix A, Volume 1 of this EIS includes an analysis of transporting N-Reactor and Single-Pass Reactor SNF currently stored at the Hanford Site to a site in England for processing. The impacts identified by this analysis are considered to be representative of the impacts of transporting and handling any specific DOE SNF that might be considered for foreign processing, because N-Reactor SNF is low-enriched SNF and is a large fraction (in MTHM) of the currently stored inventory. In addition, the analysis included transportation routes that maximize foreign and domestic distances. A summary of these transportation impacts is included in Appendix I, Volume 1 of this EIS.

Domestic commercial facilities are not available for SNF processing for interim storage and, therefore, were eliminated from further consideration.

3.2.5 Preparations for Disposal

DOE has not yet decided whether the ultimate disposition for DOE SNF is disposal in a repository or removal/recycle of the fissile material (primarily uranium). Disposal of SNF would require (a) development of the repository waste acceptance criteria, and (b) completion of the characterization of the various types of SNF that would allow a determination of the specific technology needed for SNF preparation (processing, canning, etc.) for each fuel type. Because of the large number of uncertainties at this time, it is considered too speculative to include in this EIS at this time. Therefore, preparation for disposal in a geologic repository was eliminated from further evaluation in this EIS.

3.3 Comparison of Alternatives

As discussed in Chapter 5 and the site-specific appendices, the environmental consequences and, therefore, differences among the five SNF management alternatives addressed in Section 3.1 would be small. The comparison of alternatives in this section concentrates on (a) the areas in which the public has expressed considerable interest, and (b) programmatic factors important to DOE decisionmaking. The following factors were selected for comparison:

Number of SNF shipments among sites

Public health effects

SNF-related employment
Generation of radioactive waste

Impact on DOE or Navy missions
Cost of implementation.

The alternatives that would cause the smallest impacts in these areas maximize the use of existing facilities, staff, and infrastructure.

3.3.1 Number of Shipments

Figure 3-7 shows the number of shipments that would occur under each alternative. Figure 3-7 also quantifies shipments of test specimens under each alternative. Shipments of naval test specimens are included here because of their contribution to cumulative impacts of naval SNF transportation. Details concerning naval test specimens and methodologies for calculating impacts of specimen shipments can be found in Appendix D. The No Action alternative would involve a limited number of naval spent fuel shipments (200) and test specimen shipments (320). The Decentralization alternative, 1992/1993 Planning Basis alternative, and Regionalization 4A alternative mostly involve shipments to DOE sites from the smaller reactor and storage sites and from the naval sites to DOE sites. These shipments range in number from approximately 2,300 shipments under Decentralization Options A or B to approximately 4,500 under the Regionalization 4A alternative. Decentralization Option C and the 1992/1993 Planning Basis alternative have approximately 3,200 and 3,700 shipments, respectively, over the 40-year period. For the Regionalization 4B alternative and the Centralization options, SNF is transported to one or two sites. For these alternatives and options, the number of shipments range from approximately 5,500 under the Regionalization 4B alternative (Idaho National Engineering Laboratory and Savannah River Site) to a high of about 9,200 under the Centralization Option E (centralization at the Nevada Test Site). The number of shipments is summarized in Table 3-6. A more detailed discussion can be found in Appendices D and I of Volume 1. The public health effects from such shipments are discussed in the next section.

Figure 3-7. Number of spent nuclear fuel and test specimen shipments between the years 1995 and 2035.

3.3.2 Public Health Effects

This section discusses the public health effects from radiation exposure and traffic accidents under DOE's SNF Management Program (see Section 5.1.1.4 for basic information regarding assessment methods). These effects are estimated to be small, as shown by Figures 3-8, 3-9, and 3-10. The three sources of radiation exposure are (a) normal site operations, (b) transportation, and (c) accidents. Under all alternatives, the estimated number of latent cancer fatalities from the operation of the entire DOE SNF management system over a 40-year period would range from approximately zero to about two latent cancer fatalities.

3.3.2.1 Normal Operations.

In general, the greatest radiation exposure from normal SNF site activities and incident-free transportation results when large quantities of SNF are transported among sites, such as under the Regionalization 4B alternative or Centralization alternative. Under incident-free transportation, as noted in Table 3-7, the estimated total fatalities are less than two for all alternatives, with the highest estimates associated with the Centralization options. This reflects the higher number of shipments associated with these options.

In summary, estimated radiation impacts on public health are small for all alternatives (which include many different siting options), and it would, therefore, not be possible to materially reduce the impacts through a site selection process.

3.3.2.2 Accidents.

Transportation accidents pose the lowest risk of cancer fatalities (although the consequences of some accidents can be high). The accident risks are presented in Table 3-8. The results indicated that the risks associated with traffic fatalities are greater than the risks associated with cancer caused by radiation exposure. Both normal site operations and incident-free transportation have greater risk than that expected from transportation accidents when the probability and the consequences of potential accidents are considered. The latent cancer fatalities associated with onsite accidents is small across alternatives. The transportation accident with the largest consequences would lead to 55 latent cancer fatalities; the probability of occurrence is 1.1 10-7 per year (1 in 10 million years) (see Appendix I).

In summary, for radiation-induced latent cancer fatalities to the public over 40 years of SNF management under all of the alternatives evaluated, the most likely outcome is as follows:

Essentially zero latent cancer fatalities from normal facility operations and facility accidents

Essentially zero latent cancer fatalities from transportation accidents

Table 3-6. Number of offsite spent nuclear fuel and test specimen shipments by alternative.

Alternative		Maximum number of shipments	
		Spent fuel shipments(a)	Test specimen shipment(b)
No Action		200	320
Decentralization	Option A	2,000	320
	Option B	2,000	320
	Option C	2,900	320
1992/1993 Planning Basis		2,900	760
Regionalization 4A		3,700	760
Regionalization 4B			
Hanford Site/Savannah River Site		4,800	1,750
Idaho National Engineering Laboratory/Savannah River Site		4,600	760

Nevada Test Site/Savannah River Site	6,600	1,750
Hanford Site/Oak Ridge Reservation	5,600	1,750
Idaho National Engineering Laboratory/Oak Ridge Reservation	5,400	760
Nevada Test Site/Oak Ridge Reservation	7,300	1,750
Centralization		
Hanford Site	5,700	1,750
Idaho National Engineering Laboratory	5,500	760
Savannah River Site	6,600	1,750

---

a. Assumes SNF shipments are 100 percent by truck or 100 percent by rail, except for naval SNF shipments that are by both truck (onsite) and rail (offsite).

b. Range of values in each column for the Decentralization alternative reflects the different fuel examination options for naval SNF.

Up to about one latent cancer fatality from most incident-free transportation scenarios; up to two latent cancer fatalities under the Centralization options

Up to about two fatalities from nonradiological traffic accidents.

A more detailed discussion of accidents is found in Chapter 5, Volume 1 of this EIS.

3.3.3 Employment Related to Spent Nuclear Fuel Management at DOE and Naval Sites

Under various alternatives, the total labor force involved in SNF management could decrease by 180 jobs or increase by more than 2,100 jobs averaged over the period 1995 to 2005, as compared to the 1995 baseline. This labor force is the sum of permanent employment in operating or maintaining new facilities and shorter term construction jobs. Figures 3-11 and 3-12 characterize the range of SNF jobs under each alternative. The number of jobs related to SNF management is small compared with the total number of jobs (2 to 4.5 percent) at the sites that would be involved in SNF management. SNF management-related jobs account for less than 4.5 percent of total employment at the sites and less than 8 percent of employment at any one site.

It is important to note that the relocation of large amounts of SNF under the Regionalization 4B alternative and the Centralization options would eventually result in closure of SNF management facilities at major DOE sites and, therefore, long-term job loss at the closed facilities. However, some of the job losses at closed facilities would be accompanied by job gains at the sites receiving the fuel shipments. In addition, from 1995 to 2005 several management actions already initiated at various sites to maintain a safe storage configuration for existing SNF will be completed, and much of the SNF would need to be stabilized before transport. In the near term, the combination of building facilities at some sites and stabilizing SNF before transport at other sites complicates estimating the near-term SNF employment situation.

Under the No Action alternative, employment would not increase substantially at any site, and the closure of the Expended Core Facility at the Idaho National Engineering Laboratory would result in a net loss of just over 500 jobs involved in SNF management following closure. The maximum number of jobs indicated in Figure 3-11 assumes processing for stabilization and reports the maximum number for options at each site.

For any of the alternatives, no more than an average additional 2,100 jobs over the period 1995 to 2005 would be required for implementation. Some of the larger SNF employment requirements (particularly those involving the Hanford Site) would be caused by the development and operation of processing facilities needed to stabilize stored SNF. If processing were not undertaken, less employment would be generated at those sites. In addition, the relocation of the Expended Core Facility to sites other than the Idaho National Engineering Laboratory would result in an increase of about 500 jobs per year in the support of naval SNF examinations at those sites and would result in a corresponding loss of approximately 500 jobs at the Idaho National Engineering Laboratory. However, regionalization with the Nevada Test Site as the Western Regional Site and the Oak Ridge Reservation as the Eastern Regional Site would result in the highest employment peak. The peak, estimated to be approximately 4,600 jobs in the year 2000, includes employment at sites preparing SNF for transport to the selected sites.

Figure 3-11. Change in the number of jobs averaged over the years 1995 to 2005 for spent nuclear fuel management activities.

Figure 3-12. Change in site employment between the years 1995 and 2005 for spent nuclear fuel management activities as a percent of 1995 baseline.

A more detailed discussion of socioeconomic impacts can be found in Chapter 5, Volume 1 of this EIS.

3.3.4 Generation of Radioactive Wastes

When SNF is stored onsite, very little high-level, transuranic, or mixed waste is generated (see Figure 3-13). These small quantities of radioactive wastes would usually be generated during stabilization activities.

As a result, under the No Action alternative fewer than 20 cubic meters per year (26 cubic yards per year) of transuranic wastes would be generated from SNF management nationwide because SNF would not be stabilized. Under the other alternatives, where stabilization activities are assumed to occur, it is estimated that between 20 and 190 cubic meters (26 and 250 cubic yards) of high-level waste and between 20 and 90 cubic meters (26 and 120 cubic yards) of transuranic waste would be generated each year (Figure 3-13). The lower generation rates would occur in the Decentralization alternative, where small amounts of SNF would be transported among major DOE sites (and stabilization for transport would not be necessary). For other alternatives, greater amounts of SNF would be transported among sites; therefore, more SNF would require stabilization before transport and more waste would be generated. The difference between the minimum and maximum volume of waste generated results principally from the contribution attributable to processing for stabilization.

Low-level waste is also generated as a result of SNF management. Figure 3-14 indicates the estimated annual volume for each of the alternatives. As previously noted for high-level, transuranic, and mixed waste, the higher values are principally the result of processing for stabilization.

A more detailed discussion of radioactive waste generation under each alternative can be found in Chapter 5, Volume 1 of this EIS.

3.3.5 Impacts on DOE and Navy Missions

The concerns for the missions of DOE and the Navy relate to storing SNF safely, meeting obligations, preparing SNF for ultimate disposal, and examining naval SNF.

3.3.5.1 Impacts on DOE.

The DOE mission regarding the safe storage of SNF is impacted in the No Action alternative. Under this alternative, DOE will initially suffer from a loss of margin in storage capacity. In addition, DOE may be impacted by needing to make more frequent repairs to existing facilities (potentially losing the use of a facility because it is beyond repair). In time, there would be little or no flexibility for repairs under the No Action alternative.

Figure 3-13. Average volume of high-level, transuranic, and mixed waste generated per year over the years 1995 to 2005 for spent nuclear fuel management activities.

Figure 3-14. Average volume of low-level wastes generated per year over the years 1995 to 2005 for spent nuclear fuel management activities.

Additionally, by limiting research and development to activities already approved, DOE's ability to safely store SNF would be impacted by being unable to conduct new research and development. The No Action alternative would not permit development of processing and other technologies except for those underway as of June 1995.

Under the No Action alternative, DOE would not satisfy its obligations associated with SNF from university reactors, other research reactors, and special-case commercial SNF. Also, under the No Action alternative, DOE might not be able to fulfill agreements with states or other Federal agencies that involve SNF, except those specific actions already in progress, unless the agreements are changed. Failure to meet the terms of these agreements would expose DOE to adverse legal actions. In addition, DOE would not proceed, as it has proposed, to establish a new policy for management of foreign research reactor fuel that contains United States origin uranium (see Section 1.2.4). These mission impacts could be avoided under any alternative but the No Action alternative.

The DOE recognizes a need, which is not yet well defined, to prepare SNF for its ultimate disposition. At this point, the processing and other technology required for ultimate disposition are not precisely known.

Under the No Action alternative, no new facilities or new research and development would be allowed. The No Action alternative would not permit development of processing and other technologies except for those begun as of June 1995. Although the acceptance criteria for DOE-managed SNF have not yet been defined and repository disposal may permit canned SNF, alternative approaches for ultimate disposition must be developed. By not allowing this development under this alternative, DOE would be unable to meet one of the major goals of the SNF Management Program. For the No Action alternative, no facilities could be built for converting SNF to forms acceptable for disposition. In addition, with facilities storing SNF throughout the country, more canning or other processing facilities might be required than are currently planned. Building additional facilities at multiple locations would impede efficient disposition of SNF produced at small reactor sites. Other alternatives would allow research and development to proceed as deemed appropriate to support stabilization.

3.3.5.2 Impacts on the Navy.

The Navy would incur large storage costs under the No Action and Decentralization alternatives. In addition, the Navy mission would be hindered if the full examination of fuels at an expended core facility were not possible. Full examination would not happen under the No Action alternative and Decentralization Options A and B. The examinations are a critical aspect of the Naval Nuclear Propulsion Program's ongoing advanced fuel research and development program. They provide engineering data on nuclear reactor environments, material behavior, and design performance. These data support

The design of new reactors having extended lifetimes

Continued safety of naval reactors

Improvements in nuclear fuel performance and ship operational performance

The operation of existing naval reactors by providing confirmation of their proper design and allowing maximum depletion of their fuel.

The verification of engineering methods and models to design naval nuclear fuel.

Although it is difficult to quantify the benefits of an outstanding safety record and improved operational characteristics, increased core life yields an economic advantage-a reduction in the number of reactor cores that must be procured and in the number of refuelings that must be performed. It also results in less SNF being generated. Another advantage is the increased online availability of nuclear-powered ships with life-of-ship fuel, which would reduce the number of ships required. About $5 billion would be saved if life-of-ship fuels are developed, based on an assumed force structure of fewer than 100 nuclear-powered ships by 2005. Additional details can be found in Appendix D, Volume 1 of this EIS.

3.3.6 Cost of Implementation

The DOE prepared and issued in March 1995 a cost evaluation report (DOE 1995b) that provides insight for short- and long-term planning for DOE complex-wide SNF management. This report was also used to provide costs relevant to this EIS. This section provides potential costs associated with the management of DOE SNF for the 40-year period evaluated in this EIS.

3.3.6.1 Results.

Table 3-9 provides a range of costs for interim storage. Because of the very broad scope associated with complex-wide SNF management and the uncertain nature of future actions, "best estimate" costs cannot be developed at this time. The degree to which existing facilities factor into a given alternative can vary. To account for this, each alternative was analyzed for two cost ranges to define the possible spread of cost for each alternative. The upper and lower cost ranges were defined as follows:

Upper Cost Range - Assumed construction of new facilities, except for a limited number judged adequate for 40 years.

Lower Cost Range - Assumed existing facilities used at the Idaho National Engineering Laboratory and the Savannah River Site but no existing facilities used at Hanford. Facility upgrades were limited to Phase III vulnerability costs (DOE 1994c).

Table 3-9. Cost results for storage only (billions of dollars).

Alternatives	Upper range	Lower range
No Action (1)	17.4	10.6
Decentralization-no examination (2A)	17.9	8.6
Decentralization-limited examination (2B)	18.1	8.9
Decentralization-full examination (2C)	20.1	10.8
1992/1993 Planning Basis (3)	18.0	9.4
Regionalization by fuel type (4A)	17.6	9.1
Regionalization by geography (4B)a	16.0	9.6
Centralization at Hanford (5A)	15.4	13.5
Centralization at Idaho National Engineering Laboratory (5B)	13.8	11.9
Centralization at Savannah River Site (5C)	15.1	9.5
Centralization at Oak Ridge Reservation (5D)	17.1	15.1
Centralization at Nevada Test Site (5E)	17.5	15.3

a. All options were considered, however, only Idaho National Engineering Laboratory and Savannah River Site costs are shown.

3.3.6.2 Discussion and Conclusions.

Table 3-9 shows that Alternatives 1, 2A, 2B, 3, or 4A are roughly equivalent. This is because most of the SNF would be located at the same sites (Hanford, Idaho National Engineering Laboratory, and Savannah River Site) in each alternative. Alternative 4B costs less than Alternative 3 because all SNF would be moved to two sites (Idaho National Engineering Laboratory and Savannah River Site), which have existing infrastructures, and economies of scale (fewer sites cost less) dictate that two sites would be less costly than three. The table also shows that if new facilities are required, it would be least expensive to centralize SNF management at a site with existing SNF management infrastructure (that is, Alternatives 5A, 5B, or 5C). Transportation costs, which are typically 1 percent of total costs, would not be an overriding consideration in the selection of locations for SNF management.

In the lower cost range, if existing facilities can continue to be used, it would be least expensive to manage fuel under alternatives that maximize the use of sites with existing capabilities (that is, Alternatives 2A, 2B, 4A, or 4B). The centralization alternatives, which would require the construction of storage facilities, could cost up to $6.7 billion more that the least costly alternative (2A). Before drawing conclusions based on the lower cost range results, however, the reader should recognize that the selection of an approach using existing facilities, combined with a commitment to upgrade facilities [over and above correction of vulnerabilities (DOE 1994c)] may significantly change the cost comparisons. In this situation, cost would tend to increase toward the upper cost range.

Additional details can be found in DOE (1995b). This report is available in the DOE Public Reading rooms listed in the EIS, or upon request from the Office of Communications, DOE Idaho Operations Office at the address listed in the front of the EIS.

3.3.7 U.S. Nuclear Regulatory Commission Licensing Standards

DOE is proceeding with actions to implement safe, efficient, and cost-effective interim storage of its SNF before final disposition. The need for interim storage has led DOE to evaluate storage technologies and alternative management strategies to provide an optimum solution to storage challenges. Several commercial storage technologies under evaluation for DOE SNF have been licensed and regulated by the U.S. Nuclear Regulatory Commission. In addition, DOE SNF could eventually come under the jurisdiction of the U.S. Nuclear Regulatory Commission if it is to be disposed of in a geologic repository. Therefore, DOE is considering having any new interim storage facilities reviewed to determine whether they could meet U.S. Nuclear Regulatory Commission licensing standards. This approach, if implemented, would provide a testing ground for the development of the technical and administrative protocols between the U.S. Nuclear Regulatory Commission and DOE in the event that some type of U.S. Nuclear Regulatory Commission regulatory oversight occurs in the future.

4. AFFECTED ENVIRONMENT

This chapter contains overviews of the potentially affected environments at and around the existing and potential sites under consideration for management of SNF within the various alternatives addressed in the EIS. Because of the large amount of information necessary to adequately characterize the affected environments at these sites, the space available in this chapter limits the presentations to summaries of the relevant key site characterization information. Consequently, the detailed descriptions of the affected environments are presented under separate cover as self-contained appendices to Volume 1. This approach allows the reader to compare the relative similarities and differences among the sites without having to review thousands of pages of text. These separate site-specific appendices also contain the detailed analyses of environmental impacts associated with each alternative that are rolled up and summarized in Chapter 5.

The site-specific appendices under separate cover are organized as follows:

Appendix	Focus of appendix
A	Hanford Site
B	Idaho National Engineering Laboratory
C	Savannah River Site
D	Naval Nuclear Propulsion Program
E	Other Generator/Storage Locations
F	Nevada Test Site and Oak Ridge Reservation

This chapter focuses on details about resources most likely to be affected by the actions evaluated under the various alternatives. Consequently, not every category of information addressed in the site-specific appendices is rolled up for presentation here.

4.1 Hanford Site

This section summarizes the environmental characterization information on the Hanford Site, Richland, Washington. This information has been used in evaluating environmental impacts that might result from implementing the various alternatives for management of SNF at the Hanford Site. More detailed information characterizing the affected environment of the Hanford Site is presented in Appendix A, under separate cover.

The Hanford Site covers about 1,450 square kilometers (560 square miles) of the southeastern part of the State of Washington (see Figure 4-1). It is located in parts of Benton, Grant, and Franklin Counties. The nearest city is Richland, Washington, which borders the Hanford Site on its southeast corner. About 380,000 people live within an 80-kilometer (50-mile) radius of the Hanford Site.

The population within 80 kilometers (50 miles) of the Hanford Site has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Hanford Site is shown to be 20 percent minority and 18 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

Approximately 6 percent of the Hanford Site is occupied by operational facilities. Waste management and SNF processing activities and waste storage occur near the center of the Hanford Site. Eight retired plutonium production reactors and the N Reactor are located on the south side of the Columbia River, and the nuclear research and development laboratories are located in the southeastern part of the Hanford Site near the city of Richland. The majority of Hanford's SNF is stored in basins in 100-KW and

100-KE. The Fast Flux Test Facility is located in the east-central area of the Hanford Site. The remaining area is undeveloped land that provides for buffer zones for the operating areas. The Hanford Site is a Superfund site, listed on the National Priority List.

The land adjacent to the Hanford Site is either urbanized or agricultural. Agricultural areas include irrigated and dry-land farming and grazing.

In 1992, the Hanford Site employed 16,100 people, accounting for almost 25 percent of the nonagricultural employment in Benton and Franklin Counties. Other major employers include the Siemens Nuclear Power Corporation, Sandvik Special Metals, Iowa Beef Processors, Boise Cascade, and Burlington Northern Railroad.

As of 1992, 248 prehistoric archaeological sites were recorded by the Hanford Cultural Resources Laboratory of the Pacific Northwest Laboratory. Of the 48 sites on the National Register of Historic Places, two are single sites and the remainder are in seven archaeological districts. Archaeological sites include remains of numerous pithouse villages, campsites, cemeteries along the river banks, spirit quest monuments, hunting camps, game drive complexes, quarries in mountains and rock bluffs, hunting/kill sites in lowland stabilized dunes, and small temporary camps near perennial sources of water away from the river. Native Americans have inhabited the land around the Hanford Site since prehistoric times. The Wanapum and the Chamnapum bands of the Yakama tribe were the area's primary inhabitants, being joined by Palus people, Walla Walla people, and Umatilla people for fishing the Hanford Reach of the Columbia River. These people retain traditional secular and religious ties to the region. Some native plant and animal foods, which are used in religious ceremonies performed by members of the Washane or Seven Drums religion, can be found on the Hanford Site.

Figure 4-1. Hanford Site location and site map.

The Hanford Site is on a low-lying, modified alluvial plain of the Columbia River. Altitudes range from about 105 meters (345 feet) in the southeast part to about 245 meters (804 feet) in the northwest corner. The Hanford Site is bounded to the east by the Columbia River and the White Bluffs of the Ringold Formation, to the southeast by the city of Richland, to the west by the Rattlesnake Hills, and to the north by the Saddle Mountain.

The principal geologic features beneath the Hanford Site, listed from the oldest to the youngest, include the Columbia River Basalt Group (basaltic lava flows), the Ringold Formation (weakly cemented coarse sandy gravel to compacted silt and clay), and a series of deposits called the Hanford formation (coarse gravel and sand). These units are covered by a few meters or less of recent alluvial or windblown sands. Other than gravel, there are no geologic resources of economic value on the Hanford Site.

The area of the Hanford Site is historically of low-to-moderate seismicity. On a scale of 0 to 4, the Hanford Site is in a Uniform Building Code Seismic Risk Zone 2B. (Zone 0 represents little damage, and is subject to the greatest seismic risk.) The largest seismic shock near the Hanford Site on record was approximately 4.5 to 5.0 on the Richter scale and Modified Mercalli Intensity of V; it was recorded in Corfu, 35 kilometers (22 miles) north of the Hanford Site in 1918. A Modified Mercalli Intensity V quake occurred in 1973. Many lower intensity earthquakes have occurred in the Columbia Plateau and on the Hanford Site as part of "earthquake swarms," which are clusters of several small earthquakes occurring over a short period of time.

The Hanford Site is located approximately 160 kilometers (100 miles) to the east of the Cascade Range, which includes several volcanic vents. The great distance eliminates the potential for lava flows from these volcanoes reaching the Hanford Site. The foreseeable volcanic effects at the Hanford Site are limited to windborne volcanic ash.

The general climate of the Hanford Site is hot and dry in summer and cool in winter. The average annual precipitation is 16 centimeters (6.3 inches), most of which falls during the winter. On average, thunderstorms occur 11 days per year, mostly during the summer. Tornadoes are extremely rare, occurring within 160 kilometers (100 miles) of the Hanford Site about once in 3 years. Air quality in the Hanford region is well within the State of Washington and U.S. Environmental Protection Agency standards for criteria pollutants, except that short-term particulate concentrations occasionally exceed the PM-10 standard. (PM-10 is particulate matter defined as suspended particulates with an aerodynamic diameter less than 10 micrometers.) The Class I Area (areas where degradation of air quality is to be severely restricted) nearest to the Hanford Site is at Goat Rocks Wilderness Area, 145 kilometers (90 miles) away.

Two rivers pass through or near the Hanford Site. The Columbia River passes through the northern part of the Hanford Site and forms part of the eastern boundary. The average daily flow of this river is 3,400 cubic meters per second (120,100 cubic feet per second). The Yakima River, with an average flow of 104 cubic meters per second (3,673 cubic feet per second), is located near the southern portion of the Hanford Site. Wastewaters are discharged to several ponds on the Hanford Site and the Columbia River. In addition to these surface waters, there are two intermittent creeks that form the remainder of the surface waters on the Hanford Site. The flood areas of these rivers and streams include some areas where facilities are located, but flooding is well-controlled by upstream dams on the Columbia River. Minor flooding (away from facilities) occurs from other watercourses. While specific information on the 100-year floodplain has not been defined, the projected extent of the maximum probable flood, which is greater than the area of inundation expected from a 100-year flood, would not impact proposed SNF facilities. More details on flooding, including that induced by dam failures, are given in Section 4 of Appendix A of Volume 1.

The water quality of the Columbia River is high, with minor increases in constituents resulting from Hanford Site discharges. Radiological monitoring shows low levels of radionuclides in samples of Columbia River water. Tritium, iodine-129, and uranium are found in somewhat higher concentrations downstream of the Hanford Site than upstream, but are well below concentration guidelines established by the U.S. Environmental Protection Agency drinking water standards. Nonradiological water quality parameters measured during 1989 were similar to those reported in previous years and were within Washington State Water Quality Standards.

Part of the water supply at the Hanford Site and for the nearby Tri-Cities is the Columbia River. In 1991, the combined water use for Richland, Pasco, and Kennewick was 4.3 107 cubic meters (11.38 billion gallons). Richland and Kennewick derive a portion of their water used from nearby groundwater wells and rely on groundwater as a sole source of water from November through March each year. Additional references and more detailed information on groundwater are in Appendix A of Volume 1.

In 1993, several radionuclides and nonradioactive chemicals were present in unconfined aquifers located beneath the Hanford Site in some locations at levels exceeding U.S. Environmental Protection Agency drinking water standards and/or DOE Derived Concentration Guides. These constituents are listed, as follows: radiological constituents-tritium, strontium-90, cobalt-60, antimony-125, technetium-99, iodine-129, cesium-137, uranium, and plutonium; and nonradiological constituent-nitrate, chromium, trichloroethylene, cyanide, fluoride, carbon tetrachloride, and chloroform. Groundwater beneath the Hanford Site is not used for human consumption or food production with the exception of a well utilized for drinking at the Fast Flux Test Facility visitor center. Above-background levels of tritium and iodine-129 have been detected in this well; however, these levels are well below U.S. Environmental Protection Agency drinking water standards.

DOE asserts a federally reserved water withdrawal right with respect to the Hanford Site operations. Current withdrawals from the Columbia River occur under this assertion. Of the water consumed from surface waters in the vicinity of the Hanford Site, 13 percent is used for industrial purposes. The Hanford Site uses 41 percent of the water targeted for industrial use.

The Hanford Site is a shrub-steppe environment dominated by cheatgrass and sagebrush, but it includes 10 different types of plant communities. This plant environment supports 12 species of amphibians and reptiles, 39 species of mammals, and numerous bird and insect species. Deer and elk are the major large animals, and coyotes are the major mammalian predators. Wetlands of varying size exist along the Columbia River and support extensive stands of willows, grasses, aquatic plants, and other plants. In the Hanford Reach of the Columbia River, 44 species of fish have been identified. The Hanford Reach is also used by various salmon and trout species as a spawning area and a migration route to and from upstream spawning areas. Four threatened or endangered plants classified by the State of Washington exist on the Hanford Site, as well as seven species of threatened or endangered birds or mammals and one insect species. The insect species and three of the bird species are federally listed.

No federally listed threatened or endangered species have been observed at the proposed SNF site. However, two Federal and/or state candidate species, the loggerhead shrike (Federal and state candidate) and sage sparrow (state candidate), were observed during a survey of the proposed SNF site. The sagebrush habitat at the proposed site is considered priority habitat by the State of Washington for the loggerhead shrikes, sage sparrows, burrowing owls (state candidate), pygmy rabbits (Federal candidate and state threatened), sage thrashers (state candidate), western sage grouse (Federal and state candidate), and sagebrush voles (state monitored). Although burrowing owls were not observed at the site, ground squirrel burrows used by burrowing owls and owl pellets were observed during the survey. No evidence of the other species were found at the proposed site. The closest known ferruginous hawk (Federal candidate and state-threatened species) nest is approximately 8.9 kilometers (5.5 miles) northwest of the site. The proposed site should be considered as comprising a portion of the foraging range of this species.

The Tri-Cities (Richland, Kennewick, and Pasco) serve as a regional transportation center with major air, land, and river connections. The Tri-Cities area has four major highways: U.S. Routes 12 and 395, State Route 240, and Interstate 82. State Route 240 traverses the Hanford Site from southeast to northwest. The Burlington Northern and Union Pacific railroads connect the area to more than 35 states. Docking facilities exist at the ports of Benton, Kennewick, and Pasco. The Tri-Cities Airport, located in Pasco, provides daily passenger and freight services.

For the years 1991 to 1993, the potential collective dose to the population within 80 kilometers (50 miles) from all Hanford Site effluents was calculated to be 0.9, 0.8, and 0.4 person-rem, respectively. In 1993, the dose to the maximally exposed offsite individual was calculated to be 0.00003 rem (0.03 millirem) per year from all exposure pathways. For perspective, collective dose to the same population from natural background radiation was calculated to be about 100,000 person-rem from an average individual dose of 0.3 rem (300 millirem) per year.

In 1993, about 14,500 individuals were monitored at the Hanford Site. Of those monitored, 11,000 were classified as radiation workers with a collective dose of 200 person-rem and an average annual dose equivalent of 0.02 rem (20 millirem) per individual with measurable doses. A subset of Hanford radiation workers associated with SNF storage at 100 K Basins averaged doses of 0.4 rem (400 millirem) per year. These averages are well below the 10 CFR Part 835 radiation dose limit of 5 rem (5,000 millirem) per year and the DOE Administration Control Level of 2 rem (2,000 millirem) per year for occupational exposure.

Electricity in the region is provided by several different entities, but it is ultimately generated by the Bonneville Power Administration. About 74 percent of the region's installed generating capacity is hydroelectric. Power for the Hanford Site is purchased wholesale from the Bonneville Power Administration, amounting to greater than 550 megawatts in 1988. Because of the reliance on hydropower, annual production is variable, averaging 16,400 megawatts of capacity.

Major incorporated areas in Benton and Franklin Counties are served by municipal wastewater treatment systems. The unincorporated areas are served by onsite septic systems.

High-level radioactive waste has been accumulating at the Hanford Site since 1944 in 149 single-shell tanks-no new waste has been added to these tanks since 1980. Much of the liquid waste from single-shell tanks has been transferred to newer double-shell tanks for safer storage. Transuranic wastes were disposed of onsite before 1970 in unlined trenches. Since 1970, transuranic wastes have been stored in abovegrade storage facilities. As of 1991, there were about 120,000 cubic meters (157,000 cubic yards) of transuranic waste buried or in retrievable storage. Mixed low-level waste totaling 16,745 cubic meters (21,902 cubic yards) was buried at the Hanford Site from 1987 to 1991. Another 4,225 cubic meters (5,526 cubic yards) of mixed waste has accumulated in storage. In 1992, 56,245 kilograms (124,000 pounds) of mixed low-level waste was generated. From 1944 to 1991, approximately 558,916 cubic meters (731,030 cubic yards) of low-level waste was buried at the Hanford Site. In 1991, 5,300 cubic meters (6,932 cubic yards) of low-level waste was generated at the Hanford Site. In 1992, 619,268 kilograms (1,365,000 pounds) of hazardous waste was generated. Mixed wastes are 99 percent tank wastes at the Hanford Site resulting from 108 different waste streams. Hazardous wastes generated in 1995 from SNF are expected to total 2.2 cubic meters (2.9 cubic yards). In 1992, industrial solid waste totaled 22,213 cubic meters (29,054 cubic yards) and asbestos totaled 1,017 cubic meters (1,330 cubic yards). A total of 1,484 hazardous chemicals are reported at the Hanford Site at over 783 locations, and they are found in 2,926 different hazardous materials. In 1992, the Emergency Planning and Community Right-to-Know Act reporting threshold was exceeded for 53 hazardous chemicals.

4.2 Idaho National Engineering Laboratory

This section summarizes environmental characterization information on the Idaho National Engineering Laboratory. This information has been used to evaluate impacts at the Idaho National Engineering Laboratory under various alternatives for management of SNF. More detailed information characterizing this Idaho National Engineering Laboratory is presented in Appendix B, under separate cover.

The Idaho National Engineering Laboratory is located on approximately 2,300 square kilometers (890 square miles) of land in southeastern Idaho and contains nine major facility areas (see Figure 4-2). It is located primarily within Butte County, but portions of the Idaho National Engineering Laboratory are also located in Bingham, Jefferson, Bonneville, and Clark Counties. The Idaho National Engineering Laboratory is roughly equidistant from Salt Lake City, Utah, and Boise, Idaho. Cities near the Idaho National Engineering Laboratory include Idaho Falls to the east, Blackfoot to the southeast, Pocatello to the south-southeast, and Arco to the southwest. Yellowstone National Park is 149 kilometers (90 miles) to the east.

Categories of land use at the Idaho National Engineering Laboratory include facility operations, grazing, general open space, and infrastructure, such as roads. About 2 percent of the total Idaho National Engineering Laboratory area [4600 hectares (11,400 acres)] is used for facilities and operations. The Idaho National Engineering Laboratory is a Superfund site, listed on the National Priority List.

The region of influence for the Idaho National Engineering Laboratory is a seven-county area comprising Bingham, Butte, Bonneville, Clark, Jefferson, Bannock, and Madison counties. The region of influence had a 1990 population of 219,713. Historically, the regional economy has relied predominantly on farming and ranching. Mining is also an important component of the regional economy.

The population within an 80-kilometer (50-mile) circle centered at Argonne National Laboratory-West on the Idaho National Engineering Laboratory has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Idaho National Engineering Laboratory is shown to be 7 percent minority and 14 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

During fiscal year 1990, the Idaho National Engineering Laboratory directly employed approximately 11,100 personnel, accounting for almost 12 percent of the total regional employment. Approximately 38,000 persons, or 17 percent of the total regional population, were directly supported by employment associated with the operation of the Idaho National Engineering Laboratory. In 1992, the total direct Idaho National Engineering Laboratory employment was approximately 11,600 jobs. The total number of jobs at the Idaho National Engineering Laboratory is projected to decrease to approximately 8,620 in fiscal year 1995 and to approximately 7,250 in fiscal year 2004.

More than 1,500 prehistoric and historic archaeological resources have been identified in the Idaho National Engineering Laboratory area, but only 4 percent of the Idaho National Engineering Laboratory has been surveyed, mostly near major facility areas. The resources identified include prehistoric and historic sites and isolates. Although not formally evaluated, these sites are considered potentially eligible for nomination to the National Register of Historic Places; the isolates have been categorized as unlikely to meet eligibility requirements. The Experimental Breeder Reactor-I is listed on the National Register of Historic Places, and other structures could potentially be listed. The Shoshone-Bannock Tribes are the region's primary Native American residents. Because they believe the land is sacred, the entire Idaho National Engineering Laboratory reserve is potentially culturally important to them. Cultural resources, to the Shoshone-Bannock peoples, include all forms of traditional lifeways and usage of all natural resources. This includes not only prehistoric archaeological sites, which are important in religious or cultural heritage context, but also features of the natural landscape, air, plant, water, or animal resources that might have special significance. DOE has committed to additional interaction and exchange of information with the Shoshone-Bannock Tribes at the Fort Hall Reservation.

Figure 4-2. Idaho National Engineering Laboratory location and site map.

The northwestern edge of the Eastern Snake River Plain, where the Idaho National Engineering Laboratory is located, is bordered on the north and west by the Bitterroot, Lemhi, and Lost River mountain ranges. A number of inactive volcanic buttes also form part of the Idaho National Engineering Laboratory landscape.

The Eastern Snake River Plain forms a broad, northeast-trending, crescent-shaped trough with low relief comprised primarily of basaltic lava flows. These flows at the surface range in age from 1.2 million to 2,100 years. The surface of the Eastern Snake River Plain is comprised primarily of basaltic lava flows with thin, discontinuous, interbedded deposits of wind-blown loess and sand, waterborne alluvial fan and floodplain alluvial sediments, and rhyolitic domes formed 1,200,000 to 300,000 years ago.

The Eastern Snake River Plain is on an area of low seismicity that is adjacent to the seismically active Intermountain Seismic Belt and Centennial Tectonic Belt and lies in Uniform Building Code Seismic Risk Zones 2B and 3. The largest recorded earthquake in the Centennial Tectonic Belt occurred on October 28, 1983, near Borah Peak, Idaho, and had a moment magnitude of 6.9 (surface wave magnitude of 7.3). The epicenter was about 90 to 100 kilometers (56 to 68 miles) from the Idaho National Engineering Laboratory. The largest recorded earthquake within the Intermountain Seismic Belt surface wave (Richter scale magnitude 7.5) occurred on August 17, 1959, near Hebgen Lake, Montana, with an epicenter 145 kilometers (90 miles) northeast of the Idaho National Engineering Laboratory. In addition to these earthquakes, a total of 29 earthquakes greater than magnitude 5.5 have occurred within 322 kilometers (200 miles) of the Idaho National Engineering Laboratory since 1884. The Idaho National Engineering Laboratory lies in a potentially active but long-time dormant volcanic area. The conditional probability of basaltic volcanism affecting a south-central area of the Idaho National Engineering Laboratory is one incident in 40,000 to 100,000 years. The probability of volcanic impact on Idaho National Engineering Laboratory facilities further north is estimated to be less than one incident in every million years or longer.

Within Idaho National Engineering Laboratory boundaries, the geologic resources found or produced are sand, gravel, and pumice. Several quarries or pits maintain supply material for various onsite construction projects.

The general climate of the Idaho National Engineering Laboratory is characterized by average seasonal temperatures that range from -7.3C (18.8F) in winter to 18.2C (64.8F) in summer, with an annual average temperature of about 5.6C (42F). Annual precipitation is light, averaging 221 millimeters (8.71 inches). Snowfall averages 701 millimeters (27.6 inches) per year.

Although the Idaho National Engineering Laboratory is in a belt of prevailing westerlies, these winds are normally channeled by the adjacent mountain ranges into southwest wind. The annual average windspeed measured at the 6.1-meter (20-foot) level at the Central Facilities Area weather station is 3.4 meters per second (7.5 miles per hour). Monthly average values range from 2.3 meters per second (5.1 miles per hour) in December to 4.2 meters per second (9.3 miles per hour) in April and May. The highest hourly average nearground windspeed measured at the Idaho National Engineering Laboratory is 22.8 meters per second (51 miles per hour).

Severe weather, other than thunderstorms, is uncommon. Five funnel clouds (that is, tornadoes not touching the ground) and no tornadoes have been reported between 1950 and 1988.

Neither the Idaho National Engineering Laboratory nor the surrounding counties is designated as a nonattainment area (40 CFR Part 81.313) with respect to any of the National Ambient Air Quality Standards (40 CFR Part 50). The Idaho National Engineering Laboratory is located in a Class II area. Three prevention of significant deterioration (40 CFR Part 52.21) Class I ambient air quality areas have been designated in the vicinity of the Idaho National Engineering Laboratory: Craters of the Moon Wilderness Area, Idaho, 53 kilometers (33 miles) west-southwest from the center of the Idaho National Engineering Laboratory; Yellowstone National Park, Idaho-Wyoming, 143 kilometers (89 miles) east northeast from the center of the Idaho National Engineering Laboratory; and Grand Teton National Park, Wyoming, approximately 145 kilometers (90 miles) east from the center of the Idaho National Engineering Laboratory.

The types and amounts of nonradiological emissions from Idaho National Engineering Laboratory facilities and activities are similar to those of other industrial complexes of similar size. Baseline concentrations from criteria and hazardous/toxic air pollutants are within applicable standards and guidelines. Radioactive emissions occur from Idaho National Engineering Laboratory facilities; the calculated annual dose to the maximally exposed offsite individual is 0.00005 rem (0.05 millirem).

Essentially no surface water bodies drain the Idaho National Engineering Laboratory-all creeks and streams arise in the mountains and much of their water is diverted for irrigation. There is little flow of water onsite. Water that does reach the Idaho National Engineering Laboratory through the Big Lost River flows past the Test Reactor Area/Idaho Chemical Processing Plant area before going below ground or may be diverted by an onsite dam during heavy flows onto the southern part of the Idaho National Engineering Laboratory. The remainder of the water infiltrates near Test Area North. All rivers and streams are intermittent. No surface water runs off of the Idaho National Engineering Laboratory.

The Idaho National Engineering Laboratory does not withdraw or use surface water for operations, nor does it discharge effluents to natural surface water. However, the three surface water bodies at or near the Idaho National Engineering Laboratory (Big and Little Lost Rivers and Birch Creek) have the following designated uses: agricultural water supply, cold-water biota, salmonid spawning, and primary and secondary contact recreation. In addition, waters in the Big Lost River and Birch Creek have been designated for domestic water supply and as special resource waters.

Depths to the water table at the Idaho National Engineering Laboratory range from 61 meters (200 feet) in the north to 274 meters (900 feet) in the south. Flows in the largely unconfined Snake River Plain Aquifer are generally to the southwest. Groundwater flows at speeds ranging from 1.5 to 6.1 meters per day (5 to 20 feet per day). The water quality of the aquifer is generally good, and it is designated a sole source aquifer. As of 1992, concentrations of iodine-129, cobalt-60, strontium-90, and cesium-137 had exceeded the U.S. Environmental Protection Agency's maximum contaminant levels for drinking water established for radionuclides in localized areas within the aquifer inside the Idaho National Engineering Laboratory boundary. However, concentrations of these radionuclides in groundwater are generally decreasing over time. This decrease is attributed to improved waste management practices, reduced discharges, adsorption, and radioactive decay. Individual maximum contaminant levels have not been established for plutonium-238, plutonium-239, plutonium-240, and americium-241. However, these radionuclides have not been detected above the established limits for gross alpha particle activity or the proposed adjusted gross alpha activity maximum contaminant levels for drinking water. Extremely low concentrations of iodine-129 and tritium have migrated offsite, but both concentrations are well below the current U.S. Environmental Protection Agency's maximum contaminant levels for drinking water.

Of the nonradioactive metals, only total chromium has exceeded maximum contaminant levels established by the Safe Drinking Water Act. Nitrates have exceeded the maximum contaminant levels in the past near the Idaho Chemical Processing Plant but have been below the maximum contaminant level since 1988. Carbon tetrachloride, chloroform, 1,1-dichloroethylene, cis-1,2-dichloroethylene, trans-1,2-dichloroethylene, tetrachloroethylene, trichlorethylene, and vinyl chloride have exceeded maximum contaminant levels at various times over the last 5 years.

Groundwater use on the Snake River Plain includes irrigation, food processing and aquaculture, and domestic, rural, public, and livestock supply. Water use for the upper Snake River drainage basin and the Snake River Plain Aquifer was 16.4 109 cubic meters (4.3 1012 gallons) per year in 1985. Most of this water is for agriculture. The aquifer is the source of all water used at the Idaho National Engineering Laboratory. Site activities withdraw an average of 7.4 million cubic meters (1.9 billion gallons) per year, with a substantial portion discharged to the surface or subsurface and eventually returned to the aquifer. This withdrawal represents approximately 0.4 percent of the water consumed from the Eastern Snake River Plain Aquifer, or 53 percent of the maximum yield of a single typical irrigation well.

Total consumption of water at the Idaho National Engineering Laboratory averages 0.25 cubic meters per second (8.8 cubic feet per second). DOE holds a Federal Reserved Water Right for the Idaho National Engineering Laboratory, which permits a groundwater pumping capacity of 2.3 cubic meters per second (80 cubic feet per second), though this capacity is not utilized. The DOE priority on water rights dates back to the establishment of the Idaho National Engineering Laboratory.

Localized flooding can occur at the Idaho National Engineering Laboratory when the ground is frozen and melting snow combines with heavy spring rains. Test Area North was flooded in 1969; and, also in 1969, extensive flooding caused by snowmelt occurred in the lower Birch Creek Valley. Studies have shown that both the 25- and 100-year, 24-hour rainfall/snowmelt storm event could cause flooding within the Radioactive Waste Management Complex. The drainage system, including dikes and erosion prevention features designed to mitigate potential surface water flooding, have been upgraded. The area inundated by a probable maximum flood in the vicinity of Mackay Dam, 75 kilometers (45 miles) northeast of the Idaho National Engineering Laboratory, coupled with a dam failure, probably exceeds the areas expected to be inundated by 100- and 500-year floods of the Big Lost River at the Idaho National Engineering

Laboratory.

Analyses indicate that the shallow depths and low flow velocities resulting from the Mackay probable maximum flood and dam failure would not have a significant impact on Idaho National Engineering Laboratory facilities.

Onsite vegetation is predominantly shrub-steppe. Communities range from shadscale-steppe vegetation at lower altitudes, through sagebrush and grass dominated communities, to juniper woodlands along the foothills of nearby mountains and buttes. Big sagebrush and rabbitbrush are the most common shrub species. Indian ricegrass, wheatgrasses, squirreltail, and cheatgrass are common grasses. Common forbs include phlox, mustards, and Russian thistle.

About 270 vertebrate species have been observed onsite. These include 46 mammal, 204 bird, 10 reptile, 2 amphibian, and 9 fish species. Major fur-bearing species include coyote, badger, and bobcat. Important big-game species include the pronghorn, mule deer, and elk. Two federally endangered and nine candidate animal species potentially occur on the Idaho National Engineering Laboratory. The bald eagle is a winter resident and is locally common in the far north end and the western edge of the Idaho National Engineering Laboratory. Peregrine falcons are infrequently observed in the winter. Neither species is known to nest onsite, and neither is commonly observed near facilities. The candidate species include the white-faced ibis, northern goshawk, ferruginous hawk, burrowing owl, Townsend's big-eared bat, pygmy rabbit, long-eared myotis, small-footed myotis, and Idaho pointheaded grasshopper (occurs just north of the Idaho National Engineering Laboratory).

No Federal- or state-listed plant species occur at the Idaho National Engineering Laboratory, but eight plant species identified by the U.S. Bureau of Land Management, the U.S. Forest Service, or the Idaho Native Plant Society as sensitive, rare, or unique are known to occur there. These species are not generally located near any facilities and are uncommon on the Idaho National Engineering Laboratory because they require unique microhabitats.

Two interstate highways serve the general region: Interstate 15, a north-south route that connects several cities along the Snake River, approximately 40 kilometers (25 miles) east of the Idaho National Engineering Laboratory, and Interstate 86, an east-west route that intersects Interstate 15 about 64 kilometers (40 miles) south of the Idaho National Engineering Laboratory. U.S. Highways 20 and 26 are the main access routes to the southern portion of the Idaho National Engineering Laboratory. State Route 33 provides access to the northern portion of the Idaho National Engineering Laboratory from the east, State Routes 28 and 33 from the north, and State Route 22 from the west. These roads are complemented by an onsite (controlled access) system of about 140 kilometers (87 miles) of roads.

The Union Pacific Railroad provides rail service to the Idaho National Engineering Laboratory. Idaho Falls receives railroad freight service from Butte, Montana, to the north, and from Pocatello, Idaho, and Salt Lake City, Utah, to the south. The Union Pacific's Blackfoot-to-Arco route, which crosses the southern portion of the Idaho National Engineering Laboratory, provides rail service to the Idaho National Engineering Laboratory. This branch connects with a DOE spur line that links with developed areas. Most naval reactor SNF has been transported to the Idaho National Engineering Laboratory over these rail lines. Other shipments arrive by truck.

Several airlines provide Idaho Falls with aircraft passenger and cargo service.

Recorded doses from 1987 to 1991 were used as a baseline for comparison with SNF management operations for the next 40 years. The average annual occupational dose to individuals with measurable doses was 0.156 rem (156 millirem), giving an average collective dose of about 300 person-rem.

Industrial health and safety statistics from 1987 to 1991 are used as a baseline for comparison for the alternatives. There were 1,337 total recordable injury and illness cases at the Idaho National Engineering Laboratory from 1987 to 1991, for an average of 8,385 employees working a total of 79,654,000 hours. One fatality occurred at the Idaho National Engineering Laboratory between 1987 and 1991 when an employee was struck and killed by a forklift.

The water supply for the Idaho National Engineering Laboratory is provided by a system of about 30 wells, with pumps and storage tanks. The average combined pumpage from the Idaho National Engineering Laboratory wells from 1987 through 1991 was 7.4 billion liters per year (1.9 billion gallons per year), calculated based on the cumulative volumes of water withdrawn from the wells.

Average annual wastewater discharge volume at the Idaho National Engineering Laboratory for 1989 through 1991 was 537 million liters (142 million gallons).

The rated capacity of the Idaho National Engineering Laboratory electric power transmission loop line is 124 megavolt-amperes. The peak demand on the system from 1990 through 1993 was about 40 megavolt-amperes, and the average usage was approximately 200,000 megawatt-hours per year.

No high-level liquid waste resulting from reprocessing activities has been generated at the Idaho National Engineering Laboratory since 1992; however, certain other processes generate waste classified and handled as high-level waste. These sources are estimated to generate 750 cubic meters in 1995. From 1989 through 1992, an average of approximately 48.5 cubic meters of mixed low-level waste was generated annually. From 1989 through 1992, an average of approximately 46.5 cubic meters of low-level waste was generated annually.

Burial of transuranic waste ended in 1970; since then all transuranic waste has been placed in retrievable storage. Receipt of offsite transuranic waste ended in 1988 (with minor case-by-case exceptions). After 1988, only minor amounts of transuranic waste have been generated onsite and placed into retrievable storage. About 127,000 cubic meters (166,000 cubic yards) are retrievably stored or buried at the Idaho National Engineering Laboratory. The average annual volume of hazardous waste transported offsite from 1988 through 1991 was approximately 180 cubic meters. The average annual volume of industrial and commercial solid waste disposed of at the Central Facilities Area landfill from 1988 through 1992 was approximately 52,000 cubic meters (68,000 cubic yards).

4.3 Savannah River Site

This section presents summary environmental characterization information on the Savannah River Site. This information has been used to evaluate impacts at the site under various alternatives for management of SNF. More detailed information characterizing the Savannah River Site is presented in Appendix C, under separate cover.

The Atomic Energy Commission established the Savannah River Site in 1950 as the Savannah River Project to produce nuclear materials for the national defense. The number of Savannah River Site facilities grew to include five nuclear production reactors (now inactive), two chemical separations areas, a fuel and target fabrication facility (inactive), and support facilities.

The Savannah River Site occupies an area of approximately 800 square kilometers (310 square miles) in western South Carolina, in a generally rural area about 40 kilometers (25 miles) southeast of Augusta, Georgia (see Figure 4-3). The Savannah River Site, which is bordered by the Savannah River to the southwest, includes portions of three South Carolina counties: Aiken, Barnwell, and Allendale.

Approximately 73,500 hectares (181,500 acres) of the Savannah River Site is undeveloped, and 90 percent of this area (more than 65,000 hectares) is forest land. The Savannah River Forest Station (a branch of the U.S. Forest Service) manages the forested areas, many of which are pine plantations, under a cooperative agreement with DOE. Facilities that previously produced defense nuclear materials occupy approximately 5 percent of the total Savannah River Site land area. The remaining area consists of wetlands, ponds, and reservoirs.

Approximately 90 percent of the Savannah River Site work force lives in six counties around the

Savannah River Site (Aiken, Allendale, Bamberg, and Barnwell counties in South Carolina and Richmond and Columbia counties in Georgia). In 1990, employment at the Savannah River Site was 20,230, representing approximately 10 percent of the employment in the six-county region of influence. Employment at the Savannah River Site grew to 23,351 in Fiscal Year 1992, with a payroll of more than $1.1 billion. The total number of jobs at the Savannah River Site is projected to decrease to approximately 15,800 in Fiscal Year 1995.

Between 1980 and 1990, the population in the six-county region of influence increased 13 percent, from 376,058 to 425,607. More than 88 percent of the 1990 population lived in Aiken (120,940), Columbia (66,031), and Richmond (189,719) counties. According to census data, the estimated average number of persons per household in the six-county region was 2.72, and the median age of the population was 31.2 years.

The population within 80 kilometers (50 miles) of the Savannah River Site has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Savannah River Site is shown to be 38 percent minority and 17 percent low-income based on U.S. Bureau of Census information, and the definitions and approach presented in Appendix L.

As of the end of Fiscal Year 1992, archaeological surveys have covered about 60 percent of the Savannah River Site and recorded 858 archaeological sites. Of these 858 sites, more than 200 have been evaluated, and 53 have been determined to be eligible for the National Register of Historic Places.

Three Native American groups-the Yuchi Tribal Organization, the National Council of Muskogee Creek, and the Indian Peoples Muskogee Tribal Town Confederacy-have expressed concern over sites and items of religious significance on the Savannah River Site. DOE routinely notifies these organizations about major planned actions on the Savannah River Site and asks them to comment on the Savannah River Site documents prepared in accordance with the National Environmental Policy Act of 1969.

Figure 4-3. Savannah River Site location and site map.

The Savannah River Site has gently rolling terrain and is heavily wooded. Facilities are scattered about the Savannah River Site, but major production facilities (for example, reactors and separations areas) are confined to its interior. As a result, the Savannah River Site facilities are generally not visible from outside of the Savannah River Site.

The Savannah River Site lies in the Coastal Plain physiographic province of South Carolina, approximately 32 kilometers (20 miles) southeast of the Fall Line, which separates the Atlantic Coastal Plain province from the Piedmont province. Onsite elevations range from 27 to 128 meters (89 to 420 feet) above mean sea level.

The Coastal Plain sediments underlying the Savannah River Site consist of sandy clays and clayey sands; however, occasional beds of clean sand, gravel, clay, and carbonate do occur. Underlying these sediments are dense crystalline igneous and metamorphic rock or younger consolidated sediments of the Triassic Period. A regional aquitard, the Appleton Confining System, hydrologically separates the Triassic formations and older igneous and metamorphic rocks from the overlying Coastal Plain sediments.

The area of the Savannah River Site is historically of low-to-moderate seismicity. On a scale of 0 to 4, the Savannah River Site is in a Uniform Building Code Seismic Risk Zone 2A. The partially mapped Pen Branch Fault, which spans the central portion of the Savannah River Site, is considered to be Cretaceous/Tertiary (140 million to 1.6 million years) reactivation of a northern boundary fault of the Triassic age Dunbarton basin. There is no evidence to indicate that the Pen Branch Fault is a capable fault as defined by the U.S. Nuclear Regulatory Commission. Surface mapping, subsurface boring, and geophysical investigations have not identified any faulting of the sedimentary strata at the Savannah River Site that would have an effect on facilities.

The closest offsite fault system of significance is the Augusta Fault Zone, approximately

40 kilometers (25 miles) from the Savannah River Site. In this fault zone, the Belair Fault has experienced the most recent movement, but it is not considered capable of generating major earthquakes. There is no conclusive evidence of recent displacement along any fault within 320 kilometers (200 miles) of the Savannah River Site, with the possible exception of the buried faults in the epicentral area of the 1886 Charleston, South Carolina, earthquake, approximately 145 kilometers (90 miles) away.

Two major earthquakes have occurred within 320 kilometers (200 miles) of the Savannah River Site: (a) the Charleston earthquake of 1886, which had an estimated Richter scale magnitude of 6.8, and (b) the Union County, South Carolina, earthquake of 1913, with an estimated Richter magnitude of 6.0, which occurred about 160 kilometers (100 miles) from the Savannah River Site. In June 1985, a minor earthquake with a local Richter scale magnitude of 2.6 and a focal depth of 1.0 kilometer (0.60 mile) occurred at the Savannah River Site. An earthquake with a local Richter scale magnitude of 2.0 occurred on the Savannah River Site on August 5, 1988, but was not felt by onsite workers.

The Savannah River Site is in a temperate region with mild winters and long humid summers. Average monthly temperatures range from 7.2C (45F) in January to 27.2C (81F) in July. The average annual precipitation at the Savannah River Site is approximately 122 centimeters (48 inches).

Prevailing winds are from the northeast and southwest, with an annual average windspeed of 3.8 meters per second (8.5 miles per hour). Windspeeds are typically highest in winter and lowest in summer.

On average, thunderstorms occur 56 days per year. The estimated probability of a tornado striking the Savannah River Site is 7.0 10-5 per year. Nine tornadoes have been confirmed on the Savannah River Site since 1953. Hurricane-strength winds have been recorded once at the Savannah River Site, from Hurricane Gracie in 1959.

Air quality at the Savannah River Site is generally good, meeting National Ambient Air Quality Standards for criteria pollutants. The nearest Class I Area, the Congaree National Monument, is more than 80 kilometers (50 miles) from the Savannah River Site. Tritium is the only radionuclide of Savannah River Site origin that is routinely detected in offsite air samples in concentrations above background.

Five streams drain the Savannah River Site: Upper Three Runs Creek, Fourmile Branch, Pen Branch, Steel Creek, and Lower Three Runs Creek. These streams originate on the Aiken Plateau and descend 15 to 60 meters (50 to 200 feet) before discharging to the Savannah River.

Surface-water quality in the Savannah River downstream of the Savannah River Site is generally good. In 1992, the South Carolina Department of Health and Environmental Control changed the classification of the river and its tributary streams to "freshwaters" from "Class B waters," imposing more stringent water quality standards. Two elements-iron and manganese (both naturally high constituents of local waters)-have historically exceeded maximum concentration limits.

Two distinct hydrogeologic systems underlie the Savannah River Site: (a) the southeastern Coastal Plain province, where a wedge of unconsolidated sediments of Late Cretaceous and Tertiary origin contains the major aquifer systems of the area, and (b) the Piedmont Province, where groundwater occurs in mudstones and sandstones within Paleozoic metamorphic and igneous basement rock. The vadose zone ranges in thickness from approximately 40 meters (130 feet) in the northernmost portion of the Savannah River Site to the surface in areas where the water table intersects wetlands or streams.

The sediments of the southeastern Coastal Plain hydrogeologic province are grouped into three major aquifer systems divided by two major confining systems, all underlain by the Appleton Confining System. These aquifer systems are known regionally as the Floridan, the Dublin, and the Midville systems. The local aquifers associated with these three aquifer systems are the Steed Pond, Crouch Branch, and McQueen Branch Aquifers.

The Crouch Branch and McQueen Branch hydrostratigraphic units are the most important aquifers in the vicinity of the Savannah River Site. The McQueen Branch Aquifer, in particular, is highly transmissive and serves as the main production aquifer for the Savannah River Site. The groundwater in the Crouch Branch and McQueen Branch Aquifers is suitable for most domestic and industrial purposes.

Industrial solvents, metals, tritium, or other constituents used or generated at the Savannah River Site have contaminated the groundwater over 5 to 10 percent of the Site. Contaminated groundwater generally underlies only a few facilities, and the contaminants detected reflect the material and processes used in these facilities. Contamination of groundwater in an aquifer supplying drinking water has occurred in one relatively small area in the northwest portion of the Savannah River Site: two wells in the Dublin-Midville Aquifer System (formerly known as the Tuscaloosa Formation) contain low concentrations of trichloroethylene and tetrachloroethylene.

The aquifers underlying the Savannah River Site sustain single-well yields of about 10.2 million liters per day (2.7 million gallons per day). The Savannah River Site withdraws approximately 14.0 billion liters per year (3.7 billion gallons per year) of groundwater for domestic and industrial uses. The Savannah River Site draws approximately 75.7 billion liters per year (20 billion gallons per year) of cooling water from the Savannah River. Water rights are not at issue at the Savannah River Site.

The Savannah River Site lies in the Upper Coastal Plain physiographic province. The Savannah River Site is near the transition area between the oak-hickory-pine forest and the southern mixed forest. As a consequence, species typical of both associations are present.

Plant communities adapted to dry conditions occur on more northern, upland areas of the Savannah River Site. (This area is sometimes referred to as the Aiken Plateau.) The most common community types on the northern half of the Savannah River Site are longleaf pine plantations and longleaf pine-turkey oak sandhills. Wetter areas along streams support different groups of plant species, including loblolly pine and bottomland hardwood forest communities. Other aquatic habitats, such as ponds, marshes, river swamps, and Carolina bays, add considerable botanical diversity to the Savannah River Site.

Four federally listed endangered animal species occur on the Savannah River Site or in the Savannah River upstream and downstream of the Savannah River Site: the red-cockaded woodpecker, the wood stork, the southern bald eagle, and the shortnose sturgeon. The U.S. Fish and Wildlife Service lists a fifth species, the American alligator, as "threatened due to similarity of appearance" (to the endangered American crocodile). Researchers have found one federally listed endangered plant species, the smooth coneflower, on the Savannah River Site.

In 1992, the Savannah River Site hunters (chosen by lottery from a large pool of applicants) harvested 1,519 deer and 168 feral hogs. The purpose of these hunts is to keep deer and feral hog populations in check and to reduce the number of animal-vehicle accidents on the Savannah River Site. The Savannah River Site measures each animal killed during the hunts for radioactivity. The maximum measurement of cesium-137 in a Savannah River Site deer was 22.4 picocuries per gram; the average was 6.4 picocuries per gram. For hogs, the maximum value was 22.9 picocuries per gram: and the average was 3.5 picocuries per gram. The estimated maximum dose received by a Savannah River Site hunter was 0.049 rem (49 millirem) per year. This estimate assumed a hunter whose entire meat consumption for the year consisted of the Savannah River Site deer.

The major sources of noise at the Savannah River Site are equipment and machinery (for example, cooling towers, transformers, engines, pumps, boilers, steam vents, and paging systems) in developed operational areas. Studies indicate that, because of the remote locations of the Savannah River Site operational areas, existing onsite noise sources do not adversely affect individuals offsite. Workplace noise limits established by the Occupational Safety and Health Administration protect onsite workers.

Interstate 20 is the primary east-west corridor in the general area of the Savannah River Site. U.S. Highways 1 and 25 are the principal north-south routes. Direct access to the Savannah River Site from the northwest is provided by South Carolina Highways 125 and 19; South Carolina Highway 125 is open to through traffic. South Carolina Highways 39 and 64 also provide access to the Savannah River Site. The

CSX railroad line also serves the Savannah River Site.

Atmospheric releases of radioactive material to the environment from Savannah River Site operations from 1990 to 1992 resulted in an average dose of approximately 0.00002 rem (0.02 millirem) per year to individuals living within an 80-kilometer (50-mile) radius of the Savannah River Site. The collective dose equivalent due to atmospheric releases from the 1992 Savannah River Site operations to the population of 620,100 occupying the 80-kilometer (50-mile) radius was 6.4 person-rem. Atmospheric releases of tritium accounted for more than 90 percent of the estimated offsite population dose.

Similarly, liquid releases of tritium account for more than 99 percent of the total radioactivity discharged to the Savannah River from the Savannah River Site activities. The calculated average annual dose to the maximum exposed individual resulting from liquid releases from 1990 to 1992 was 0.00021 rem (0.21 millirem). This resulted in average doses of 0.00004 and 0.00005 rem (0.04 and 0.05 millirem) per year to consumers of drinking water from the downstream Beaufort-Jasper (South Carolina) and Port Wentworth (Georgia) water treatment plants, respectively.

The Savannah River Site purchases power from South Carolina Electric and Gas Company through three purchased power-line interconnects to the Savannah River Site transmission grid. Recent total annual power consumption for the Savannah River Site was approximately 659,000 megawatt hours. The average load was 75 megavolt-amperes, and the peak demand was about 130 megavolt-amperes.

Average annual wastewater discharge volume at the Savannah River Site is about 2 million liters per day (528,400 gallons per day), which is about 50 percent of capacity. Eighteen waste treatment plants currently process all Savannah River Site sanitary waste. A new centralized sanitary wastewater treatment facility, scheduled for completion in mid-1995, will replace 14 of these plants.

The Savannah River Site had 127.9 million liters (33.8 million gallons) of radioactive high-level waste onsite at the end of 1991, in 50 underground tanks, which is more than 90 percent of existing capacity. By 1993, the Savannah River Site had 9,900 cubic meters (350,000 cubic feet) of transuranic waste in storage. The current volume of mixed low-level waste at the Savannah River Site is 1,700 cubic meters (60,000 cubic feet). Low-level waste is packaged for disposal onsite in carbon steel boxes and deposited in trenches. Hazardous wastes in storage at the Savannah River Site total some 1.6 million kilograms (3.6 million pounds), with a volume of 2,430 cubic meters (86,000 cubic feet).

4.4 Nevada Test Site

This section presents summary environmental characterization information on the Nevada Test Site. This information has been used to evaluate impacts at the Nevada Test Site under various alternatives for management of SNF. More detailed information characterizing the Nevada Test Site is presented in Appendix F, under separate cover.

The Nevada Test Site is located in southwestern Nevada in southern Nye County. The Nevada Test Site is bordered on three sides by the Nellis Air Force Base Bombing and Gunnery Range (see Figure 4-4). The Nellis Range serves as a buffer zone between Nevada Test Site test areas and land open to the public. The Nevada Test Site comprises about 3,500 square kilometers (1,350 square miles), making this one of the largest contiguous, unpopulated land areas in the United States. The Nevada Test Site has been used for underground weapons testing and as a nonnuclear test area. Congress has mandated that the Federal Government pursue the development of mined geologic repositories for the permanent disposal of SNF and high-level waste and has directed DOE to study the Yucca Mountain, Nevada, site to determine whether it is a suitable site for the nation's first geologic repository.

Figure 4-4. Nevada Test Site location and site map.

The majority of the land near the Nevada Test Site is managed by the U.S. Bureau of Land Management and used for livestock grazing. The area is surrounded by recreational areas used for activities such as hunting, fishing, and camping.

The economy of the two-county area near the Nevada Test Site is dominated by support services for contractor personnel at the Nevada Test Site, with a direct link to Clark County and the Las Vegas area where most of the employees reside. Most of the offsite supporting contractors and the labor and capital supporting indirect economic activity connected to the Nevada Test Site are also located in Clark County. In 1990, the population of the Las Vegas Metropolitan Statistical area was 735,000, with a 4.7 percent annual growth rate since 1980. In contrast, Nye County is sparsely populated, with employment provided by service industries, some mining, and Government-sector jobs. As of January 1994, the work force totaled 8,563.

The population within 80 kilometers (50 miles) of the Nevada Test Site has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Nevada Test Site is shown to be 6 percent minority and 12 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

On the Nevada Test Site, numerous prehistoric sites and prehistoric/historic sites have been recorded and recommended as eligible for the National Register of Historic Places. However, none of them are located in the vicinity of the proposed SNF management facility. Historic activities began in 1849 with the Emigrant Trail, mining camps, and later the settlements of Bullfrog-Goldfield, Las Vegas, and Tonopah. Southern Nevada, including parts of what is now the Nevada Test Site, was inhabited by peoples of the Southern Paiute and Shoshone Tribes. Areas in the northern portion of the Nevada Test Site, including the Pahute and Rainier Mesas, contain sites of cultural affiliation to these peoples. However, no known Native American resources are located within the areas proposed for SNF facilities. Some late Pleistocene terrestrial vertebrate fossils also occur in the area, notably at Tule Springs.

The Nevada Test Site is in a visual setting of low-lying valleys and flats interspersed with mountains and the vegetation of the Mojave Desert and Great Basin. Because the public can be expected to have little concern about changes in the area's landscape and views are not regionally unique, the area may be considered to have low to moderate visual sensitivity.

The Nevada Test Site is located in the southern part of the Great Basin section of the Basin and Range Physiographic Province. Local geology is characterized by mountains of Precambrian and Paleozoic sedimentary rocks and Tertiary volcanic tuffs and lavas separated by alluvial, topographically closed valleys. Sedimentary rocks are complex, folded, and faulted carbonates in the upper and lower parts and shale and sandstone in the middle section. Volcanic rocks are predominantly Tertiary tuffs with some basalts and scattered granitic plutons. Potential geologic resources within the Nevada Test Site boundaries include silver, gold, tungsten, molybdenum, zeolites, barite, and fluorite.

The area of the Nevada Test Site is historically of low-to-moderate seismicity. On a scale of 0 to 4, the Nevada Test Site is in Uniform Building Code Seismic Risk Zones 2B and 3. Seismic activity in the Nevada Test Site area generally occurs as thrust faults, normal faults, and strike-slip faults. Recent displacements are thought to have occurred as a consequence of underground nuclear explosions. Recorded seismic activity before 1978 within 10 kilometers (6 miles) of Yucca Mountain shows seven earthquakes; two had magnitudes 3.6 and 3.4 on the Richter scale, and five had magnitudes that were smaller or could not be determined because of instrument problems. Two historical earthquakes with a magnitude of 6 (Richter scale) have been reported 110 kilometers (68 miles) southwest of Yucca Mountain and 210 kilometers (130 miles) to the northeast. Most earthquakes in the area are less than 10 kilometers (6.2 miles) in depth. Historic seismic events and the length of active faults can be used to infer a maximum magnitude of 7 to 8 for earthquakes in the Yucca Mountain region. Recurrence intervals for earthquakes with magnitudes greater than 7 are 25,000 years, greater than 6 are 2,500 years, and greater than 5 are 250 years.

The climate in the Nevada Test Site region is characterized by high solar radiation, limited precipitation, low humidity, and large diurnal temperature ranges. At Area 6, the mean daily minimum and maximum temperatures are -6.1 to 10.6C (21 to 51F) in January and 14 to 36C (57 to 96F) in July. Average precipitation at Area 6 is 15 centimeters (6 inches).

DOE maintains an extensive network of air sampling stations for radiological parameters such as particulates, reactive gases, tritium, and noble gases. Nonradiological air pollutants are within state and Federal standards. In recent years, the majority of radioactive effluents at the Nevada Test Site have resulted from underground nuclear tests. In addition, some of the radioactivity detected by onsite air monitors can be attributed to resuspension of radioactive particulate matter remaining from the atmospheric testing conducted from 1951 to 1962. Monitoring of airborne particulates, noble gases, and tritiated water vapor on the Nevada Test Site in 1992 indicated onsite concentrations that were generally not statistically different from background concentrations. External gamma exposure monitoring has indicated that the gamma environment has been consistent from year to year. Although airborne releases of radioactivity to offsite areas occurred during the years that atmospheric testing was performed, in recent years, no Nevada Test Site-related radioactivity has been detected offsite at any air sampling station.

Surface drainage in the Nevada Test Site area is ephemeral, and almost no streamflow data have been collected. Perennial surface waters occur as springs and in short reaches of the Amargosa River. Potential evaporation is 152 to 170 centimeters per year (60 to 67 inches per year). Run-off still occurs in response to infrequent storm events, which may cause local flooding, especially in Fortymile Canyon, the Amargosa River, and Jackass Flats drainage. There is the potential for a 100-year magnitude flood to transport radioactive contaminants released as a result of historic underground nuclear testing beyond the boundaries of the Nevada Test Site.

Six major aquifers occur in the area of the Nevada Test Site, including some perched groundwater. The hydrogeology is characterized by great depths to the groundwater table of 200 to 500 meters (660 to 1,640 feet) and slow velocity in the saturated and unsaturated zones. Flow velocities in these systems range from 1.8 to 183 meters (6 to 600 feet) per year. Regional groundwater flow is from the north and northeast toward the regional discharge area near Ash Meadows in the Amargosa Desert. Modeling studies for the Radioactive Waste Management Site at Area 5 indicate that the travel time from the surface to the regional water table is on the order of thousands of years.

Water in southern Nevada (excluding the Las Vegas area) is used chiefly for irrigation and to a lesser extent for livestock, municipal needs, and domestic supplies. Almost all water supplies are pumped from the groundwater aquifers, although some springs supply water to Death Valley and other areas south of the Nevada Test Site. The Nevada Test Site obtains its water supply from the aquifers underlying the Nevada Test Site in the Ash Meadows Subbasin and Alkali Flat-Furnace Creek Ranch Subbasin. Nevada Test Site water use is discussed in detail in Appendix F of Volume 1.

Groundwater meets U.S. Environmental Protection Agency secondary standards for major cations and anions and the primary standards for deleterious constituents. Contamination by radionuclides occurs below the water table as well as in the unsaturated zone above it as a result of underground nuclear testing. The extent of this contamination is currently being studied.

The Nevada Test Site lies in a transition area between the Mojave Desert and Great Basin, supporting flora and fauna from both areas. Less than 1 percent of the area has been developed. Natural vegetation occurs in nine plant communities identified as creosote bush; blackbrush; creosote-blackbrush, hopsage-desert thorn; sagebrush; saltbush; mountains, hills, and mesas; and two distinct desert thorn plant communities. Introduced weedy species, such as cheatgrass and Russian thistle, are common in disturbed areas.

Approximately 273 vertebrate wildlife species have been observed onsite, including over 30 species of reptiles, 190 species of birds, and 50 species of mammals. Common species include reptiles, rodents, raptors, and wild horses. A number of game and fur-bearing species are found on the Nevada Test Site, but hunting and trapping are not permitted.

National Wetland Inventory maps of the Nevada Test Site have not been prepared, nor have wetlands been delineated onsite. Available information indicates that wetlands on the Nevada Test Site are limited in distribution and extent. Small riverine and palustrine wetlands may occur adjacent to surface drainages, springs, playas, and reservoirs on the Nevada Test Site. There are no perennial streams on the Nevada Test Site, and permanent surface water sources are limited to a few small springs and reservoirs. Springs do not support fish populations onsite, while reservoirs support introduced bluegill, goldfish, and golden shiner.

Twenty-five federally and state-listed threatened, endangered, and other special status species have been identified on and in the vicinity of the Nevada Test Site, including 9 birds, 2 reptiles, 1 fish, 2 mammals, and 11 plant species. Federally endangered species include the American peregrine falcon, bald eagle, and Devil's Hole pupfish. The federally threatened species is the desert tortoise.

The major noise sources at the Nevada Test Site occur primarily in developed operational areas and include various facilities; equipment and machines (for example, engines, pumps, boilers, steam vents, paging systems, construction equipment, and vehicles); aircraft operations; and testing. At the Nevada Test Site boundary away from most facilities, noise levels are barely distinguishable from background noise levels. Some wildlife disturbances may occur as a result of these activities.

Vehicular access to the Nevada Test Site is provided by U.S. Route 95 from the south and off-road access via State Route 375 from the northeast. No major improvements are scheduled for these segments providing immediate access to the Nevada Test Site.

The major railroad in the area is the Union Pacific, which runs through Las Vegas and is located approximately 80 kilometers (50 miles) east of the Nevada Test Site. A 15-kilometer (9-mile) railroad serves Area 25, but it does not connect with the Union Pacific line.

Background radiation exposure and releases of radionuclides to the environment from Nevada Test Site operations provide the sources of radiation exposure to people in the Nevada Test Site region. The estimated dose-equivalent during 1992 for the population within 80 kilometers (50 miles) of the Nevada Test Site was 5.2 10-3 person-rem. The average dose was 1.1 10-5 rem (1.110-2 millirem) in 1992 for a person at the Nevada Test Site boundary. This dose is well below the National Emission Standards for Hazardous Air Pollutants standard of 0.01 rem (10 millirem) per year and is a very small percentage of the background dose.

From 1988 to 1993, water use at the Nevada Test Site varied from a high of 134 liters per second (2,125 gallons per minute) in 1989 to a low of 60 liters per second (949 gallons per minute) in 1993. Significant changes in consumption are not anticipated.

From 1989 to 1993, Nevada Test Site electrical consumption ranged from 144,521 to 183,188 megawatt hours, with peak demands varying from 30.9 to 38.4 megavolt-amperes. In 1995, consumption is projected to be 176,440 megawatt hours, with a peak demand of 39.5 megavolt-amperes.

Nevada Test Site manages the following categories of waste: low-level waste, transuranic waste, hazardous waste, radioactive mixed waste, and nonhazardous waste. The Nevada Test Site does not currently manage high-level waste or SNF. Waste management activities include onsite treatment, onsite storage, onsite disposal, and preparation for appropriate offsite disposal. In addition, the Nevada Test Site uses and manages an onsite inventory of hazardous materials, including some managed in underground storage tanks.

Total nonradioactive waste generated at the Nevada Test Site in 1992 included approximately 90,000 kilograms (100 tons) of Resource Conservation and Recovery Act hazardous waste and 218,000 kilograms (240 tons) of hazardous non-Resource Conservation and Recovery Act waste.

4.5 Oak Ridge Reservation

This section presents summary environmental characterization information on the Oak Ridge Reservation. This information has been used to evaluate impacts at the Oak Ridge Reservation under various alternatives for management of SNF. More detailed information characterizing the Oak Ridge Reservation is presented in Appendix F, under separate cover.

The Oak Ridge Reservation is located on approximately 34,667 acres (140 square kilometers) of federally owned land. The reservation comprises forested lands, public lands, buffer zones and three operations areas: Y-12 Plant, Oak Ridge National Laboratories, and the K-25 Site (formerly the Oak Ridge Gaseous Diffusion Plant) (see Figure 4-5). The Oak Ridge Reservation is located within the incorporated city limits of Oak Ridge, Tennessee. Bordering land uses are predominantly rural, including residences, small farms, forest, and pasture.

Most of the industrial and commercial development, by energy-related companies in support of the Oak Ridge Reservation, has occurred in the City of Oak Ridge in Anderson and Roane counties. Regional economic linkages at the Oak Ridge Reservation occur primarily within Anderson, Knox, Roane, and Loudon counties, where most of the offsite contractors, labor, and capital are located. Employment at the Oak Ridge Reservation in 1990 was approximately 17,080 people, and it is projected to decrease to approximately 16,980 by the year 1999.

The population within 80 kilometers (50 miles) of the Oak Ridge Reservation has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Oak Ridge Reservation is shown to be 6 percent minority and 16 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

There are no identified archaeological sites or historic structures on the proposed site for the SNF management facilities on the Oak Ridge Reservation. Invertebrate fossils remains are found in early Cambrian to early Mississippian aged formations underlying the Oak Ridge Reservation. In the early 1700s, the Overhill Cherokee lived in the area of the Oak Ridge Reservation. These Native Americans were forcibly moved to Oklahoma in 1838. While the Cherokee may retain cultural affiliation with their ancestral home, there are no known Native American resources on the proposed site for SNF facilities.

Figure 4-5. Oak Ridge Reservation location and site map.

Visual resources are characterized by a series of low ridges and valleys trending northeast to southwest. Deciduous and coniferous forest covers about 80 percent of the Oak Ridge Reservation. The DOE facilities are brightly lit at night, making them highly visible.

The area of the Oak Ridge Reservation is historically of low-to-moderate seismicity. On a scale of 0 to 4, the Oak Ridge Reservation is in a Uniform Building Code Seismic Risk Zone 2A. The Oak Ridge Reservation lies entirely within the western portion of the Valley and Ridge Province, near the boundary with the Cumberland Plateau. This province is characterized by numerous linear ridges and valleys. There are three regional thrust faults in the area. From 1811 to 1975, five major earthquakes have affected the Oak Ridge Reservation area, but none has been at an intensity that caused severe damage. There is no evidence of any volcanic activity in the area for more than one million years.

The climate of the region is characterized by moderate to high precipitation in all seasons, high humidity, low winds, and low diurnal temperature ranges. At Oak Ridge, mean annual precipitation was 54 inches (137 centimeters) from 1961 to 1990. Mean daily temperatures range from 2.6C (36F) in January to 24.8C (76.7F) in July. Daytime winds are usually southwesterly, while nighttime winds are northeasterly. In Tennessee, tornadoes are infrequent. The western half of the state has experienced three times as many tornadoes as the eastern half where the Oak Ridge Reservation is located. The Oak Ridge Reservation experienced a tornado from a severe thunderstorm on February 21, 1993.

A network of air monitoring stations at the Oak Ridge Reservation measures several types of uranium particulates, heavy metals, and several materials released by a Toxic Substances Control Act incinerator. The total dose of 0.0033 rem (3.3 millirem) per year to the maximally exposed individual is well within the 0.01 rem (10 millirem) per year National Emission Standards for Hazardous Air Pollutants standard. The estimated collective committed effective dose equivalent to the approximately 880,000 persons within 80 kilometers (50 miles) of the Oak Ridge Reservation was approximately 52 person-rem for 1992. This represents about 0.02 percent of the 280,000 person-rem that the surrounding population might receive from all sources of natural radiation. The Oak Ridge Reservation meets the state and Federal standards for all criteria pollutants.

The surface drainage of the Oak Ridge Reservation includes numerous creeks (such as White Oak, Poplar, and Bear Creeks) and the Clinch River, which subsequently flow to the Tennessee River. Melton Hill Dam, immediately south of the Oak Ridge Reservation, controls the flow of the Clinch River near the Oak Ridge Reservation. Average discharge from the dam was 150 cubic meters (5,300 cubic feet) per second from 1963 to 1979. The Clinch River supplies water for the Oak Ridge Reservation and for regional industrial uses.

Geologic units of the Oak Ridge Reservation comprise two hydrologic groups: (a) the Knox Aquifer, formed by the Knox Group and Maynardsville Limestone, and (b) the Oak Ridge Reservation aquitards, which include other geologic units of the area including sandstones, siltstones, and shales. The Knox Aquifer has solution conduits that store and transmit relatively large volumes of water, while the aquitards are controlled by fractures and transmit limited amounts of water. The aquifer is the primary source of sustained stream flow on the Oak Ridge Reservation. However, some flowpaths of the Knox Aquifer lead to discharge points outside the Oak Ridge Reservation boundary. Because of the abundance of surface water in the area, groundwater wells are not common. Groundwater quality is good above 300 meters (1,000 feet), but it has high total dissolved solids at depth.

Groundwater contamination has occurred in the general area of past-practice waste disposal sites, waste storage tanks, spill sites, and contaminated inactive facilities. Principal contaminants include volatile organics, nitrates, heavy metals, and radioactivity. Exact rates and extent of the contamination have not been quantified. However, data indicate that most contamination remains relatively close to the source. As an example of the maximum extent of groundwater contamination, nitrate has been detected in wells 3,000 feet (900 meters) southwest of the source. Nitrate is relatively mobile in groundwater and may therefore define the maximum horizontal migration of contamination. At Oak Ridge National Laboratory, 20 waste area groups have been identified and are being monitored for groundwater contamination. Monitoring data from each waste area group will direct further groundwater studies. At the K-25 Site, organics are the most commonly detected groundwater contaminants. Elevated levels of gross alpha and gross beta have been detected in a number of wells. Uranium and technetium-99, respectively, appear to be primarily responsible for the elevated gross alpha and gross beta levels. The metals chromium, lead, arsenic, and barium have been detected in a number of wells at concentrations exceeding drinking water standards. Elevated levels of fluoride and polychlorinated biphenyls have also been detected in some wells.

The offsite residential drinking water quality monitoring program has detected radionuclides and organics in some offsite monitoring wells; however, concentrations have been below drinking water standards. Fluoride has been detected at concentrations exceeding drinking water standards in one offsite well. The high fluoride concentration and accompanying pH are most likely from natural chemical reactions in the substrate.

The Clinch River supplies most of the water to the Oak Ridge Reservation, the City of Oak Ridge, and other cities along the river. Major surface water uses include withdrawals for industrial and public water supplies, commercial and recreational navigation, and other recreational water activities. Because of the abundance of surface water, most community and Oak Ridge Reservation water supplies come from surface supplies rather than groundwater. One supply well exists on the reservation for use as a supplemental water supply to a laboratory. Groundwater is used for some domestic, municipal, farm, irrigation, and industrial purposes. A typical well in the aquitard yields under 0.25 gallons per minute (0.02 liters per second), and in many places wells are incapable of producing enough water to support a typical household.

The Oak Ridge Reservation area was cleared by logging and agricultural practices in the past, but it is currently dominated by pine and pine hardwood, and oak hickory, as well as northern hardwood and hemlock-white pine-hardwood forest types.

Approximately 267 different vertebrate wildlife species have been recorded onsite, including 39 mammals, 169 birds, 33 reptiles, and 26 amphibians. Local habitats include wetlands, fields, pasture, and pine plantations in addition to forest. Undeveloped areas on the Oak Ridge Reservation support game and fur-bearing populations.

Wetlands have been identified on the Oak Ridge Reservation, based primarily on the National Wetland Inventory maps. Wetlands on the Oak Ridge Reservation include emergent, scrub/shrub, and forested wetland. These wetlands are located in embayments of the Melton Hill and Watts Bar Reservoir that border the reservation; along all major streams, including East Fork Poplar Creek, Bear Creek, and their tributaries; in old farm ponds; and around groundwater seeps. Commercial fishing occurs adjacent to the Oak Ridge Reservation for catfish and carp. Sport fishing for bass, catfish, and other fresh-water fish is also popular.

Forty-seven species of federally and state-listed threatened, endangered, and other special status species have been identified on and in the vicinity of the Oak Ridge Reservation, including 19 plants, 3 amphibians, 4 reptiles, 2 fish, 14 birds, and 5 mammals. Virginia spirea is a federally threatened plant species; bald eagle, peregrine falcon, gray bat, and Indiana bat are federally endangered species found in the area. The state-listed Tennessee dace has been recorded in Bear Creek and tributaries of East Fork Poplar Creek.

The major noise sources within the Oak Ridge Reservation occur primarily in developed operational areas and include facilities and equipment and machines, such as transformers, engines, pumps, boilers, and vehicles. Outside the operations area major sources of noise are vehicles and railroad operations. At the Oak Ridge Reservation boundary, away from most of these activities, noise from these sources is barely distinguishable from background noise levels. Some disturbances of wildlife may occur on the Oak Ridge Reservation as a result of operations and construction activities.

Bear Creek Valley Road provides vehicular access to the Oak Ridge Reservation. Tennessee State Routes 58, 62, 95, and 162 pass through the Oak Ridge Reservation and are open to the public. Road construction and modification are planned for segments of Bear Creek Valley Road, Scarboro Road, and State Routes 58, 62, and 95 in the near future. Interstate 40 is within 8 kilometers (5 miles) to the south. Railroad service on the Oak Ridge Reservation is provided by CSX Transportation and the Norfolk and Southern Corporation. Knoxville is the closest major airport, 64 kilometers (40 miles) away.

Low-level, hazardous, and mixed wastes are generated and managed at the Y-12 Plant, K-25 Site, and the Oak Ridge National Laboratory. Nonhazardous wastes are generated at all three sites and disposed of at the Y-12 Plant Sanitary Landfill. Oak Ridge Reservation generates and manages SNF and transuranic waste. Waste management at the Y-12 Plant and the Oak Ridge National Laboratory includes onsite waste treatment, onsite waste disposal, preparation for proper offsite waste disposal, and onsite waste storage.

Liquid and solid hazardous wastes are disposed of offsite. Some low-level radioactive wastes are disposed of onsite.

4.6 Naval Sites

This section presents summary environmental characterization information on the naval sites that have been evaluated under various alternatives for management or examination of naval SNF. This information has been used to evaluate impacts at the sites under various alternatives for management of SNF.

More detailed information characterizing these sites is presented in Appendix D, under separate cover.

The average annual radiation exposure for each naval shipyard radiation worker is 0.26 rem (260 millirem) (NNPP 1993). The average lifetime accumulated exposure for shipyard workers is 1.2 rem (1,200 millirem) (NNPP 1993).

4.6.1 Puget Sound Naval Shipyard

The Puget Sound Naval Shipyard is located in Bremerton, Washington, 23 kilometers (14 miles) west of Seattle and 32 kilometers (20 miles) northwest of Tacoma (Figure 4-6). The population within 80 kilometers (50 miles) of the shipyard is about 3 million people.

The population within 80 kilometers (50 miles) of the Puget Sound Naval Shipyard has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Puget Sound Naval Shipyard is shown to be 13 percent minority and 8 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

Puget Sound Naval Shipyard is on 132 hectares (327 acres) of highly developed land. The waterfront dry dock area is the high-security portion of the shipyard where most production activities take place. This area includes production shops, administration, and some public works and supply functions.

The upland area of the shipyard provides services to military personnel, including housing, retail goods and services, recreation, counseling, dental care, and other support services. The industrial support area in the southwestern portion of the shipyard includes several piers for homeported ships and inactive fleet, the power plant, warehouses, a steel yard, public works shops, and parking.

There are about 10,200 civilians working at the shipyard. With other Government facilities in the area, the Federal payroll in Kitsap County, where the shipyard is located, provides about 45 percent of the total employment.

There are no prehistoric archaeological sites identified at the shipyard. There are four National Registered Historical Districts and one National Historic Landmark within the boundaries of the shipyard.

Until the mid-1880s, Kitsap County was inhabited by several Native American tribes of the Salish language group who lived on the shores of Puget Sound. For about

Figure 4-6. Puget Sound Naval Shipyard location and vicinity map.

100 years, the principal settlement of the Suquamish Tribe lay along the west shore of Agate Passage. There are no Native American properties or ceremonial sites in the shipyard areas where SNF activities would be conducted.

The natural topography of the shipyard has been altered significantly from its original condition.

Portions of the upland areas of the complex were cut to fill marshes and create level land. The resulting fill material was predominantly a silty, gravelly sand with occasional pockets of silts and clays. The remaining areas of natural soils vary from dense glacial deposits to soft bay mud and peat. The upland soil is a stiff, hardpacked, clay soil with low permeability.

The site lies within Uniform Building Code Seismic Risk Zone 3. There have been approximately

200 earthquakes in the area since 1840, most of which caused little or no damage. The most recent earthquakes of high magnitude were near Olympia [64 kilometers (40 miles) from Bremerton] in 1949 (7.1 on the Richter scale) and near Seattle in 1965 (6.5 on the Richter scale). The central Puget Sound area could experience an earthquake of intensity 7.5 on the Richter scale. There has been no known surface faulting in conjunction with earthquakes in the shipyard region. Potential hazards from volcanism are minimal and limited to windborne volcanic ash.

The potential hazard from tsunamis and seiches is minimal because the system of straits and inlets that surround Puget Sound provides a natural barrier, effectively damping the propagation of distantly generated tsunamis.

The general area around Bremerton is damp, cool, and cloudy much of the year. Average windspeed at the Seattle-Tacoma Airport is 4 meters per second (9 miles per hour), with prevailing winds from the southwest.

The Code of Federal Regulations (40 CFR Part 81) states that the Air Quality Control Region for this site is better than national standards for total suspended particulate matter and sulfur dioxide. The area has no specific classification for ozone, carbon monoxide, and nitrogen dioxide. The nearest Class I Area is Olympic National Park, approximately 24 kilometers (15 miles) from the site.

Puget Sound Naval Shipyard has no important surface freshwaters. Groundwater is generally found within 30 meters (100 feet) of the ground surface in sand and gravel layers. The quality of most groundwater near Bremerton is good. Groundwater is used for approximately 35 percent of the public water supply. Current shipyard use is about 2.6 billion liters (676 million gallons) annually.

Vegetation and wildlife on the Puget Sound Naval Shipyard are limited to undeveloped areas that comprise approximately 19 hectares (46 acres) of the entire Bremerton Naval Complex. Most of these areas have been previously disturbed and are currently landscaped with native and ornamental trees and shrubs. No sensitive, threatened, or endangered aquatic or terrestrial species have been observed at the shipyard.

Land access to the Seattle/Tacoma area is over two interstate highways: Interstate 90 and Interstate 5. The major thoroughfare in south Kitsap County is State Route 16, which runs south from Bremerton to Tacoma where it connects with Interstate 5. Bremerton's primary access routes include State Routes 3, 303, and 304.

The Burlington Northern Railroad provides scheduled and on-demand freight service to southern and central Kitsap County. A Navy-owned spur line from Shelton, Washington, provides additional rail service to the shipyard. SNF originating at Bremerton and Pearl Harbor has historically been transported by rail from Bremerton to the Expended Core Facility at the Idaho National Engineering Laboratory. Since 1962, all 134 shipments of SNF have been sent from Bremerton to the Idaho National Engineering Laboratory by rail-114 originating from Puget Sound Naval Shipyard and 20 transported by ship from Hawaii to the Puget Sound Naval Shipyard, where the containers were transferred to railcars for the journey to the Idaho National Engineering Laboratory.

The annual airborne emissions from the site do not result in any measurable radiation exposure to the general public. Emissions of radionuclides from the site result in a calculated effective dose equivalent of less than 0.0001 rem (0.1 millirem) per year to any member of the general public.

In addition, normal activities associated with current naval nuclear operations at the site do not result in the intentional discharge of any radioactive liquid effluent. Environmental monitoring programs conducted by the site and independent U.S. Environmental Protection Agency monitoring of shipyard sites have shown that the operations at the site have had no adverse impacts on public health or safety. Additional discussion of these monitoring programs is found in Section 4.1.1 of Appendix D of Volume 1 of this EIS.

4.6.2 Norfolk Naval Shipyard

Norfolk Naval Shipyard is located in the Tidewater region of Virginia and is contiguous with the city of Portsmouth (see Figure 4-7). Newport News Shipyard, where some naval nuclear ships are defueled, is located in Newport News, Virginia (see Figure 4-8). Six city areas are within 24 kilometers (15 miles) of the Norfolk Naval Shipyard: Portsmouth, Chesapeake, Norfolk, Virginia Beach, Hampton and Newport News, and Suffolk. About 1.5 million people (USBC 1992) reside within an 80-kilometer (50-mile) radius of the shipyard, and about 8,500 shipyard workers are employed at the shipyard.

The population within 80 kilometers (50 miles) of the Norfolk Naval Shipyard has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Norfolk Naval Shipyard is shown to be 33 percent minority and 11 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

Figure 4-7. Norfolk Naval Shipyard location and vicinity map.Figure 4-8. Newport News Shipyard location and vicinity map.

Norfolk Naval Shipyard occupies over 486 hectares (1,200 acres) and includes over 500 administrative, industrial, and support structures along 4 miles of shoreline. Over 95 percent of the land within its boundaries is covered with structures or paved with concrete or asphalt. The facility is divided into a controlled industrial area and a nonindustrial area. All piers, dry docks, and work facilities involved with naval nuclear propulsion plant work are within the controlled industrial area.

No prehistoric archaeological sites or submerged cultural resources have been identified at the shipyard. Drydock I is a National Historic Landmark. There are no Native American properties or ceremonial sites in the areas where naval SNF activities would be conducted.

Norfolk Naval Shipyard is located in Uniform Building Code Seismic Risk Zone 1, which is the second lowest of four risk categories. No volcanic hazards exist.

The general climate of the area is mild and moist, with predominant winds from the south to southwest. In summer, afternoon thunderstorms are very common. Thunderstorms occasionally spawn isolated tornadoes throughout the region, but they move through the area rapidly along with storm centers. Hurricanes and tidal flooding are not uncommon; tornados are infrequent. The Code of Federal Regulations (40 CFR Part 81) states that the Air Quality Control Region that includes this site is in marginal nonattainment for ozone and is better than national standards for total suspended particulate matter and sulfur dioxide. The area has no specific classification for carbon monoxide and nitrogen dioxide. The nearest Class I Area is the Swanquarter National Wilderness Area, which is approximately 160 kilometers (100 miles) from the site.

Norfolk Naval Shipyard is located on the Southern Branch of the Elizabeth River in a highly industrialized area of the city of Portsmouth, Virginia, 13 kilometers (8 miles) upstream from the confluence of the James and Elizabeth Rivers. The Southern Branch is a deep water river that provides access to heavy industry in the vicinity of the shipyard. The Southern Branch is brackish and is not a source of drinking water.

Shallow groundwater underlies the whole region. Designated as the Columbia Aquifer, the aquifer is comprised of interbedded gravel, sand, silt, and clay and is unconfined throughout the region. Underneath the Columbia Aquifer is the Yorktown Aquifer, which is a major source of domestic, commercial, and light industrial water. This aquifer is the usual source of drinking and domestic consumption water for those localities within the region not served by municipal water systems.

The shipyard area is highly developed, and its surface is about 95 percent covered with impervious materials. Several federally designated threatened or endangered species exist in the region; however, habitats have not been identified on shipyard property. No state-listed rare, threatened, or endangered species exist within the 24-kilometer (15-mile) tidal influence zone.

There are three main road corridors within the city of Portsmouth. These roads are High Street, Portsmouth Boulevard, and George Washington Highway, and they provide access to suburban commercial and residential areas. The Downtown and Midtown Tunnels link Portsmouth and Norfolk and join via connecting arteries to the regional interstate highway network consisting of Interstates 64, 262, 464, and 664. Interstate 64 crosses Hampton Roads and Interstate 664 crosses the lower James River, linking the south-side cities to Newport News and Hampton on the peninsula.

Norfolk Southern and CSX operate extensive rail transportation networks for freight and bulk cargo. Norfolk and Newport News are the Nation's largest terminals for coal exports, and, along with Portsmouth, have a large capacity for containerized and bulk cargos. Lines operated by CSX and Norfolk Southern subsidiaries serve the shipyard at the north and south ends and at Southgate and St. Juliens Creek annexes. Since 1965, all 10 shipments of naval SNF originating at the Norfolk Naval Shipyard have been made by rail to the Expended Core Facility at the Idaho National Engineering Laboratory.

The annual airborne emissions from the site do not result in any measurable radiation exposure to the general public. Emissions of radionuclides from the site result in a calculated effective dose equivalent of less than 0.0001 rem (0.1 millirem) per year to any member of the general public.

In addition, normal activities associated with current naval nuclear operations at the site do not result in the intentional discharge of any radioactive liquid effluent. Environmental monitoring programs conducted by the site and independent U.S. Environmental Protection Agency monitoring of shipyard sites have shown that the operations at the site have had no adverse impacts on public health or safety. Additional discussion of these monitoring programs is found in Section 4.1.2 of Appendix D of Volume 1 of this EIS.

4.6.3 Portsmouth Naval Shipyard

Portsmouth Naval Shipyard is located in York County, in the southeast corner of Maine. It is on Seavey Island, near the mouth of the Piscataqua River (see Figure 4-9). Seavey Island has an area of 113 hectares (278 acres). To the north lies the low-density residential community of Kittery, Maine. South of the shipyard, across the river, is the city of Portsmouth (population 22,300) and the town of New Castle in New Hampshire. The population within an 80-kilometer (50-mile) radius of the site is approximately 2.4 million. The shipyard is the region's largest employer, with 5,000 employees.

Figure 4-9. Portsmouth Naval Shipyard location and vicinity map.

The population within 80 kilometers (50 miles) of the Portsmouth Naval Shipyard has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Portsmouth Naval Shipyard is shown to be 5 percent minority and 7 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

On November 17, 1977, the National Park Service, U.S. Department of the Interior, entered the Portsmouth Naval Shipyard Historic District on the National Register of Historic Places. The district includes 54 acres of land and 59 buildings and structures. There are no known cultural resources in the area of the site where naval SNF would be stored.

Seavey Island is a rock knob, a prominent bedrock outcrop. The bedrock is a fine-grained, lime-silicate material consisting of chalky sandstone formed under heat and pressure, siltstone, and gray sandstone shale. There are no economic geologic resources at the site.

The shipyard is in Uniform Building Code Seismic Risk Zone 2A. Numerous small faults are found in rock units across the region, but only the Rye-Kittery contact is important enough to show on a geologic map.

The typical weather is caused by various incursions of cold, dry arctic air; warm land air from the Gulf States; and cool, damp air from the Atlantic Ocean. Dominance of these systems can change on a daily basis, creating highly variable weather conditions. Precipitation is evenly distributed over the year for an annual total of 108 centimeters (42.6 inches). Local fog is observed 15 percent of the time, and it is dense enough to restrict visibility to 2 kilometers (1.2 miles) or less about 35 percent of that time.

Winds average 3.9 meters per second (8.8 miles per hour), but speeds greater than 17.9 meters per second (40 miles per hour) can occur any time of year. Severe weather from tornadoes and hurricanes is rare.

The Code of Federal Regulations (40 CFR Part 81) states that the Air Quality Control Region for this site is in moderate nonattainment for ozone and is better than national standards for total suspended particulate matter and sulfur dioxide. The area has no specific classification for carbon monoxide and nitrogen dioxide. The nearest Class I Area to the site is the Presidential Range-Dry River Wilderness Area, which is approximately 120 kilometers (75 miles) from the shipyard.

The Piscataqua River, formed by the confluence of the Cocheco River and the Salmon Falls River, flows southeasterly for 21 kilometers (13 miles) until it enters the ocean at Portsmouth Harbor. The entire 21 kilometers (13 miles) of the river is tidal. The river is one of the fastest flowing tidal waterways of any commercial port in the northeastern United States. The Piscataqua River is designated as having acceptable water quality.

The limited amount of vegetation and the industrial nature of the shipyard limit the availability of suitable habitat for most terrestrial species. There is one small freshwater wetland located at the shipyard. No threatened or endangered species have been identified at the site.

Vehicles can reach the Kittery-Portsmouth area by means of Interstate 95 and U.S. Route 1. The shipyard is accessible by two federally owned bridges that cross to the residential streets of Kittery, Maine. Walker Avenue is the primary access route to Bridge 1, and Whipple Road provides direct access to Bridge 2.

There is daily freight rail service to the Shipyard by the Boston and Maine Railroad. The railroad connects Portsmouth with Manchester, New Hampshire; Portland, Maine; and Boston, Massachusetts.

Naval SNF has been removed from Navy nuclear ships at the shipyard and transported to the Idaho National Engineering Laboratory since 1959. There have been 43 shipments made, all by rail.

The annual airborne emissions from the site do not result in any measurable radiation exposure to the general public. Emissions of radionuclides from the site result in a calculated effective dose equivalent of less than 0.0001 rem (0.1 millirem) per year to any member of the general public.

In addition, normal activities associated with current naval nuclear operations at the site do not result in the intentional discharge of any radioactive liquid effluent. Environmental monitoring programs conducted by the site and independent U.S. Environmental Protection Agency monitoring of shipyard sites have shown that the operations at the site have had no adverse impacts on public health or safety. Additional discussion of these monitoring programs is found in Section 4.1.3 of Appendix D of Volume 1 of this EIS.

4.6.4 Pearl Harbor Naval Shipyard

The Pearl Harbor Naval Shipyard is located in the Southeast Loch of Pearl Harbor, Oahu, Hawaii (see Figure 4-10). The population of the island of Oahu was approximately 820,000 people in 1990.

The population within 80 kilometers (50 miles) of the Pearl Harbor Naval Shipyard has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Pearl Harbor Naval Shipyard is shown to be 68 percent minority and 7 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

Figure 4-10. Pearl Harbor Naval Shipyard location and vicinity map.

The shipyard employs about 5,000 civilian employees, and, combined with other U.S. Department of Defense civilian employees, it accounts for 10,900 local jobs.

Pearl Harbor has been the site of several important historical events, and it is most noted for its role in the Pacific Theater Defense during World War II. Naval Base Pearl Harbor was designated as a National Historic Landmark in 1964; in 1974, it was listed on the National Register of Historic Places. There are no archaeological sites located within the boundary of the shipyard. There are no Native Hawaiian properties or ceremonial sites in the shipyard areas where naval SNF activities would be conducted.

Pearl Harbor estuary lies on the coastal sedimentary plain of southern Oahu. Streams, springs, and groundwater flow into the harbor. The estuary was formed by freshwater flows that have eroded the coastal plain and retarded coral growth. The west side of the harbor is primarily comprised of limestone reef material. The east side of the harbor is mainly compacted volcanic ash. Hard, dense volcanic rock forms the bulk of the rock material to the north. Much of the land area in Pearl Harbor is fill land created by dredge spoils. There are no geologic resources of economic value at the shipyard.

The Pearl Harbor Naval Shipyard is located in Uniform Building Code Seismic Risk Zone 1. Except for the island of Hawaii, the islands are not a highly seismic area. Even on Hawaii, most of the earthquakes originate from volcanic activity and do little or no damage, although a few have been quite severe. The Hawaiian Islands were formed by volcanic eruptions; however, the only active volcanic area is on the island of Hawaii. There are no volcanic hazards on the Island of Oahu.

Past tsunami inundation levels have been about 1 meter (3 feet) above mean sea level. Projected tsunami wave elevations for the 10-, 100-, and 500-year event are 0.2, 0.6, and 1.2 meters (0.8, 2.0, and 3.8 feet), respectively, for adjacent coastal areas. Maximum reasonably foreseeable typhoon storm water level rise would be approximately 4.3 meters (14.5 feet) above mean sea level.

The predominant winds are from the northeast, particularly from February to November. At certain times of the year, south to southwest winds and mild offshore breezes can be expected. Winds with speeds up to 22 meters per second (49 miles per hour) occasionally strike from the north or northeast, but they rarely reach gale velocities. Southerly winds are usually accompanied by wet tropical air and frequent heavy showers. Destructive hurricanes with high tidal surges have hit the Hawaiian Islands twice in the past 25 years (both times centered on Kauai), in 1982 and 1992.

The Code of Federal Regulations (40 CFR Part 81) states that the Air Quality Control Region for this site is better than national standards for total suspended particulate matter and sulfur dioxide. The area has no specific classification for ozone, carbon monoxide, and nitrogen dioxide. The nearest Class I Area is Haleakala National Park, on the Island of Maui, which is 188 kilometers (117 miles) from the shipyard.

Eight streams discharge into Pearl Harbor. Some flooding occurs along the major streams, but it is not a problem at the naval complex, affecting only a narrow strip along Aiea Stream. Naval Base Pearl Harbor receives most of its water from the Koolau Aquifer and a small portion from the Waianae Aquifer, which are located in south central Oahu.

No federally or state-listed threatened or endangered species or critical habitats are known to exist within the confines of the shipyard. Because the area has been greatly disturbed and native vegetation completely eliminated, there is little remaining terrestrial habitat of any consequence. Some migratory birds and indigenous waterfowl occasionally frequent the shoreline areas of the shipyard, but none are residents.

There are several wetland areas within the Pearl Harbor area, including the Pearl Harbor National Wildlife Refuge, which provides habitat for the endangered Hawaiian Coot and Hawaiian Stilt.

The traffic into and out of the base is a combination of commuting traffic, residential-related traffic, and service traffic. Kamehameha Highway is the primary access route to the base from the Ewa/ Pearl City/ central Oahu direction. Both Kamehameha Highway and Interstate Highway H-1 provide access to the Naval Base from Honolulu.

Naval SNF has been removed from Navy nuclear-powered ships and transported to the Expended Core Facility at the Idaho National Engineering Laboratory. Naval SNF shipments to the Idaho National Engineering Laboratory were initiated in 1962. Since then, 20 shipments have been made. The shipments were taken by ship to the Puget Sound Naval Shipyard, where the containers were then transported to the Idaho National Engineering Laboratory by rail.

The annual airborne emissions from the site do not result in any measurable radiation exposure to the general public. Emissions of radionuclides from the site result in a calculated effective dose equivalent of less than 0.0001 rem (0.1 millirem) per year to any member of the general public.

In addition, normal activities associated with current naval nuclear operations at the site do not result in the intentional discharge of any radioactive liquid effluent. Environmental monitoring programs conducted by the site and independent U.S. Environmental Protection Agency monitoring of shipyard sites have shown that the operations at the site have had no adverse impacts on public health or safety. Additional discussion of these monitoring programs is found in Section 4.1.1 of Appendix D of Volume 1 of this EIS.

4.6.5 Kesselring Site

The Kenneth A. Kesselring Site is located about 24 kilometers (15 miles) north of the City of Schenectady, New York, and 13 kilometers (8 miles) west of Saratoga Springs (see Figure 4-11). It contains three operating naval nuclear propulsion prototype plants and support facilities. The site also includes one prototype plant that is being permanently shut down and one prototype that has been permanently shut down. All operating facilities are located in a secure area near the center of the 1,578-hectare (3,900-acre) reservation.

In 1993, the site employed about 1,450 civilian workers. About 1.15 million people live within an 80-kilometer (50-mile radius) of the site according to the 1990 Census, but most of the land immediately adjacent to the site is either wooded or used for agriculture. The nearest cities include those previously mentioned and Gloversville, Amsterdam, and Albany.

The population within 80 kilometers (50 miles) of the Kesselring Site has been characterized for the purposes of identifying whether any disproportionately high and adverse impacts exist to minority and low-income communities. The population surrounding the Kesselring Site is shown to be 6 percent minority and 9 percent low-income, based on U.S. Bureau of Census information and the definitions and approach presented in Appendix L.

The Kesselring Site reservation was used primarily for agricultural purposes before Federal Government acquisition in 1948. There are no known archaeological, architectural, cultural, or Native American Indian sites in the secure area where SNF storage would take place.

The site lies on primarily unconsolidated material, primarily of glacial origin, that overlies bedrock. Where it exists, the overburden can be up to several hundred feet thick. The overburden consists of three basic kinds of depositional units: glacier debris, lake, and ice-contact/outwash deposits. Deposits from glaciers overlie much of the bedrock and form the elliptical hills throughout most of the reservation. The glacier deposits are a dense and poorly sorted mixture of clay, silt, sand, gravel, and boulders. Thinly stratified lake clay and silt deposits are mapped over the southeastern quadrant of the site. The ice-contact/outwash deposits mostly consist of stratified sands and gravels.

The general area of the site is in Uniform Building Code Seismic Risk Zone 2, with a moderate risk of damage caused by earthquakes. There is a Zone 1 (minor damage) area to the south and a Zone 3 (major damage) area to the north of the site. The maximum intensity earthquake within 161 kilometers (100 miles) of the site had a Modified Mercalli Intensity Scale value of VII. The most recent earthquake of that intensity occurred at Lake George, New York, on April 30, 1931. Because the site is located near the fault system that caused this quake, an earthquake of similar intensity could occur at the site. There are no volcanic hazards in the vicinity of the site.

Figure 4-11. Kesselring Site location and vicinity map.

The general climate of the site is cold in winter and cool to warm in summer. Winds originate mostly from the west or northwest during the winter, but come from the south in the warmer months. Wind velocities are moderate and generally average less than 4.5 meters per second (10 miles per hour).

Destructive winds [greater than 36 meters per second (80 miles per hour)] occur infrequently, and tornadoes are rare.

The Code of Federal Regulations (40 CFR Part 81) states that the Air Quality Control Region that includes this site is in marginal nonattainment for ozone and is better than national standards for total suspended particulate matter and sulfur dioxide. The area has no specific classification for carbon monoxide and nitrogen dioxide. The nearest Class I Area is at Lye Brook Wilderness, Suarderland, Vermont, which is 74 kilometers (46 miles) from the site.

The Kesselring Site is located in a predominately rural area. There are 13 wetlands on the Kesselring Site; current operations do not impact these wetlands. Federally or state-listed threatened and endangered species located in the Saratoga County area include the bald eagle, the karner blue butterfly, the peregrine falcon, and the red-shouldered hawk. There are, however, no records of any of these species on the site.

Only secondary roads follow the boundary of the site. They are used primarily by Kesselring Site employees and as delivery routes for small products and produce. State Route 29 runs 3 kilometers (2 miles) to the north, State Route 147 runs 6 kilometers (4 miles) to the west, and State Route 67 runs 6 kilometers (4 miles) to the south. State Route 50, 10 kilometers (6 miles) east, running from Saratoga Springs to Scotia, carries the only appreciable amount of truck and bus traffic. The majority of through traffic uses either Interstate 87 or parallel route U.S. Highway 9, 16 kilometers (10 miles) to the east.

Two lines of the Delaware and Hudson Railroad cross the region within 16 kilometers (10 miles) of the site. The main north-south line runs through Ballston Spa, just over 8 kilometers (5 miles) to the east, and a trunkline runs just over 8 kilometers (5 miles) to the northeast into the central Adirondack area.

SNF from the Kesselring Site has been sent to the Expended Core Facility at the Idaho National Engineering Laboratory since 1961. Shipping containers are transported by truck to a nearby commercial rail line where the containers were loaded onto rail cars. Since 1961, 20 shipments of naval SNF have been sent to the Expended Core Facility from the Kesselring Site.

The annual airborne emissions from the site do not result in measurable radiation exposure to the general public. Emissions of radionuclides from the site result in a calculated effective dose equivalent of less than 0.0001 rem (0.1 millirem) per year to any member of the general public.

In addition, normal activities associated with current naval nuclear operations at the site do not result in the intentional discharge of any radioactive liquid effluent. Environmental monitoring programs conducted by the site have shown that the operations at the site have had no adverse impacts on public health or safety.

4.7 Other Generator/Storage Locations

In addition to the five major sites, DOE is responsible for the management of SNF generated at several other DOE sites and other locations. These sites include DOE reactors at sites other than the Hanford Site, Idaho National Engineering Laboratory, the Savannah River Site, and the Oak Ridge Reservation; university and domestic research reactors; and three locations where specific types of commercial power reactor SNF for which DOE is responsible are stored. This section summarizes environmental characterization information for these sites that might be affected by programmatic decisions on SNF management. More detailed information characterizing the sites is presented in Appendix E, under separate cover.

The facilities and installations included in this category preclude the definition of their affected environments in a consistent and uniform manner without describing each site. The information available in existing facility documents varies widely depending on the nature of the installation and the requirements for describing the environment by the overseeing or regulatory agencies. For example, the environmental parameters required to be described by the U.S. Nuclear Regulatory Commission for licensing of small research reactors or material processing and storage facilities are fewer in number and less detailed than those required for larger reactor installations at DOE facilities. Thus, the ability to represent these environmental parameters in a consistent manner based on existing documentation is limited, and several parameters addressed for the major DOE sites are not discussed at all or are discussed only to a limited degree for many of these other generator/ storage locations. Because alternatives evaluated will not require alteration of these sites, the sites are not described in detail. See Appendix E, Chapter 4 for more information.

4.7.1 DOE Test and Experimental Reactors

In addition to facilities at the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, and Oak Ridge Reservation, experimental reactors are located at, and small quantities of SNF are in storage at, the following four DOE sites: Brookhaven National Laboratory, Los Alamos National Laboratory, Sandia National Laboratories, and Argonne National Laboratory-East.

4.7.1.1 Brookhaven National Laboratory.

Brookhaven National Laboratory is located on a 2,131-hectare (5,265-acre) site on Long Island, New York, approximately 97 kilometers (60 miles) east of New York City, in a primarily suburban area. About 410,000 people reside in Brookhaven Township, which houses the Laboratory, and 8,000 people live within 0.8 kilometer (0.5 mile) of the Laboratory boundary.

In terms of meteorology, the laboratory can be characterized, like most Eastern Seaboard areas, as a well-ventilated site. The annual precipitation during 1991 was 45.3 inches (115 centimeters), which is about 3.1 inches (8.0 centimeters) below the 40-year annual precipitation average of 48.4 inches (123 centimeters).

Suffolk County, in which the site is located, is classified as being in nonattainment of the standards for the criteria pollutant ozone. The county is in attainment of standards for carbon monoxide, particulates, sulfur dioxide, nitrogen dioxide, and lead.

No active earthquake-producing faults are known in the Long Island area. The area lies in a Uniform Building Code Seismic Risk Zone 2A (moderate seismic hazard) area.

Groundwater flow under the Laboratory site is complex, moving in different directions in different sections of the site, but generally with a velocity estimated to range from 30 to 45 centimeters per day (12 to 18 inches per day), flowing either toward the Peconic River or in deeper layers recharging the Atlantic Ocean. The Nassau/Suffolk Aquifer System underlying the Brookhaven National Laboratory has been designated a sole source aquifer by the U.S. Environmental Protection Agency.

The releases of radioactive gaseous and liquid effluents from Brookhaven National Laboratory from 1988 to 1992 have resulted in calculated average doses to hypothetical maximally exposed individuals of 0.000113 and 0.000722 rem (0.113 and 0.722 millirem) per year, respectively.

4.7.1.2 Los Alamos National Laboratory.

Los Alamos occupies an area of about 11,000 hectares (28,000 acres) located primarily in Los Alamos county in northern New Mexico, about 39 kilometers (24 miles) northwest of Santa Fe. The resident population of Los Alamos county in 1990 was 18,115; about 3,900 Los Alamos National Laboratory employees reside in the adjacent Rio Arriba and Santa Fe counties.

The climate at Los Alamos National Laboratory is characterized as semi-arid steppe, with an average annual rainfall of about 21 centimeters (8.1 inches). Severe weather affecting facility design or operation is extremely rare. Los Alamos National Laboratory is located in the New Mexico Intrastate Air Quality Control Region. Areas in Los Alamos National Laboratory and its surrounding counties are designated as in attainment with respect to the National Ambient Air Quality Standards.

The Los Alamos National Laboratory is located on the Pajarito Plateau, which is dissected by deep canyons separated by long narrow mesas. It lies within Seismic Zone 2B, and seismic hazards studies have identified three active faults in the area. Studies suggest seismic events with a magnitude of 6.5 to 7.8 have been produced in the last 500,000 years.

Surface water at Los Alamos consists of intermittent streams; several canyons receive treated industrial or sanitary effluents that rarely extend aboveground beyond Los Alamos National Laboratory boundaries. The depth to the main groundwater aquifer, which supplies nearly all water at Los Alamos National Laboratory, ranges from about 366 meters (1,200 feet) in the west to about 183 meters (600 feet) in the east part of the site, and groundwater discharges to springs along the Rio Grande.

The releases of radioactive effluents from Los Alamos National Laboratory over the period 1987 to 1991 have resulted in a calculated average dose to the hypothetical maximally exposed individual of about 0.004 rem (4 millirem) per year.

4.7.1.3 Sandia National Laboratories.

The Sandia National Laboratories reactor and SNF operations are located on about 3,360 hectares (8,300 acres) of Kirtland Air Force Base allocated to DOE, approximately 10 kilometers (6.5 miles) southeast of downtown Albuquerque, New Mexico. The 1990 population of Albuquerque was about 385,000.

The climate at Sandia National Laboratories is characteristic of a semi-arid steppe, with an average annual rainfall of about 21 centimeters (8.1 inches). Severe weather affecting facility design or operation is extremely rare. The Sandia National Laboratories is within the Albuquerque-Mid Rio Grande New Mexico Intrastate Air Quality Control Region, portions of which are designated as nonattainment by the U.S. Environmental Protection Agency for Colorado.

The Sandia National Laboratories is located on the Albuquerque East Mesa in a Seismic Zone 2B, in a region of high seismic activity but of low magnitude and intensity. More than 1,100 earthquakes have occurred during the last 127 years, but only 3 have caused damage in Albuquerque.

The Rio Grande is the main surface drainage route for the area, with an average flow of about 28.5 cubic meters per second (37.3 cubic yards per second). No perennial streams flow through the Sandia National Laboratories area, and flooding is not a high probability at Kirtland Air Force Base. The groundwater is distinguished by a fault complex underlying the area; depths range from 15 to 30 meters (50 to 100 feet) on the east side of the complex and from 115 to 152 meters (380 to 500 feet) on the west side. Groundwater flow west of the complex is generally toward the north and northwest, and groundwater flow east of the fault complex is typically west toward the fault system.

4.7.1.4 Argonne National Laboratory-East.

Argonne National Laboratory-East occupies about a 688-hectare (1,700-acre) site located in DuPage County, Illinois, within the Chicago metropolitan area. The site is surrounded by a 826-hectare (2,040-acre) green belt forest preserve operated by DuPage County. The 1990 population of the Chicago metropolitan area was about

6.6 million people.

The climate in the Argonne National Laboratory-East area is characterized as continental, with an average annual precipitation of 80 centimeters (31.5 inches). The area experiences about 40 thunderstorms annually, occasionally accompanied by hail, damaging winds, or tornadoes. The theoretical probability of a tornado strike at Argonne National Laboratory-East is about one every 1,200 years, although the site was struck by tornadoes in 1976 and 1978, with minor damage.

The Argonne National Laboratory-East site is located above about a 30-meter- (100-foot)-thick glacial till deposit on top of dolomite bedrock. The site is in Uniform Building Code Seismic Zone 1. Several areas of seismic activity are present at moderate distances from the site, but ground motions induced by these seismic sources are expected to be minimal at the site.

The Argonne National Laboratory-East site contains a number of small ponds and surface streams that enter the Des Plaines River about 2.0 kilometers (1.25 miles) southeast of the site center. Groundwater is extracted from two underlying aquifers. No aquifers in the region are considered sole-source aquifers by the U.S. Environmental Protection Agency.

4.7.2 Domestic Research and Test Reactors

Appendix E also identifies 55 non-DOE facilities representing domestic, licensed, small generators of SNF. They include training, research, and test reactors at universities, commercial establishments, and several Government installations. These facilities have been licensed by the U.S. Nuclear Regulatory Commission for reactor operation and the storage of the SNF they generate. Although they are not DOE facilities, past practices and long-term plans and agreements have always called for the SNF they generate to be transported to DOE facilities. In the past, this SNF was generally processed at the Savannah River Site, Hanford Site, or Idaho National Engineering Laboratory for recovery of the highly enriched uranium in their fuel. Under all but the No Action and Decentralization alternatives, these fuels would be transported to a DOE site for storage until ultimate disposition.

These 55 U.S. Nuclear Regulatory Commission licensed facilities, 40 of which are operated by universities, are located in 28 states. They are located in a wide variety of areas, ranging from rural locations to industrial research parks and urban university campuses, which does not permit a description of a typical affected environment for these facilities. Information on the environments of three of the larger of these U.S. Nuclear Regulatory Commission-licensed research reactors [the National Institute of Standards and Technology (former National Bureau of Standards), the Massachusetts Institute of Technology, and the University of Missouri reactors] is summarized in the following sections.

4.7.2.1 National Institute of Standards and Technology.

The National Institute of Standards and Technology reactor is located on the Institute's 233-hectare (576-acre) campus in the city of Gaithersburg, Maryland, about 20 miles northwest of downtown Washington, D.C. The 1990 population of Gaithersburg, a Washington suburban area, was about 39,500. The nearest site boundary is about 0.40 kilometer (0.25 mile) southwest of the reactor.

The climate of the area is moderate, with infrequent occurrences of severe weather. Although a number of winter storms and hurricanes have affected the general area, the site is not subject to flooding, and the recurrence interval for a tornado at the site is about one in 2,000 years. Air quality is primarily determined by the presence of 12-lane Interstate Highway 270, used by commuters to and from the downtown Washington, D.C., area and suburban residential areas.

There are no known major faults in the site vicinity, although the site region is moderately seismic (Seismic Zone l). The maximum ground acceleration for the site area was estimated to be 0.07g.

There are no discharges from the National Institute of Standards and Technology reactor to surface streams or groundwater; liquid wastes are processed before discharge to the local sanitary sewer system and have averaged 2.7 curies of tritium and 1.9 millicuries of other beta-gamma emitters per year from 1988 to 1992. Over the same period, the site released airborne emissions containing an average of 710 curies of argon-41 and 353 curies of tritium per year, well below the license limits for the site. However, individual or collective doses are not reported, and because site meteorological data are not monitored, doses cannot be reliably estimated.

4.7.2.2 Massachusetts Institute of Technology.

The Massachusetts Institute of Technology reactor, housed in a gas-tight building with 0.6-meter (2-feet) concrete shielding, is located on a 0.39-hectare (1-acre) site in a heavily industrialized section of Cambridge, Massachusetts, a few blocks from the main Massachusetts Institute of Technology campus and about 1.6 kilometer (1 mile) from Boston across the Charles River. The population of Cambridge was about 95,800 in 1990.

The meteorological conditions vary from highly stable with light winds to unstable atmospheric conditions with strong winds. Severe weather conditions are uncommon, and flooding of the area is not expected even under record rainfall conditions. Air quality is typical of an urban area.

The Cambridge area has been relatively free of earthquakes over the past 150 years, but it did experience an earthquake in 1755, which destroyed some buildings. The region is located in Seismic Zone 2, and the reactor is conservatively designed to withstand projected seismic activity.

There are no discharges from the Massachusetts Institute of Technology reactor to surface streams or groundwater; liquid wastes are processed before discharge to the local sanitary sewer system and have averaged 0.074 curies of tritium and 9.5 millicuries of other beta-gamma emitters per year from 1988 to 1992. Over the same period, the reactor released airborne effluents containing an annual average of 1,215 curies of argon-41, well below the license limits for the reactor. However, individual or collective doses are not reported, and because site meteorological data are not monitored, doses cannot be reliably estimated, particularly given the highly urbanized vicinity.

4.7.2.3 University of Missouri.

The Columbia Research Reactor is sited within a 34-hectare (85-acre) Research Park about 1.6 kilometers (1 mile) southwest of the main campus of the University of Missouri, located south of the main business district of Columbia, Missouri. The population of Columbia was about 69,000 in 1990. Agriculture is the predominant regional activity, although there are a number of small industrial activities in the area.

The climate of the region is continental, and high windspeeds are not uncommon; 150 kilometer per hour (94 mile per hour) winds have a recurrence interval of once in 100 years, but tornadoes are very uncommon. Air quality is representative of the nonurban midwest. Surface drainage from the site moves eventually to the Missouri River.

Columbia is located in the stable area of Missouri and, despite the proximity to the New Madrid area, the probability of seismic damage in the area is low as reflected by its location in Seismic Zone 1.

There are no discharges from the University of Missouri/Columbia Research Reactor to surface streams or groundwater; liquid waste is processed before discharge to the local sanitary sewer system and has averaged 0.21 curie of tritium and 25.6 millicuries of other beta-gamma emitters per year from 1988 to 1992. Over the same period, the reactor released airborne effluents containing an annual average of about 660 curies of argon-41 and about 7 curies of tritium, well below the license limits for the reactor. However, individual or collective doses are not reported, and because site meteorological data are not monitored, doses cannot be reliably estimated.

4.7.3 Spent Nuclear Fuel from Special Nuclear Power Plants

Three facilities house SNF from power reactors for which DOE has assumed responsibility. Unlike the facilities discussed previously, no additional SNF is either being generated at or being transported to these storage facilities. These facilities include the West Valley Demonstration Project, in West Valley, New York; the former Fort St. Vrain Nuclear Power Plant in Colorado; and the Babcock & Wilcox Research Center, Lynchburg, Virginia. Their environmental characterizations are summarized in the following sections and presented in more detail in Appendix E.

4.7.3.1 West Valley Demonstration Project.

The West Valley Demonstration Project occupies an 88-hectare (220-acre) site formerly housing the first United States commercial nuclear fuel processing plant, within a larger 1,341-hectare (3,345-acre) site known as the Western New York Nuclear Service Center. The Center is located in Cattaraugus County, a rural area of western New York State, about 50 kilometers (31 miles) south of Buffalo, New York, and 40 kilometers (25 miles) east of Lake Erie.

A 60-meter (200-foot) onsite meteorological tower is operated by DOE at the West Valley Demonstration Project. A review of the West Valley Demonstration Project tower's 1992 data indicates that the prevailing wind was from the south-southeast with a mean wind speed of 2.4 meters per second (5.4 miles per hour). The precipitation for 1992 was 18 centimeters (7.1 inches) above the annual average of 104 centimeters (40.9 inches). The onsite 1992 wind data and National Weather Service wind data collected at the Buffalo airport did not compare well, thereby indicating that the Buffalo airport is not representative for predicting conditions at the West Valley Demonstration Project.

The West Valley Demonstration Project is located within the Cattaraugus Highlands, which is a transitional zone between the Appalachian Plateau Province and the Great Lakes Plain. No fold or fault of any consequence is recognized within the site. The Clarendon-Linden structure is the closest active "capable" earthquake- (fault-) producing feature known to exist in the region. It is approximately 37 kilometers (23 miles) from the site. The site has experienced a moderate amount of relatively minor seismic activity. During historical times, ground motion at the site probably has not exceeded a Modified Mercalli Intensity of IV or a horizontal acceleration of 0.05g. It is estimated that the maximum earthquake on the Clarendon-Linden structure would produce an earthquake of Modified Mercalli Intensity of VI or VII and a maximum horizontal acceleration of approximately 0.12g at the site.

The West Valley Demonstration Project is located in the Cattaraugus Creek drainage basin, which is part of the Great Lakes - St. Lawrence watershed. All surface drainage from the West Valley Demonstration Project is to Buttermilk Creek, which flows into Cattaraugus Creek and ultimately into Lake Erie. The uppermost water-bearing unit underlying the West Valley Demonstration Project is a hydrologically isolated part of the Cattaraugus Creek Aquifer System, which has been designated a sole source aquifer by the U.S. Environmental Protection Agency. This unit is included in the sole source designation due to its hydrologic similarity and proximity to the producing Cattaraugus Creek Aquifer.

4.7.3.2 Fort St.

Vrain. The Fort St. Vrain site is located in Weld County in northeastern Colorado, approximately 5.6 kilometers (3.5 miles) northwest of the town of Platteville, 0.8 kilometer (0.5 mile) west of the South Platte River, and 56 kilometers (35 miles) north of Denver. The Fort St. Vrain site consists of 1,132 hectares (2,798 acres). Based on the 1980 census, the population within an 8-kilometer (5-mile) radius of the site was estimated to be 3,148, with 1,662 residing in the town of Platteville (USBC 1982). Most of the land in the immediate area of the site is disturbed, agricultural land.

The general climate around the Fort St. Vrain site is generally mild. In this semi-arid region, the precipitation averages 25 to 38 centimeters (10 to 15 inches) a year, mostly from thunderstorms in late spring and summer. Northeastern Colorado has moderate thunderstorm activity. The region typically experiences 5 tornadoes per year per 25,900 square kilometers (10,000 square miles), with peak tornado activity occurring during the month of June. A study of tornadoes in the area concluded that 161-kilometer-per hour- (100-mile-per-hour) winds should constitute maximum wind forces to be expected at Fort St. Vrain.

The Fort St. Vrain site is located on the east flank of the Colorado Front Range, a complexly faulted anticlinal arch. Numerous faults and smaller folds are superimposed on the arch and are related to the uplift of the Front Range. The Fort St. Vrain site has not experienced any observed earthquake activity. A field examination of the area produced no evidence of recent movement along any of the known faults. The closest area of recent activity is about 40 kilometers (25 miles) south of the site. The site is located in Seismic Zone 1.

The nearest major surface water features to the Fort St. Vrain site are the South Platte River, about 0.8 kilometer (0.5 mile) east of the site, and the St. Vrain Creek, about 1.2 kilometer (0.75 mile) west of the site. Local surface water diversions from these rivers, which feed irrigation ditches to support agriculture, are somewhat closer, about 0.5 kilometer (0.33 mile) east and west of the site and about 0.64 kilometer (0.4 mile) to the north of the site, and an irrigation ditch is located 0.16 kilometer (0.1 mile) to the south of the site.

4.7.3.3 Babcock & Wilcox Research Center, Lynchburg.

The Babcock & Wilcox Research Center occupies a 1.6-hectare (4-acre) fenced area within Babcock & Wilcox's 374-hectare (925-acre) Mount Athos site. The research center is in Campbell County, Virginia, near the James River, approximately 6.5 kilometers (4 miles) east of the city of Lynchburg. The research facility and the nearby city of Lynchburg are centrally located within the area of Amherst, Appomattox, Bedford, and Campbell Counties. The combined population of these counties is about 180,000.

The climate of the Lynchburg area is influenced by cold and dry polar continental air masses in the winter and warm and humid gulf maritime air masses in the summer. Rainfall amounts can be expected to reach 102.4 centimeters (40.3 inches) in any given year. Severe weather is limited to thunderstorms with a low probability of tornadoes. The mean number of thunderstorms occurring at Lynchburg is approximately 22 per year. The probability of a tornado actually striking the site is 3.0 10-4 per year, with a recurrence interval of 3,333 years.

The land at the Babcock & Wilcox Research Center is characterized by scattered hills of various dimensions lying eastward from the main chain of the Blue Ridge Mountains. The site is located in a western part of the central Virginia cluster region, which is classified as Seismic Zone 2. Approximately 121 earthquakes with epicenters in Virginia have occurred during the last 236 years. Two earthquakes have been recorded with intensities sufficient to cause some damage, but these were not in the area of the Center. Earthquakes are not expected to cause serious damage to the Lynchburg facilities nor result in release of hazardous materials.

The James River is formed about 154 kilometers (96 miles) upstream of the site by the confluence of the Jackson and Cowpasture Rivers. The James River flows generally south-southeast from the Valley and Ridge Province to the Atlantic Ocean through the Hampton Roads and Chesapeake Bay. The annual average flow rate of the James River at the plant is estimated to be about 110 cubic meters per second (3,900 cubic feet per second). The largest recent flood occurred in November 1985 and had a flood stage of 163 meters (534 feet) above mean sea level at Lynchburg. The groundwater elevation is between 134 and 140 meters (440 and 460 feet) above mean sea level, which is 3 meters (10 feet) below surface elevation at the annual average flow rate. Because of the relative impermeability of the silt and clay topsoils, neither the water in surface soils nor river flood water has a major effect on the groundwater supply or quality.

5. ENVIRONMENTAL CONSEQUENCES

This chapter presents the potential environmental consequences of implementing each of the alternatives described in Chapter 3. To focus on the most significant issues in the design of the SNF Program, this chapter summarizes and simplifies the more detailed site-specific analyses of environmental consequences presented under separate cover as self-contained appendices to Volume 1. The intent is to provide a collection of summary information across DOE sites, SNF interim storage alternatives, and issue areas without recounting the detail of the separate appendices.

The Centralization alternative generally produces the greatest impacts, with somewhat smaller impacts associated with the 1992/1993 Planning Basis and Regionalization alternatives. The No Action alternative may appear to have the least impact in some of the categories analyzed, such as transportation, but it also produces larger impacts in others, such as estimated radiation doses as the result of accidents. In addition, the increased exposure of workers to radiation and the increased risks of release of radioactive material to the environment with the continuing degradation of certain types of DOE SNF are potential impacts that cannot be completely analyzed.

This chapter is organized into eight sections. The disciplines (topical areas) studied that result in potential impacts, are of general public interest, or may help to discriminate among sites for alternatives are discussed in Section 5.1. In general, the consequences presented in Section 5.1 relate to socioeconomic impacts, electricity use, waste generation, and radiological and transportation impacts. The disciplines that were studied that showed small impacts or clearly did not discriminate among sites or alternatives are discussed in Section 5.2. Sections 5.3 through 5.8 address cumulative impacts, unavoidable adverse environmental effects, the relationship between short-term use and long-term productivity, irreversible and irretrievable commitments of resources, potential mitigation measures, and environmental justice, respectively.

The period covered in this EIS is the 40 years from 1995 to 2035. Detailed impact analyses are performed for the time period from 1995 to 2005. Normal operation impacts at the Idaho National Engineering Laboratory are then projected for the remaining 30 years covered by this EIS. The level of site-specific detail presented in Sections 5.1 and 5.2 is commensurate with the size of the SNF inventory and the number and types of sites where SNF would be stored. Therefore, the analyses of the major DOE and naval sites are more detailed than the analyses for the other generator/storage locations that would have limited inventories under the No Action and Decentralization alternatives. There are five major DOE sites that are or may be responsible for managing the great majority of SNF: Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site. The DOE did not consider the Nevada Test Site to be a preferred site for the management of SNF because of the State of Nevada's current role as the host site for the Yucca Mountain Site Characterization Project and the Nevada Test Site's lack of SNF management facilities and high-level waste infrastructure. Minor sites are the university and government reactor sites and the three facilities that store small quantities of SNF for which DOE has responsibility: West Valley Demonstration Project, Babcock & Wilcox Research Center, Lynchburg, and Fort St. Vrain.

For more detailed information on analyses of environmental impacts, and for a discussion of the analyses supporting the consequences reported here, refer to the appropriate site-specific appendix. These site-specific appendices, under separate cover, are organized as follows:

Appendix	Focus of Appendix
A	Hanford Site
B	Idaho National Engineering Laboratory
C	Savannah River Site
D	Naval Nuclear Propulsion Program
E	Other Generator/Storage Locations
F	Nevada Test Site and Oak Ridge Reservation

Appendix K presents site-specific data compiled from Appendices A through F that were used in developing the discussion of environmental consequences. The summary tables in Appendix K allow comparison of quantitative impacts (for example, increases or decreases in direct employment resulting from implementation of an alternative) among sites.

Appendix L presents an evaluation of environmental justice considerations at each of the alternative sites considered in this EIS. Environmental consideration and exposure pathways were evaluated within a 80-kilometer (50-mile) radius surrounding each of 10 potential sites of proposed activities. This 80-kilometer (50-mile) radius is in keeping with analysis conducted under the National Environmental Policy Act regarding proposed DOE activities to identify environmental impacts from proposed activities. This 80-kilometer (50-mile) radius represents the limit in which any impacts are considered to be of any potential significance. Minority and low-income communities surrounding each alternative site were identified through the use of a Geographical Information System, based on 1990 U.S. Census data. Demographic maps are provided for each site under consideration in Appendix L.

5.1 Environmental Consequences of Key Discriminator Disciplines

This section presents the environmental consequences of the alternatives, focusing on the key discriminator disciplines-those that may differentiate among sites, have the potential for a more significant impact, or are of general public interest. This section is organized in two parts: a background discussion providing perspective for each discipline and a presentation of consequences by alternative, discipline, and site.

5.1.1 Background

The following discussion provides background and perspective for the environmental consequences presented in Section 5.1.

5.1.1.1 Socioeconomics.

Socioeconomic impacts are defined in terms of direct and secondary effects. Direct effects include changes in site employment and expenditures resulting from SNF-related construction and operation. Secondary effects include changes that result from regional purchases, nonpayroll expenditures, and payroll spending by site employees. For the major DOE sites, existing projections (regardless of SNF management decisions) indicate that jobs will be lost during the next few years for all sites. Potential SNF management impacts onsite and regional employment were considered in light of this trend.

For the sites considered, only minor increases in site employment over the declining job baseline would result from SNF management; therefore, secondary effects were considered as a lessening of the rate of job loss, without substantial impacts on associated regions. At the Idaho National Engineering Laboratory, the potential for appreciable job losses exists under certain alternatives. These reductions would contribute to an overall regional decline. The reductions are not anticipated to be significant, however, because they would occur over several years. For the naval sites, the number of staff required to manage SNF management facilities would be approximately less than 1 percent of site employment and less than 1/25 of 1 percent of regional employment, so secondary impacts were also considered small in this analysis. For other generator/storage locations, job creation was expected to be minimal even under the No Action alternative where long-term management of SNF would be required should operating reactors be required to shut down. The number of staff involved for long-term SNF management would be small in relation to existing staffing levels at these reactors.

With employment as an indicator, small changes in population are anticipated, creating minimal changes in demand on regional supporting infrastructures. The number of direct jobs that would be created under each alternative as a result of SNF management activities was estimated for each site. The employment graphs shown on Figures 5-1 through 5-9 (presented and discussed fully with the alternatives) represent the 10-year average of the incremental change in direct employment resulting from SNF management. Secondary effects, such as the need for additional housing and improved community services are discussed if an impact is indicated. Details on the socioeconomic impact analysis, as well as the baseline projections from which comparisons were made, are provided in Appendices A through F. Employment increases and decreases that are presented in the text are 10-year averages rather than the actual maximum increase or decrease in any single year as presented in Appendix A through F. Please see the specific site appendix for actual annual employment values.

5.1.1.2 Utilities (Electricity).

New facilities (or the restarting of idle facilities) would result in increased demands on water, power, and sewage. Water and sewage requirements are considered minimal and are discussed in Section 5.2.9. However, power consumption under some of the alternatives would exceed existing capacity at certain sites and this is discussed in more detail in this section. Electricity requirements by site and by alternative vary significantly depending on whether a site is processing or storing SNF. For example, at the Hanford Site, the annual increase in power use from SNF management activities could vary from 0 megawatt-hours per year under the No Action alternative when storing only, to a maximum of about 130,000 megawatt-hours per year under the Centralization alternative when processing (Appendix K, Volume 1). In addition, the operation of an expended core facility consumes approximately 10,000 megawatt-hours per year of electricity. Therefore, the power requirements would be highest under alternatives where both processing and operating an expended core facility occur simultaneously. The graphs of electricity use in Figures 5-1 through 5-9 show the maximum and minimum incremental change in power consumption that would result from implementing the alternative. Current capacities and baseline usage of utilities and energy from which comparisons are made are discussed in Appendices A through F of Volume 1.

5.1.1.3 Materials and Waste Management.

There are few impacts on materials and waste management activities except when SNF is processed. Stabilization of SNF, depending on the technology, may yield high-level, transuranic, low-level, mixed, and hazardous wastes. The wastes must usually be further treated to make them safe for transport, storage, or disposal. The capacity of sites for additional storing of high-level and transuranic wastes is generally limited. Low-level wastes are normally disposed of onsite at the major DOE facilities. Hazardous wastes are normally treated in some way and then disposed of in approved disposal facilities onsite or offsite. A few categories of mixed waste are being treated, but most are in storage awaiting development of treatment capabilities. The graphs of waste generation in Figures 5-1 through 5-9 illustrate the estimated annual average of low-level waste and high-level, transuranic, and mixed waste that each alternative would generate between 1995 and 2005. Site-specific details on materials and waste management and the current status of waste management activities at the sites are discussed in Appendices A through F.

5.1.1.4 Occupational and Public Health and Safety.

Radiation Effects-Radiation exposure and its consequences are topics of interest to the general public near nuclear facilities. Therefore, this EIS places more emphasis on the consequences of exposure to radiation than on other topics, even though the effects of radiation exposure under most of the circumstances evaluated in this EIS are small. This subsection explains basic concepts used in the evaluation of radiation effects to provide the background for later discussions of impacts.

The effects on people of radiation that is emitted during disintegration (decay) of a radioactive substance depends on the kind of radiation (alpha and beta particles, and gamma and x-rays) and the total amount of radiation energy absorbed by the body. The total energy absorbed per unit quantity of tissue is referred to as absorbed dose. The absorbed dose, when multiplied by certain quality factors and factors that take into account different sensitivities of various tissues, is referred to as effective dose equivalent, or where the context is clear, simply dose. The common unit of effective dose equivalent is the rem (1 rem equals l,000 millirem).

An individual may be exposed to ionizing radiation externally, from a radioactive source outside the body, and/or internally, from ingesting or inhaling radioactive material. The external dose is different from the internal dose. An external dose is delivered only during the actual time of exposure to the external radiation source. An internal dose, however, continues to be delivered as long as the radioactive material remains in the body, although both radioactive decay and elimination of the radionuclide by ordinary metabolic processes decrease the dose rate with the passage of time. The dose from internal exposure is calculated over 50 years following the initial exposure.

The maximum annual allowable radiation dose to an individual of the public from DOE-operated nuclear facilities is 0.1 rem (100 millirem) per year (DOE Order 5400.5) (DOE 1993b). All DOE and naval facilities covered by this EIS operate well below this limit (see Chapter 4). It is estimated that the average individual in the United States receives a dose of about 0.3 rem (300 millirem) per year from natural sources of radiation. For perspective, a modern chest x-ray results in an approximate dose of 0.008 rem (8 millirem), while a diagnostic hip x-ray results in an approximate dose of 0.083 rem (83 millirem). A person must receive an acute (short-term) dose of approximately 600 rem (600,000 millirem) before there is a high probability of near-term death (NAS/NRC 1990).

Radiation can also cause a variety of ill-health effects in people. The most significant ill-health effect to depict the consequences of environmental and occupational radiation exposures is the induction of latent cancer fatalities. This effect is referred to as latent cancer fatalities because the cancer may take many years to develop and for death to occur.

The collective (or population) dose to an exposed population is calculated by summing the estimated doses received by each member of the exposed population. This total dose received by the exposed population is measured in person-rem. For example, if 1,000 people each received a dose of 0.001 rem (1 millirem), the collective dose is 1,000 persons 0.001 rem (1 millirem) = 1 person-rem. Alternatively, the same collective dose (1 person-rem) results from 500 people each of whom received a dose of 0.002 rem (2 millirem) (500 persons 0.002 rem = 1 person-rem).

The factor that this EIS uses to relate a dose to its effect is 0.0004 latent cancer fatalities per person-rem for workers and 0.0005 latent cancer fatalities per person-rem for individuals among the general population. The latter factor is slightly higher because of the presence of individuals in the general public that may be more sensitive to radiation than workers (for example, infants).

These concepts may be applied to estimate the effects of exposing a population to radiation. For example, in a population of 100,000 people exposed only to background radiation [0.3 rem (300 millirem) per year], 15 latent cancer fatalities per year would be inferred to be caused by the radiation [100,000 persons 0.3 rem (300 millirem) per year 0.0005 latent cancer fatalities per person-rem = 15 latent cancer fatalities per year].

Sometimes, calculations of the number of latent cancer fatalities associated with radiation exposure do not yield whole numbers, and, especially in environmental applications, may yield numbers less than 1.0. For example, if a population of 100,000 were exposed as above, but to a total dose per individual of only 0.001 rem (1 millirem), the collective dose would be 100 person-rem, and the corresponding estimated number of latent cancer fatalities would be 0.05 [100,000 persons 0.001 rem (1 millirem) 0.0005 latent cancer fatalities/person-rem = 0.05 latent fatal cancers].

How should one interpret a noninteger number of latent cancer fatalities, such as 0.05? The answer is to interpret the result as a statistical estimate. That is, 0.05 is the average number of deaths that would be expected if the same exposure situation were applied to many different groups of 100,000 people. In most groups, nobody (0 people) would incur a latent cancer fatality from the 0.001 rem (1 millirem) dose each member would have received. In a small fraction of the groups, 1 latent fatal cancer would result; in exceptionally few groups, 2 or more latent fatal cancers would occur. The average number of deaths over all the groups would be 0.05 latent fatal cancers (just as the average of 0, 0, 0, and 1 is -, or 0.25). The most likely outcome is 0 latent cancer fatalities.

These same concepts apply to estimating the effects of radiation exposure on a single individual. Consider the effects, for example, of exposure to background radiation over a lifetime. The "number of latent cancer fatalities" corresponding to a single individual's exposure over a (presumed) 72-year lifetime to 0.3 rem (300 millirem) per year is the following:

1 person 0.3 rem (300 millirem)/year 72 years 0.0005 latent cancer fatalities/person-rem = 0.011 latent cancer fatalities.

Again, this should be interpreted in a statistical sense; that is, the estimated effect of background radiation exposure on the exposed individual would produce a 1.1-percent chance that the individual might incur a latent fatal cancer caused by the exposure. Said another way, about 1.1 percent of the population is estimated to die of cancers induced by the radiation background.

The dose-to-risk conversion factors presented above and used in this EIS to relate radiation exposures to latent cancer fatalities are based on the "1990 Recommendations of the International Commission on Radiation Protection" (ICRP 1991). These conversion factors are consistent with those used by the U.S. Nuclear Regulatory Commission in its rulemaking "Standards for Protection Against Radiation" (FR 1991). In developing these conversion factors, the International Commission on Radiological Protection reviewed many studies, including Health Effects of Exposure to Low Levels of Ionizing Radiation (BEIR V) and Sources, Effects and Risks of Ionizing Radiation. These conversion factors represent the best-available estimates for relating a dose to its effect; most other conversion factors fall within the range of uncertainty associated with the conversion factors that are discussed in NAS/NRC (1990). The conversion factors apply where the dose to an individual is less than 20 rem (20,000 millirem) and the dose rate is less than 10 rem (10,000 millirem) per hour. At doses greater than 20 rem (20,000 millirem), the conversion factors used to relate radiation doses to latent cancer fatalities are doubled. At much higher doses, prompt effects, rather than latent cancer fatalities, may be the primary concern. Unusual accident situations that may result in high radiation doses to individuals are considered special cases.

In addition to latent cancer fatalities, other health effects could result from environmental and occupational exposures to radiation. These effects include nonfatal cancers among the exposed population and genetic effects in subsequent generations. Table 5-1 shows the dose-to-effect factors for these potential effects, as well as for latent cancer fatalities. For clarity and to allow ready comparison with health impacts from other sources, such as those from chemical carcinogens, this EIS presents estimated effects of radiation only in terms of latent cancer fatalities. The nonfatal cancers and genetic effects are less probable consequences of radiation exposure. Estimates of the total detriment (fatal cancers, nonfatal cancers, and genetic effects) due to radiation exposure may be obtained from the estimates of latent cancer fatalities presented in this EIS by multiplying by 1.4 for workers and by 1.46 for the general public.

Table 5-1. Risk of latent cancer fatalities and other health effects from exposure to radiation. ,b

Population(c)	Latent cancer fatality	Nonfatal cancer	Genetic effects	Total detriment
Workers	0.0004	0.00008	0.00008	0.00056
General public	0.0005	0.0001	0.00013	0.00073

---

a. When applied to an individual, units are lifetime probability of latent cancer fatalities per rem (or 1,000 millirem) of radiation dose. When applied to a population of individuals, units are excess number of cancers per person-rem of radiation dose. Genetic effects as used here apply to populations, not individuals.

b. Source: ICRP (1991).

c. The difference between the worker risk and the general public risk is attributable to the fact that the general population includes more individuals in sensitive age groups (that is, less than 18 years of age and over 65 years of age).

During SNF handling and transportation, the principal radiation hazard is the direct radiation emitting from the SNF. In comparison, the hazard from release of radioactive fission products (gases and particulates) from within the solid SNF is small. Without adequate shielding, the radiation levels at the surface of the SNF are often high enough to induce a prompt fatality. Fortunately, this radiation is easily attenuated or stopped with the insertion of shielding materials such as lead, steel, or water between the SNF and the worker. Because radiation intensity decreases with distance, maintaining a distance of a few hundred meters also offers adequate protection from the radiation from unshielded SNF. For example, 10 CFR 71 requires sufficient shielding on shipping casks to reduce radiation levels at 2 meters (7 feet) from the cask to 0.01 rem (10 millirem) per hour or less. At 100 meters (328 feet), the distance effect would reduce this 0.01 rem (10 millirem) per hour by a factor of about 2,500, which would not be detectable.

During SNF interim storage, trace quantities of radioactive isotopes (principally gases and particulate fission products) may also be released to the environment from severely corroded SNF. These releases would result in small doses to the workers in the immediate vicinity of the SNF and, through atmospheric dispersion and groundwater pathways, would ultimately result in very small doses to members of the nearby general population.

Accidents involving SNF can also result in radiation releases and exposures. For most accidents, a very small fraction of the radioactive material within the SNF is released. This is because the SNF is in a solid form and the radioactive elements are intermingled within the solid SNF. Significant quantities of these radioactive elements can be released only when the accident generates enough energy to break up or cause particles of SNF to be released to the atmosphere. For most accidents, the energy is not high enough to cause much damage to the SNF and a small fraction of the radioactive material is released.

One type of accident, an accidental nuclear criticality (uncontrolled chain reaction), can release large quantities of direct radiation, as well as fission products and heat. Within a few tens of meters of the incidents, doses from direct radiation can be fatal. Further away, doses are principally from the released fission product gases and particulates. This type of accident is well understood and is easily prevented when handling solid materials such as SNF.

Risk-Another concept important to the presentation of results in this EIS is the concept of risk. Risk is most important when presenting accident analysis results. The chance that an accident might occur during the conduct of an operation is called the probability of occurrence. An event that is certain to occur has a probability of 1 (as in 100 percent certainty). The probability of occurrence of an accident is less than one because accidents, by definition, are not certain to occur. If an accident is expected to happen once every 5 years, the frequency (and probability) of occurrence is 0.2 per year (1 occurrence 5 years = 0.2 occurrences per year).

Once the frequency (occurrences per year) and the consequences (for radiation effects, measured in terms of the number of latent cancer fatalities caused by the radiation exposure) of an accident are known, the risk can be determined. The risk per year is the product of the annual frequency of occurrence times the number of latent cancer fatalities. This annual risk expresses the expected number of latent cancer fatalities per year, taking account of both the annual chance that an accident might occur and the estimated consequences if it does occur.

For example, if the frequency of an accident were 0.2 occurrences per year and the number of latent cancer fatalities resulting from the accident were 0.05, the risk would be 0.01 latent cancer fatalities per year (0.2 occurrences per year 0.05 latent cancer fatalities per occurrence = 0.01 latent cancer fatalities per year). Another way to express this risk (0.01 latent cancer fatalities per year) is to note that if the operation subject to the accident continued for 100 years, one latent cancer fatality would be likely to occur because of accidents during that period. This is equivalent to 1 chance in 100 that a single latent cancer fatality would be caused by the accident source for each year of operation.

A frame of reference for the risks from accidents associated with SNF management alternatives can be developed in the same way. For an average resident in the vicinity of the Idaho National Engineering Laboratory, the risk of a latent cancer fatality caused by the water draining from the Expended Core Facility after a large earthquake would be approximately 1.7 10-7 per year (see Chapter 5 of Appendix D). This risk can be compared with the lifetime risks of death from other accidental causes to gain a perspective. For example, the risk of dying from a motor vehicle accident is about 1 in 80. Similarly, the risk of death for the average American from fires is approximately 1 in 500, and for death from accidental poisoning, the risk is about 1 in 1,000 (NNPP 1993). These comparisons are not meant to imply that risks of a latent cancer fatality caused by DOE operations are trivial, only to show how they compare with other, more common risks. Radiological risks to the general public from DOE operations are considered to be involuntary risks, as opposed to voluntary risks such as operating a motor vehicle.

Radiological Accidents-Activities associated with transporting, receiving, handling, processing, and storing SNF involve substantial quantities of radioactive materials and limited quantities of toxic chemicals. Either routine SNF operations or accidents involving either radioactive materials or toxic chemicals can result in exposure to workers or members of the public, or contamination of the surrounding environment.

A number of existing accident analyses were evaluated to find a small group with relatively severe consequences or risks. These accidents included events such as small fires; severe accidents that a facility is designed to withstand; and beyond-design-basis events, which a facility is not designed to withstand. These accidents included those initiated by internal events, such as operational errors; those initiated by natural external phenomena, such as floods, tornados, and earthquakes; and those initiated by human-influenced external events, such as aircraft crashes and nearby explosions or toxic material releases. The accidents evaluated included those with an estimated probability ranging from 1 chance in 1,000,000 to 1 chance in 10,000,000 per year.

Appendices A through F summarize the possible accidents involving SNF operations at each of the sites and evaluate the potential consequences of the accidents that present the highest risk, in terms of estimated frequency of occurrence multiplied by consequences, to the workers and the general public. As might be expected, the highest consequences, though frequently not the highest risk, were often found to be associated with the accidents with the lowest probabilities.

The accidents selected, the amount of radioactive and toxic materials released under the accident conditions, and the estimated probabilities were based on existing safety analyses for the SNF-related operations at each site, or for comparable operations at other sites. The accident evaluations also considered the 40 to 50 years of operational experience with SNF at the sites.

Accident consequences were analyzed utilizing radioactive and toxic material release estimates for each accident. The downwind concentrations of materials released in accidents were then calculated for a range of potential receptor locations and potential doses to individuals or people at those locations evaluated. Doses were evaluated for (a) an individual 100 meters (328 feet) downwind of the facility location where the release occurs, (b) a hypothetical resident at the site boundary nearest to the facility where the release occurs (called the maximally exposed offsite individual), and (c) the general population within 80 kilometers (50 miles) of the release location. The potential impacts to workers in the immediate vicinity of the accident were analyzed qualitatively.

Dispersion in air from the release site was estimated with both typical (50th percentile) and unlikely (95th percentile) meteorological conditions. The unlikely weather conditions represent those that would result in high air concentrations of the material released, elevating the exposure of affected individuals. Concentrations and human exposures are lower than these values 95 percent of the time. Dispersion was calculated using the GENII computer code (Napier et al. 1988) for all sites except Savannah River Site, for which the site-specific AXAIR89Q code was used (including 95 percent meteorologic conditions). Although the modeling for the Savannah River Site was performed using a different code, that code has been validated and shown to be consistent with the GENII code and conservative in its model results. The dispersion of nonradioactive materials was modeled using EPIcode (Homann 1988).

Nonradiological Accidents-Accidents with nonradiological effects include industrial hazards from construction and normal operation. Accidents that may affect occupational or public health were evaluated for each of the alternatives at each of the potentially affected sites and facility locations. The maximum reasonably foreseeable accidents include chemical spills, fires, and worker accidents. The accidents estimated to exceed the most widely accepted accident exposure (toxicological) guidelines, such as the Emergency Response Planning Guideline-3 and the Threshold Limit Value of the American Conference of Governmental Industrial Hygienists, are summarized in Section 5.1, Volume 1. Exceeding these concentrations would result in an unacceptable likelihood that the worker or public would experience or develop life-threatening or very serious toxicological effects. The analysis methodologies and the accident descriptions are discussed in Appendices A through F.

Industrial accidents that do not involve the release of chemicals could occur at each of the existing or proposed storage and generation locations during the transition/construction phase at approximately current rates. Construction accidents would primarily occur during the construction period (estimated to be approximately 8 years under the Centralization alternative). Construction fatalities are estimated to be approximately one per year at the centralized site for the Centralization alternative only. After the SNF is transported to the centralized facility, normal operations would not be expected to be fatal accident-free, but fatal accident frequency is estimated to be less than one accident per year. The sites that are not selected for the centralized facilities would be expected to have less than one fatal accident per year throughout the SNF interim management period.

5.1.1.5 Transportation.

In this EIS, one of the ways that may be used to discriminate between alternatives is through the transportation impacts associated with each alternative. Some alternatives, such as the No Action alternative, would involve limited transportation of SNF and have few transportation impacts; while other alternatives, such as the Centralization options, would involve extensive transportation of SNF and have greater transportation impacts.

SNF is transported in large, heavy containers called shipping casks. Shipping casks must meet stringent Federal standards and are designed and constructed to contain the radioactivity in SNF during severe transportation accidents. There are also standards that describe the routing requirements for SNF shipments. Because of the stringent standards for SNF shipping casks, the U.S. Nuclear Regulatory Commission has estimated that shipping casks will withstand 99.4 percent of truck and rail accidents without sustaining damage sufficient to breach the shipping cask. Only in the worst physically conceivable conditions, which are clearly of low probability, can the shipping cask be so damaged that there is a significant release of radioactivity to the environment.

Transportation impacts may be divided into two parts: (1) the impacts due to incident-free transportation and (2) the impacts due to transportation accidents. For incident-free transportation and transportation accidents, impacts may be further divided into two parts: (1) nonradiological impacts and (2) radiological impacts. The nonradiological impacts are composed of the vehicular impacts of transportation, such as vehicular emissions and traffic accidents, and are not related to the radioactivity present in the shipments.

In contrast to the nonradiological impacts, the radiological impacts are due to the radioactivity present in SNF shipments. In the case of incident-free transportation, the radiological impacts result from the radiation field that surrounds the SNF shipping cask. These impacts are estimated for workers and the general population along the transportation route. In the case of transportation accidents, the radiological impacts would result from the radioactivity released from the SNF shipping cask during an accident. These impacts are also estimated for the general population along the transportation route.

This EIS evaluated a full range of transportation accidents, up to and including accidents with very low probability, estimated to be on the order of one in 1 million years. In addition, the consequences of severe transportation accidents were evaluated. The probability of these severe accidents was estimated to be on the order of one in 10 million years.

For both incident-free transportation and transportation accidents, methodology developed by the

U.S. Nuclear Regulatory Commission was used to estimate impacts. These impacts were quantified in terms of the estimated number of radiation-related cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions and traffic accidents associated with each alternative. Appendices A, B, C, D, F, and I contain more details on the methodology, data, and assumptions used to develop these estimates.

5.1.1.6 Uncertainties and Conservatism.

The calculations in this EIS have generally been performed in such a way that the estimates of risk provided are unlikely to be exceeded during either normal operations or in the event of an accident. For routine operations, the results of monitoring actual operations provide realistic estimates of source terms, which when combined with conservative estimates of the effects of radiation, produce estimates of risk that are very unlikely to be exceeded. The effects for all alternatives have been calculated using the same source terms and other factors, so this EIS provides an appropriate means of comparing potential impacts on human health and the environment.

The analyses of hypothetical accidents are based on the calculations that in turn must be based on sequences of events and models of effects that have not occurred. The models have attempted to provide estimates of the probabilities, source terms, pathways for dispersion and exposure, and the effects on human health and the environment that are as realistic as possible. In many cases, the probability of the accidents postulated is very low and little experience is available; thus, the consequences are uncertain. This has required the use of models or values for input that produce estimates of consequences and risks that are higher than would actually occur because of the desire to provide results that will not be exceeded.

All the alternatives have been evaluated using the same methods and data, allowing a fair comparison of all the alternatives on the same basis. It should be observed that, even using these conservative analytical methods, the risks associated with implementing any of the alternatives are small.

5.1.2 No Action Alternative

Under the No Action alternative, minimal actions would be taken for safe and secure management of SNF. SNF would not be transported to or from DOE facilities after a transition period, and facility upgrades or replacements and onsite fuel movements at DOE sites would be limited. Existing research and development activities at DOE sites would continue, but no new projects would be initiated. Naval SNF would be stored at naval sites at or near the point of refueling or defueling without examination at the Idaho National Engineering Laboratory. SNF from smaller DOE sites and university and other Government reactors would be stored at those reactors, and the special-case commercial fuels would remain at their current location. No foreign research reactor fuels would be accepted.

If this alternative were implemented, the Expended Core Facility at the Idaho National Engineering Laboratory would be shut down, the naval sites would store SNF in transport casks at naval sites, and the smaller DOE and university and other Government reactor sites would store the SNF they generate onsite. After a period of time, some smaller reactors would shut down to avoid the expense of building storage facilities, and the spent fuel would be stored in the reactor vessel.

In reviewing the impacts of the No Action alternative, it should be recognized that the consequences summarized in Figure 5-1 only approximately represent the consequences of this alternative. These consequences fall within four categories that may apply to one or more sites: increasing the potential for higher radiation exposures because of degrading fuels, increasing the potential for higher radiation exposures because of the location of SNF in or near major population centers, causing a potential loss of employment because research reactors would be shut down, and postponing the generation of wastes associated with research and converting SNF to a form acceptable for disposition. These issues are discussed in the following paragraphs.

Because there would be minimal actions taken to stabilize fuel under the No Action alternative, the frequency of an SNF-related radiation accident could increase as the stored fuels deteriorate with time. The lack of structural integrity of the fuel in some instances could result in an increase in handling-related accidents. In addition, releases from stored fuels could increase, increasing population doses, as the number of cladding failures increase. While the DOE is committed under the No Action alternative to ensure safe and secure management of SNF, future deterioration of fuels and facilities may increase accident risks over current risk estimates.

Under this alternative, DOE-managed SNF would be stored in over 50 locations around the country, many of which are in areas of relatively high population density. While the risk of exposure would be small for this alternative as with other alternatives, and the worst consequence accident is expected to be associated with one of the major DOE sites, the potential consequence of accidents could be greater because of the proximity of a larger population at many of the potential storage sites.

Figure 5-1. Summary of impacts for the No Action alternative. (The maximum incremental change from baseline is illustrated in graphs. Input data are summarized in Appendix K.)

The employment associated with SNF management at other generator/storage locations would be higher under this alternative than others because economies of scale would not be achievable with storage facilities being distributed among more than 50 sites. At the same time, however, non-SNF-related employment would decrease because of SNF management-related concerns. Several hundred reactor operations and research jobs could be lost if research reactors were forced to close because of the inability to store SNF onsite. This job loss is not represented in the SNF management employment consequences presented in Section 5.1.2.1.

Under the No Action alternative, no new research would be initiated on appropriate technologies for converting fuels to an acceptable form for ultimate disposition and no new facilities would be built over the next 40 years for that purpose. Because this research was not initiated, potential adverse environmental impacts associated with research activities were not assessed under the No Action alternative. The lack of adverse environmental impacts makes the No Action alternative appear to be more environmentally acceptable than the other alternatives, when in fact the adverse impacts cannot be assessed until the research projects are planned.

The sites that would be affected by the No Action alternative are the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, naval sites, and other generator/storage locations. The environmental consequences at these sites are described below.

5.1.2.1 Socioeconomics.

As shown in Figure 5-1, the graph of the maximum incremental change in employment from SNF management activities for the major DOE sites, except the Idaho National Engineering Laboratory, indicates there would be little socioeconomic impact associated with the No Action alternative between 1995 and 2005. Implementation of the No Action alternative would result in the shutdown of the Expended Core Facility at the Idaho National Engineering Laboratory, resulting in the loss of approximately 500 permanent jobs from a region with a relatively low population and few jobs. Closure of the Expended Core Facility would initially result in an increase in direct employment at the facility by 50 jobs over 3 years to handle the transport of containers, but then the 500-person work force would decrease to a caretaker work force of 10 (see Appendix D, Volume 1). This results in the loss of an average of approximately 240 jobs over the 10-year period or 3 percent of the Idaho National Engineering Laboratory's work force, as shown in Figure 5-1. At the Hanford and Savannah River Sites, there would either be no change or less than a 1 percent increase in direct employment, respectively, from implementing the No Action alternative. The peak employment would be 50 additional workers at the Savannah River Site, approximately 0.3 percent of the 1995 baseline.

Naval sites would require very few additional workers to secure the naval SNF in storage and monitor its condition. The incremental labor required for SNF management at the naval sites would be drawn from the existing work force and would be insignificant with respect to current employment levels at those sites. At the university and other Government reactors, there would be a need for security and maintenance personnel for reactors that would shut down. While this would not be an increase in employment at those sites because the staff required to run the reactors would no longer be required, it would be an increase in the staff that would be involved directly in SNF management. Across all sites, there would be a decrease in employment of less than 0.1 percent of the total workforce. Therefore, implementation of the No Action alternative would have no socioeconomic effect on a nationwide scale.

5.1.2.2 Utilities (Electricity).

Figure 5-1 illustrates the maximum incremental power use with the No Action alternative in terms of percentage increase or decrease over baseline site use. For each of the sites, this change is very small and easily accommodated. Ongoing SNF operations are included in the baseline electric power usage, and the proposed actions under the No Action alternative are not power-intensive. At the Idaho National Engineering Laboratory, the shutdown of the Expended Core Facility would result in about a 5 percent reduction in electric power consumption below existing site usage. At naval and other generator/storage locations, there would be no discernable increase in power consumption over baseline use.

5.1.2.3 Materials and Waste Management.

Figure 5-1 illustrates the annual average volume of high-level, transuranic, and mixed wastes and low-level waste that would be generated from SNF management over the next 10 years under the No Action alternative. Day-to-day SNF management and storage activities would annually generate approximately 20 cubic meters per year (26 cubic yards per year) of transuranic wastes and approximately 400 cubic meters per year (520 cubic yards per year) of low-level waste at the Savannah River Site. These volumes would be generated by activities required to safely store SNF, including the onsite consolidation of existing fuels and refurbishment of existing SNF storage pools.
No high-level waste would be generated at any of the sites under the No Action alternative, and very small levels of all wastes would be generated by the Hanford Site and the Idaho National Engineering Laboratory.

At the naval sites, implementation of the No Action alternative would result in the production of limited amounts of solid municipal wastes and low-level radioactive waste. Wastes produced from the storage of naval SNF would be controlled and managed in accordance with existing site management programs. These small amounts of waste are shown as zero in Figure 5-1.

5.1.2.4 Radiological Impacts.

For the No Action alternative, the radiological impacts from normal operations and accident risks are expected to be small at each of the major DOE and naval sites that handle and store SNF. Radiological impacts from normal operations and accidents are discussed by site below.

Radiological Impacts From Normal Operations-The airborne releases from the SNF interim storage pools at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site were estimated to result in low-level exposures to the population in the vicinity of the site with no additional latent cancers within that population expected. For naval sites, there would be no airborne releases; direct radiation is the only mechanism of exposure associated with the dry SNF interim storage technologies that would be used under this alternative. The estimated annual latent cancer fatalities for the general population are illustrated in Figure 5-1.

Radiological Impacts From Accidents-

Hanford Site. Under the No Action alternative, a wide range of accident scenarios was considered, including accidents initiated by operational events, external hazards such as aircraft crashes, and natural phenomena such as earthquakes. The highest risk SNF-related accidents identified in Section 5.15 of Appendix A are a liquid metal (sodium) fire in the Fast Flux Test Facility fuel storage area (highest to general population) and a spent fuel cask drop at the 105-K Basin (highest to workers). Major seismically induced accidents were also identified in buildings containing SNF (324 Building and 325 Building). Releases from these buildings were associated with materials other than SNF and therefore are not discussed here. Aircraft-crash initiated accidents were not considered to be reasonably foreseeable because of their very low frequency.

For both of the SNF-related accidents identified, the probabilities of occurrence are estimated to be less than one chance in 10,000 per year of operation. The estimated population doses, using very conservative meteorology and assuming no protective action, for the Fast Flux Test Facility sodium fire accident corresponds to an estimated 37 latent cancer fatalities in the general population within 80 kilometers (50 miles). The estimated risk per year, taking into account the probability of occurrence of this accident, is less than 3.7 10-3 potential latent cancer fatalities in the general population.

The potential dose to the maximally exposed offsite individual corresponds to an estimated probability of a latent cancer fatality of 2.5 10-4 for the Fast Flux Test Facility sodium fire. Emergency actions would likely reduce the actual exposures to any offsite individuals.

An onsite worker at the maximum exposure location downwind of the spent fuel cask drop is estimated to receive doses that correspond to an estimated probability of a latent cancer fatality of 1.4 10-3. The estimated risk for a worker is 1.4 10-7 latent cancer fatalities per year.

Workers (up to 12) in the immediate vicinity of the cask drop accident could receive doses on the order of 70 to 140 rem (70,000 to 140,000 millirem). Acute doses of this magnitude are in the lower end of the range of doses that might produce symptoms of acute radiation syndrome in humans. For that accident, workers could be near the cask when it drops and receive direct radiation and inhale airborne fission products.

Potential secondary impacts identified for the Fast Flux Test Facility liquid metal fire (Table 5.15-2 of Appendix A) include temporary closure of the Hanford Reach of the Columbia River to boat traffic, temporary restriction of water use locally, possible loss of crops, environmental contamination in the vicinity of the facility and near offsite environs, potential restriction on land use for agriculture, temporary restriction on fishing access, and cleanup costs. The secondary impacts associated with the K Basin cask drop would be somewhat lower but similar in nature.

Idaho National Engineering Laboratory. Under the No Action alternative, a wide range of accident scenarios were also considered, including accidents initiated by operational events, external hazards such as aircraft crashes, and natural phenomena such as earthquakes. A number of SNF-related accidents are identified in Section 5.15 of Appendix B.

The highest risk to the general population is associated with the melting of a small number of assemblies as a result of a major earthquake and hot cell breach at the Hot Fuel Examination Facility. The estimated probability of this accident is about 1 chance in 100,000 per year of operation. General population consequences are estimated to be approximately 7 latent cancer fatalities, with an estimated risk of a latent cancer fatality of 7.0 10-5 latent cancer fatalities per year.

The highest risk to workers is an inadvertent nuclear criticality in the Idaho Chemical Processing Plant CPP-603 Underwater Fuel Storage Facility, which has an estimated probability of 1 chance in 1,000 per year of operation. The estimated probability of a latent cancer fatality in a worker approximately 100 meters (about 330 feet) downwind of the accident would be 3.9 10-5. The estimated risk for a worker is 4.0 10-8 latent cancer fatalities per year.

If workers were in the immediate vicinity, doses under some circumstances could be very high but are not likely to be fatal immediately. In the criticality accident, the criticality would occur under approximately 6.1 meters (20 feet) of water. Shielding by the water would be sufficient to prevent exposure of nearby workers. Expulsion of a cone of water above the criticality might lead to significant exposure to any workers who were directly above the location of the criticality.

Fuel-handling accidents have the highest estimated frequency of occurrence at 1.0 x 10-2 per year, but because of their lower consequences, fuel-handling accidents do not represent the highest risk accidents under the No Action alternative. The frequency of fuel-handling accidents is directly related to the amount of fuel handled and the annual number of SNF shipments projected under the alternative.

Potential secondary impacts identified (Table 5.15-8 of Appendix B) for the criticality accident at the Idaho Chemical Processing Plant are limited adverse effects to vegetation or wildlife and local contamination requiring cleanup around the accident site. More extensive contamination and impacts are expected should a cell breach occur at the Hot Fuels Examination Facility. Additional secondary impacts identified include the potential for a 1-year restriction in agricultural use of up to 10,000 acres on and off the Idaho National Engineering Laboratory site, the potential interdiction of affected agricultural products on nearby lands, and the potential for temporary restricted access to affected public land (less than 10,000 acres).

The Expended Core Facility at the Idaho National Engineering Laboratory would be shut down after a transition period of approximately 3 years. Potential accidents during this period are presented in Attachment F of Appendix D under the subheading of the Decentralization alternative.

Savannah River Site. Under the No Action alternative, a wide range of accident types and accident initiators were considered for the existing SNF wet storage activities, including accidents initiated by operational events, external hazards such as aircraft crashes, and natural phenomena such as earthquakes. Five types of SNF-related accidents are identified in Section 5.15 and Attachment A of Appendix C. These include (a) a fuel assembly breach because of dropping, objects falling onto the assembly, or accidental cutting into the fuel part of an assembly, (b) an inadvertent nuclear criticality in an SNF interim storage pool, (c) a fire and explosion in an adjacent facility, and (d) spills of contaminated storage pool water either within the storage facility or to the ground outside of the facility. The initiators for these accidents include both operational events and natural phenomena such as earthquakes. Aircraft-crash-initiated accidents were not considered to be reasonably foreseeable because of their very low frequency.

The highest risk accident, both to the general population and workers, was identified as the fuel assembly breach accident with an estimated frequency of 0.16 per year. The estimated population dose for this accident corresponds to 8.5 10-3 latent cancer fatalities in the general population within 80 kilometers (50 miles). The estimated risk, taking into account the probability of occurrence of this accident, is 1.4 10-3 latent cancer fatalities per year. The estimated dose to the maximally exposed offsite individual corresponds to an estimated probability of a latent cancer fatality of 1.6 10-7 per year.

A co-located worker downwind of the accident is estimated to receive a dose that corresponds to an estimated probability of 4.8 10-6 latent cancer fatalities. The estimated risk for a worker is 7.7 10-7 latent cancer fatalities per year.

Based on past experience at the Savannah River Site (two fuel cutting/breach accidents have occurred in the Receiving Basin for Offsite Fuels), no fatalities nor high exposures to facility workers are expected for this type of accident. This type of accident would likely occur with the assembly under 0.3 to 6 meters (1 to 20 feet) of water and result in small amounts of fuel and fission products being released to the pool water. The shielding effects of the pool water would attenuate most of the radiation released, but the noble gases released would rise to the surface of the water and enter the room atmosphere, causing a direct radiation exposure to workers in the area. Upon releases into the room's atmosphere, radiation alarms would sound requiring evacuation of nearby workers. Timely evacuation would likely prevent substantial radiation exposure.

Potential secondary impacts identified for the SNF-related accidents (Table 5-25 of Appendix C) are land contamination around the site of the accident, with minor contamination outside of the immediate facility area. This would not likely require cleanup of more than 4 hectares (10 acres).

Naval Facilities. Under the No Action alternative, newly generated SNF would be stored at naval sites, which differs from the historical practice of SNF management at the Idaho National Engineering Laboratory. The naval sites are generally located in densely populated areas. As a result, the consequences of an accident involving naval SNF at a naval site would be higher than the same accident at the Idaho National Engineering Laboratory.

After a limited transition period, naval SNF would be stored dry in shipping containers at Puget Sound, Pearl Harbor, Norfolk, and Portsmouth Naval Shipyards and the Kesselring Site. A review of a wide range of potential accidents (see Attachment F of Appendix D) indicated the limiting hypothetical accident scenario with the potential to release radioactive material from the storage containers was an airplane crash into the dry storage area. This accident is the highest risk accident for the general population and workers among all of the sites.

The highest risk to the general population occurs at Pearl Harbor. The probability of an aircraft crash at the Pearl Harbor facility is estimated to be 1 chance in 100,000 per year of operation. The estimated population consequences, using very conservative meteorology, is estimated to be 26 latent cancer fatalities in the general population within 80 kilometers (50 miles) of the site. The estimated risk to the general population, taking into account the probability of occurrence of this accident, is 2.6 10-4 latent cancer fatalities per year. The probability of a latent cancer fatality in the maximally exposed offsite individual is estimated to be 9.5 10-3.

The highest risk to workers occurs at Norfolk. The probability of an airplane crash at Norfolk is estimated to be 1 chance in 1,000,000 per year of operation. An onsite worker approximately 100 meters (about 330 feet) downwind of the accident is estimated to receive a dose that corresponds to a probability of a latent cancer fatality of 7.4 10-2. The estimated risk for a worker is 7.4 10-8 latent cancer fatalities per year.

It is not likely that any fatalities would occur in workers in the vicinity because workers are normally near the containers for only brief periods when a container is being placed in the dry storage array. At most, two or three nearby workers might receive significant radiation exposure from inhalation of airborne radioactivity if the container seal were breached. The low probability of the airplane crash itself, coupled with the probability that workers would be close enough to be affected, coupled with the probability that the wind would be blowing in the direction of the workers, makes it very unlikely that any worker would receive substantial radiation exposure.

Secondary impacts are principally land contamination around the site of the accident and temporary contamination of naval vessels at the shipyard. A total of approximately 43 hectares (106 acres) might require cleanup. The contamination could extend about 0.6 kilometers (0.4 miles) beyond the closest site boundary.

Other Generator/Storage Locations. Accident analyses were evaluated for these facilities. These accidents included (a) handling accidents that resulted in fuel drops with potential for fuel cladding breaches that could release portions of the more volatile fission products, such as noble gases and iodine, (b) accidental nuclear criticalities, (c) building collapse due to natural phenomena or external events such as major earthquakes or aircraft crashes, and (d) release of contaminated storage pool water. The analysis of these accidents indicated that they were similar in kind and consequence to those described for the major DOE sites and, therefore, these problems are not presented for each of the 57 other generator/storage locations. For the No Action alternative, no accidents related to SNF management were identified for the Nevada Test Site because no SNF is currently managed at the site. Two accidents were evaluated for the No Action alternative at the Oak Ridge Reservation. The first involved a dropped dam during refueling at the High Flux Isotope Reactor fuel pool. This accident resulted in an estimated 9.2 10-6 latent cancer fatalities to the worker and 1.7 latent cancer fatalities to the general population with a risk to the worker of 9.2 10-10 and to the general population of 1.7 10-4. A beyond design basis accident at the High Flux Isotope Reactor could result from a roof collapse triggered by a tornado. This accident could result in an estimated 2.0 10-2 latent cancer fatalities to the worker and 2.3 latent cancer fatalities to the general population with a risk to the worker of 3.8 10-9 and to the general population of 4.4 10-6.

5.1.2.5 Nonradiological Impacts.

A series of the maximum reasonably foreseeable accidents was evaluated at each of the SNF management sites that would potentially release hazardous or toxic chemicals to the workplace or the environment. The specific accident was defined and effects were estimated based on the characteristics of the specific facility, potentially affected public adjacent to the facility, and local residents (at the site boundary).

The maximum reasonably foreseeable chemical accident at SNF management facilities at the Hanford Site could result in the release of polychlorinated biphenyls and sulfuric acid at the 105-KE and 105-KW Basins. Should these releases occur, workers and the general public travelling adjacent to the accident could be subjected to chemical concentrations that might cause fatalities or serious health effects. The general public at the reservation boundary would be subjected to approximately 20 percent or less of the guideline value.

A maximum reasonably foreseeable chemical accident at the Idaho Chemical Processing Plant would be expected to release chlorine and nitric acid. Should such an event occur, workers would be subjected to chemical concentrations that might cause fatalities or serious health effects. The general public at the site boundary would be subjected to approximately 7 percent or less of the guideline value (Emergency Response Planning Guideline-3). The expected concentration on public access adjacent to the spill would be approximately 30 percent of the guideline value. Because these accidents would occur in each of the alternatives evaluated and do not discriminate among alternatives, they are not discussed further.

The release of nitrogen dioxide vapor from the interaction of target cleaning solution and sodium nitrite at the Receiving Basin for Offsite Fuel is the maximum reasonably foreseeable chemical accident at the Savannah River Site. Should this accident occur, the estimated concentration would be approximately 1 percent of the concentration that would be expected to cause fatalities or serious health effects for the worker and 0.1 percent for the maximally impacted offsite individual.

A diesel spill and fire was identified as the maximum reasonably foreseeable accident at each of the naval sites. Such an accident would be expected to produce toxic gas concentrations. Such an incident, should it occur, would be expected to cause fatalities or serious health effects from three chemicals (sulfur dioxide, oxides of nitrogen, and nitric acid) that are produced during the fire. Workers and the public on the nearest public access point at each of the five naval sites would be affected. The releases might also be expected to adversely affect the public immediately outside the facility boundary at the Norfolk Naval Shipyard site.

5.1.2.6 Transportation.

Shipments-Under the No Action alternative, the only offsite transportation of SNF involves shipments of naval SNF from the Newport News Shipyard to the Norfolk Naval Shipyard and shipments of irradiated test specimens from the Expended Core Facility at the Idaho National Engineering Laboratory to offsite locations. Onsite transportation of SNF would occur at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site.

Incident-Free Transportation-For the No Action alternative, the incident-free transportation of SNF was estimated to result in a total of 0.0089 fatalities over the 40-year period 1995 through 2035. These fatalities were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions. The estimated number of radiation-related latent cancer fatalities for transportation workers was 0.0026, the estimated number of radiation-related cancer fatalities for the general population was 0.00032, and the estimated number of nonradiological fatalities from vehicular emissions was 0.0059.

Onsite shipments of SNF were estimated to result in 0.0022 fatalities. Offsite shipments of SNF were estimated to result in 0.0067 fatalities. These fatalities represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

Transportation Accidents-The cumulative transportation accident risks over the 40-year operational period were estimated to be 4.1 10-6 latent cancer fatalities and 0.047 traffic fatalities. If an accident occurred, it would be unlikely to result in the release of any radioactivity. The maximum reasonably foreseeable accident has a chance of occurrence between 1 10-6 and 1 10-7 per year. If it occurred in an urban or suburban population zone, the likelihood of a single latent cancer fatality within the exposed population was estimated to be about 1 in 100. In a rural population zone, the likelihood of a single latent cancer fatality was estimated to be about 1 in 500.

Onsite transportation of SNF would occur under the No Action alternative at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The maximum reasonably foreseeable accident for this alternative would occur at the Idaho National Engineering Laboratory, with a latent cancer fatality risk of about 7.5 10-7 for a rural population zone and about 1.1 10-5 for a suburban population zone. In the extremely unlikely event that this accident occurred under stable (worst-case) weather conditions, it could result in 6 latent cancer fatalities in a rural population, such as around the Idaho National Engineering Laboratory, within 80 kilometers (50 miles) of the accident, or 85 latent cancer fatalities in a suburban population zone. For comparison, the rural population zone would be expected to experience 350 cancer fatalities and the suburban population zone would experience 42,000 cancer fatalities from other causes.

5.1.3 Decentralization Alternative

Under the Decentralization alternative, SNF currently stored or generated at DOE sites would remain at those sites, and SNF generated by university, other Government reactors, and foreign research reactors would be transported to either the Idaho National Engineering Laboratory or the Savannah River Site. Special-case commercial SNF would be transported to the Idaho National Engineering Laboratory. Storage facilities would be upgraded or replaced at DOE sites to improve the safe and secure storage of SNF. Existing research and development of technologies improving the safe and secure storage of SNF at DOE sites would continue, and new projects would commence. The Navy would store SNF at or near the point of refueling or defueling (Option A), transport about 10 percent of its SNF to the Puget Sound Naval Shipyard for limited examinations and storage with the remainder stored at or near the point of fueling or defueling (Option B), or transport all naval SNF to the Expended Core Facility at the Idaho National Engineering Laboratory for examination and then transport it back to naval sites for storage (Option C).

The implications of this alternative would be the closure of the Expended Core Facility at the Idaho National Engineering Laboratory under Options A and B and the modification of an existing facility at Puget Sound Naval Shipyard to provide limited examination under Option B. Major DOE sites might build new storage facilities to replace existing facilities or to accept newly generated SNF from other sites. Degraded fuels at the major DOE sites might be stabilized to improve safe storage.

The sites affected by the Decentralization alternative include the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, and naval sites. The environmental consequences at these sites are described below.

5.1.3.1 Socioeconomics.

For the Decentralization A and B options, one socioeconomic consequence would be similar to that described for the No Action alternative-closing the Expended Core Facility would result in the loss of an average of approximately 240 direct jobs over 10 years at the Idaho National Engineering Laboratory (Figure 5-2), with an ultimate loss of about 500 jobs. This represents a decrease in employment at the Idaho National Engineering Laboratory of approximately 6 percent. Under the Decentralization C option, the Expended Core Facility would continue to operate at the Idaho National Engineering Laboratory with no socioeconomic consequences. At the Hanford and Savannah River Sites, this alternative would result in significant new construction, employing an additional 80 to 640 workers at the Hanford Site and 200 to 220 workers at the Savannah River Site over a 10-year period depending on the options chosen for SNF management at those sites. The higher value reflects an increase above baseline site employment of approximately 3 percent at the Hanford Site and approximately 1 percent at the Savannah River Site. The peak in employment would be an additional 1,100 workers at the Hanford Site, approximately 6 percent of the 1995 baseline.

Figure 5-2. Summary of impacts for the Decentralization alternative. (The maximum incremental changefrom baseline is illustrated in all graphs. Input data are summarized in Appendix K).

Increases in construction activity over the short-term at the Hanford Site could strain the housing market and put additional demands on school capacity. Operations after the construction period would have very small consequences through the overall project timeframe. No secondary effects on the local community are expected at the Savannah River Site.

At the naval sites, the Decentralization alternative would require construction workers and laborers to construct fuel storage areas and to staff these areas, but it is expected that these workers would come from the sites or the local area, and there would not be a significant socioeconomic impact on the surrounding communities. Nevertheless, staff required would be approximately 1 percent increase over existing naval site staffing.

5.1.3.2 Utilities (Electricity).

Figure 5-2 illustrates the minimum and maximum incremental change in power use with respect to existing site usage from implementing the Decentralization alternative. As previously discussed in Section 5.1.1.2, the variation in power use by site shown on this graph reflects whether processing occurs or not. As an example, if the Hanford Site were to choose a storage option over a processing option, the power required for the storage option would be less than 1 percent of the overall site use; however, if a processing option were selected, then power use could increase to 37 percent above existing site use (see Appendix K). At each of the sites, the increase in electricity consumption could be accommodated with the existing site electric power infrastructure. At Hanford, if a processing option were selected, an extension of existing utilities in the 200 Area to the project area would be necessary. The maximum potential electricity usage shown at the Savannah River Site would be associated with the processing option that requires the operation of the F- and H-Canyons. These have operated for many years, and onsite and offsite utilities are adequate for their operation. At the Idaho National Engineering Laboratory, the principal differences among options are due to the operation or shutdown of the Expended Core Facility as was discussed in Section 5.1.2.2.

5.1.3.3 Materials and Waste Management.

The minimum and maximum volumes of high-level, transuranic, mixed, and low-level wastes that would be generated by SNF management activities over the next 10 years relative to the baseline are shown in Figure 5-2. The combined volume of high-level, transuranic, and mixed waste generated annually, if processing options were implemented, is estimated to average from approximately 18 to 44 cubic meters per year at the Savannah River Site and Hanford Site, respectively. In contrast, if wet storage options for N-Reactor fuel were selected at the Hanford Site then no high-level, transuranic, or mixed waste would be expected to be generated. Figure 5-2 also illustrates the volume of low-level waste that would be generated from implementation of the Decentralization options. It should be noted that the volume of low-level waste would increase if a processing option were selected at either the Hanford Site or the Savannah River Site. Additional volumes of low-level waste would be generated at the Savannah River Site from the limited receipt of SNF shipments from offsite and by the addition of a new canning facility. Low-level waste would only be generated at the Idaho National Engineering Laboratory under the Decentralization alternative, where the Expended Core Facility would continue to operate. Operation of an Expended Core Facility could result in the annual production of approximately 430 cubic meters (526 cubic yards) of low-level waste (Appendix D).

At the naval sites, the implementation of the Decentralization alternative would have the same impact as that described in Section 5.1.2.3 for the No Action alternative because interim storage would be at the naval sites under both alternatives.

5.1.3.4 Radiological Impacts.

Radiological exposures to both workers and the public from normal operations for the Decentralization alternative were estimated to be small, similar to the No Action alternative, with the principal differences associated with possible implementation of the processing options at the Hanford and Savannah River Sites because of higher radionuclide releases to the atmosphere. This increases the offsite population doses and potential for latent cancer fatalities. Figure 5-2 illustrates the estimated latent cancer fatalities associated with SNF operations at the major sites. The estimated latent cancer fatalities from 40 years of SNF operation would be less than one for each site.

Hanford Site-The Decentralization alternative considers several options for construction of new facilities at the Hanford Site, including a new wet storage facility for N-Reactor SNF and a new dry storage facility for fuels currently stored at other onsite locations. A second option for implementation of the Decentralization alternative at the Hanford Site is processing of the N-Reactor SNF followed by dry storage.

Under this alternative, one of the highest risk SNF-related accidents identified for the No Action alternative remains-the spent fuel cask drop at a wet storage facility. Because of the locations of the new storage facility, the offsite consequences and risks associated with this accident could be reduced to 25 percent of those described under the No Action alternative. The other highest risk accident, the sodium fire in the Fast Flux Test Facility fuel storage area, is no longer applicable because the Fast Flux Test Facility SNF would be moved to a new dry storage facility.

Potential accidents at the proposed new facilities include a severe cask impact followed by a fire at a new dry storage facility and a uranium metal fire at a new facility for processing N-Reactor SNF. Appendix A indicates that the cask impact and fire accident scenario presents the highest estimated risk to both the onsite workers and the general public of the accident scenarios identified for this alternative at Hanford.

For the severe cask impact accident, the estimated probability is 6 in 1,000,000 per year of operation. The estimated population dose, using very conservative meteorology, corresponds to 81 latent cancer fatalities in the general population within 80 kilometers (50 miles). The estimated risk per year, taking into account the chance of occurrence of this accident, would be 4.9 10-4 latent cancer fatalities per year in the general population. The potential dose to the maximally exposed offsite individual, assuming no protective action, corresponds to an estimated probability of a latent cancer fatality of 2.5 10-4.

An onsite individual approximately 100 meters (about 330 feet) downwind of the accident who remains within the plume while the fire burns could receive a dose of 120 rem (120,000 millirem). Acute doses of this magnitude are in the lower end of the range of doses that might produce symptoms of acute radiation syndrome in humans. Because a fire is also involved, the close-in dose is highly dependent on the meteorological conditions at the time, the amount of plume rise that is generated by the heat from the fire, the exact location of the accident relative to buildings, etc. An individual 100 meters (about 330 feet) downwind is estimated to receive a dose that is sufficient to cause immediate health impacts, but probably would not be lethal. This dose corresponds to an estimated worker probability of a latent cancer fatality of 9.4 10-2. The estimated risk for a worker is 5.6 10-7 latent cancer fatalities per year.

Workers in the immediate vicinity of this accident could receive very high doses that could be lethal unless they immediately evacuated the area of the accident. There are likely to be two time scales for releases associated with this accident: immediately following the accident and while the fire burns. Nearby workers may not be able to avoid the immediate radiological impacts but could likely evacuate the area and avoid most of the fire-related radiological releases unless incapacitated by the accident.

Potential secondary impacts identified for the severe cask impact with fire accident (Table 5.15-2 of Appendix A) include possible restriction of use of the Hanford Reach of the Columbia River for recreation, potential loss of crops, moderate environmental contamination in the vicinity of the facility and near offsite environs, temporary restriction on land use for agriculture, possible short-term restriction on fishing access, and cleanup costs.

Idaho National Engineering Laboratory-Under the Decentralization alternative at the Idaho National Engineering Laboratory the highest consequence and highest risk SNF-related accidents are associated with SNF storage and are the same as described under the No Action alternative. Under the Decentralization alternative, there are more SNF shipments, and consequently more handling of SNF compared to the No Action alternative. As a result, the potential frequency of fuel-handling accidents could be about 20 percent higher than under the No Action alternative, but because of lower consequences, fuel-handling accidents would not represent the highest risk accidents under the Decentralization alternative (see DOE-ID 1994).

Savannah River Site-The Decentralization alternative considers several options for SNF management at the Savannah River Site, including wet storage (Option 2b), new facilities for dry storage (Option 2a), and processing the SNF followed by dry storage (Option 2c), which were not considered under the No Action alternative.

The highest risk accident for both the general population and workers, however, would be the fuel assembly breach accident that was discussed under the No Action alternative.

The accident frequency is expected to be about 0.35 fuel assembly breaches per year of operation with implementation of this alternative. The risks to the general public, the maximally exposed offsite individual, and co-located workers were estimated to be 3 10-3, 3.5 10-7, and 1.7 10-6 latent cancer fatalities per year of operation, respectively.

Naval Facilities-The accident risks for the three subalternatives were evaluated for the naval facilities under the Decentralization alternative: (a) decentralization with SNF retained at the shipyards and the Kesselring Site without examination of the SNF, (b) decentralization with limited examination at Puget Sound Naval Shipyard, and (c) decentralization with performance assessment examination at the Expended Core Facility at the Idaho National Engineering Laboratory followed by storage at naval sites. Attachment F of Appendix D presents a full discussion of the accident risks at each of the naval sites.

The accident risks associated with this alternative would be the same as with the No Action alternative, with the highest risk accident being an aircraft crash into a dry storage container. The consequences and risks of this maximum risk accident would be the same as those described under the No Action alternative.

Other Generator/Storage Locations-For the Decentralization alternatives, the accident risks at the Oak Ridge Reservation and other SNF interim storage sites that do not transport their SNF elsewhere would be expected to be similar to and bounded by the accident risks under the No Action alternative.

5.1.3.5 Nonradiological Accidents.

The maximum reasonably foreseeable chemical accident at the Idaho National Engineering Laboratory, Savannah River Site, naval sites, and other generator/storage locations would be similar to those described under the No Action alternative. An accident at the wet storage facility on the Hanford Site could release sulfuric acid vapor and subject workers to up to 130 percent of the chemical concentrations that are associated with fatalities or serious health effects.

5.1.3.6 Transportation.

Shipments-Under the Decentralization alternative, university, foreign, and non-DOE research reactors would transport SNF to the Idaho National Engineering Laboratory and the Savannah River Site. In addition, naval SNF shipments would be equal to or greater than those under the No

Action alternative, depending on the choice of subalternative with respect to fuel examination options. Onsite shipments at major DOE sites would occur to relocate SNF from one facility to another for stabilization or storage.

Incident-Free Transportation-For the Decentralization alternative, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.12 to 0.38 over the 40-year period 1995 through 2035. These fatalities represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The reason for a range of fatalities was because of three factors: (a) different examination options for naval SNF (see Appendix D), (b) the option of using truck or rail transport for DOE SNF (see Appendix I), and (c) different SNF management options at the Savannah River Site (see Appendix C). Navy shipments would be made using a combination of truck and rail; DOE shipments were assumed to be made using 100 percent truck or 100 percent rail.

The estimated number of radiation-related latent cancer fatalities for transportation workers ranged from 0.026 to 0.090, the estimated number of radiation-related latent cancer fatalities for the general population ranged from 0.041 to 0.24, and the estimated number of nonradiological fatalities from vehicular emissions ranged from 0.047 to 0.050 for this alternative.

Onsite shipments of SNF were estimated to result in 0.0025 to 0.0036 fatalities. Offsite shipments of SNF were estimated to result in 0.12 to 0.37 fatalities. These fatalities also represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

Transportation Accidents-The cumulative transportation accident risks over the 40-year operational period were estimated to be in the range of 0.00085 to 0.0009 latent cancer fatalities, and 0.20 to 1.01 traffic fatalities, if all SNF were transported by truck. If all SNF were transported by rail, the corresponding risks were estimated to be in the range of 0.00029 to 0.00034 latent cancer fatalities, and 0.26 to 1.07 traffic fatalities. The range of fatality estimates reflects the different fuel examination options for naval SNF (see Appendix D).

The maximum reasonably foreseeable offsite transportation accident under the Decentralization alternative involves transport of naval SNF by rail in a suburban area. The consequences of such an accident were estimated to be 1.7 latent cancer fatalities. The probability of occurrence of such an accident would be slightly greater than 1.0 10-7 per year. This probability accounts for the accident rate per mile traveled, the number of miles traveled, the percentage of the total distance that occurs in a suburban area, the meteorological conditions, and the severity of the accident. Based on DOE guidance (DOE 1993b), accidents with a probability of occurrence less than 1.0 10-7 per year are not reasonably foreseeable and are not evaluated in this EIS. Consistent with this guidance, an accident of similar severity to that above for the suburban area, but occurring in an urban area, would not be reasonably foreseeable. This is because the total miles traveled in an urban area would be only a few percent of the total transportation route, resulting in a probability of occurrence of less than 1.0 10-7 per year. Thus, the maximum reasonably foreseeable offsite transportation accident in an urban area would be less severe than postulated to occur in a suburban area and is estimated to result in 0.065 latent cancer fatalities. (A more complete discussion of this apparent anomaly is presented in Section A.5.2 of Volume 1, Appendix D, Part B, Attachment A.)

Onsite transportation of SNF would occur under the Decentralization alternative at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The maximum reasonably foreseeable accident for this alternative occurs at the Idaho National Engineering Laboratory, and the potential impacts would be the same as those described under the No Action alternative.

5.1.4 1992/1993 Planning Basis Alternative

Under the 1992/1993 Planning Basis alternative, SNF currently stored at major DOE sites would remain at those sites, and newly generated SNF from DOE, university, and other Government reactors would be transported to the Idaho National Engineering Laboratory or the Savannah River Site for storage. Special-case commercial SNF and naval SNF would be transported to the Idaho National Engineering Laboratory for storage. Existing research and development of technologies improving the safe and secure storage of SNF at DOE sites would continue, and new projects would commence. Examination of naval fuels would be conducted at the Expended Core Facility at the Idaho National Engineering Laboratory.

The implications of this alternative for major DOE sites would be similar to those described for the Decentralization alternative. New storage facilities would be built at the major DOE sites to replace existing facilities or to accept newly generated SNF from other sites. Degraded fuels at the Savannah River Site and the Hanford Site might be stabilized to improve safe storage.

The sites that would be affected by the 1992/1993 Planning Basis alternative are the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The environmental consequences at these sites are described below.

5.1.4.1 Socioeconomics.

Implementation of the 1992/1993 Planning Basis alternative would not have a significant socioeconomic impact at any of the major DOE or naval sites (Figure 5-3). The impacts at the Hanford and Savannah River Sites would be similar to those described for the Decentralization alternative in Section 5.1.3.1 and shown on Figure 5-2. Proposed new construction and maintenance activities at the Idaho National Engineering Laboratory would result in the addition of approximately 130 workers over 10 years, less than a 2 percent increase above baseline site employment. The peak employment at Hanford would be the same as that described for the Decentralization alternative, a maximum of about 1,100 additional workers at the Hanford Site, an increase of approximately 6 percent above the 1995 baseline. Secondary socioeconomic impacts at the Hanford Site would be similar to those described under the Decentralization alternative.

There would be no socioeconomic impact at the naval sites because current practices would not be altered. Storage facilities would not need to be constructed at the individual naval sites, and no employment would be generated at naval sites.

5.1.4.2 Utilities (Electricity).

The minimum and maximum change in power use from implementing the 1992/1993 Planning Basis alternative with respect to the site baseline is shown in Figure 5-3. The impact on power consumption at the sites would be the same as that described for the Decentralization alternative in Section 5.1.3.2 (compare with Figure 5-2) except at the Idaho National Engineering Laboratory. The variation in power use over site baseline use at the Savannah River and Hanford Sites reflects whether a storage or processing option is selected for SNF management. The increase in power use at the Idaho National Engineering Laboratory would be because of the Electrometallurgical Process Demonstration Project. If processing options were implemented at the Hanford Site, an extension of existing utilities to the project area would be necessary.

Figure 5-3. Summary of impacts for the 1992/1993 Planning Basis alternative. (The maximum incremental change from baseline is illustrated in all graphs. Input data are summarized in Appendix K).

5.1.4.3 Materials and Waste Management.

Figure 5-3 illustrates the combined average annual volumes of high-level, transuranic, and mixed wastes and of low-level wastes that would be generated over the next 10 years as a result of SNF management activities with the implementation of the 1992/1993 Planning Basis alternative. The volume of low-level waste and the combined volume of high-level, transuranic, and mixed waste would be similar to the volumes generated under the Decentralization alternative for the Hanford and Savannah River Sites (see Figures 5-2 and 5-3). The minimum and maximum values shown for these sites reflect whether a storage option or a processing option would be implemented, respectively.

At the Idaho National Engineering Laboratory, implementation of the 1992/1993 Planning Basis alternative would result in the generation of high-level, transuranic, and mixed wastes. These wastes would be generated by the Electrometallurgical Process Demonstration Project. The volume of low-level waste generated at the Idaho National Engineering Laboratory would be from the construction and operation of new storage and characterization facilities at the site. Adequate storage capacity exists at the site for these wastes until 2005, when additional capacity would be expected to be required for managing low-level waste (Appendix B).

5.1.4.4 Radiological Impacts.

Radiological exposures to both workers and the public from normal SNF management operations and onsite accidents for the 1992/1993 Planning Basis alternative would be essentially the same as estimated for the Decentralization option. Figure 5-3 illustrates the estimated latent cancer fatalities associated with SNF operations at the major sites.

SNF Facility Accidents-

Hanford Site. The implementation of the 1992/1993 Planning Basis alternative at the Hanford Site would not result in accident risks significantly different from those identified for the Decentralization alternative (Section 5.15 of Appendix A).

Idaho National Engineering Laboratory. Under the 1992/1993 Planning Basis alternative at the Idaho National Engineering Laboratory, the consequences and risks of accidents associated with SNF storage would be the same as described under the No Action alternative (Section 5.15 of Appendix B). The consequences of fuel-handling accidents would be the same as described under the No Action alternative, but increased SNF shipments, and consequently more handling of SNF, could result in a frequency of fuel-handling accidents about three times higher than for the No Action alternative (Slaughterbeck et al. 1995). Because of the increased frequency of fuel-handling accidents, risk to the public from fuel-handling accidents may exceed the risk from SNF storage accidents.

Savannah River Site. The implementation of the 1992/1993 Planning Basis alternative at the Savannah River Site would not result in accident consequence estimates that differ from those identified under the Decentralization alternative (Section 5.15 and Attachment A of Appendix C). Because of increases in amount of SNF handled, the accident frequencies would be expected to increase.

The accident frequency for the highest risk accident, the fuel assembly breach, would be expected to be about 0.40 fuel assembly breaches per year of operation with implementation of this alternative. This results in estimated risk to the general public, maximally exposed offsite individual, and co-located worker of 3.4 10-3, 4.0 10-7, and 1.9 10-6 latent cancer fatalities per year of operation, respectively.

Naval Facilities. With implementation of the 1992/1993 Planning Basis alternative for naval facilities, all storage and examination activities occur at the Idaho National Engineering Laboratory. The maximum risk accident at this facility was not the maximum risk accident at the Idaho National Engineering Laboratory, so it is not discussed further in this volume. See Attachment F of

Appendix D for details.

Other Generator/Storage Locations. For the 1992/1993 Planning Basis alternative, the accident risks at the Oak Ridge Reservation and other SNF interim storage sites that do not transport their SNF elsewhere would be similar to the accident risks under the No Action alternative.

5.1.4.5 Nonradiological Accidents.

The maximum reasonably foreseeable chemical accident at the Idaho National Engineering Laboratory, Savannah River Site, and other generator/storage locations would be similar to those described under the No Action alternative. The Hanford Site accidents would be similar to those in the Decentralization alternative.

Two independent accidents were evaluated to describe the maximum reasonably foreseeable chemical hazards during the operation of the Expended Core Facility at the Idaho National Engineering Laboratory. Such a release could subject workers to chemical concentrations that could cause fatalities or serious health effects but would not subject the public to such concentrations.

5.1.4.6 Transportation.

Shipments-Under the 1992/1993 Planning Basis alternative, university, foreign, and non-DOE research reactors would transport SNF to the Idaho National Engineering Laboratory and the Savannah River Site. Commercial SNF stored at the West Valley Demonstration Project and graphite SNF stored at the Fort St. Vrain site would be transported to the Idaho National Engineering Laboratory. DOE research reactor SNF stored at various DOE sites would be transported to the Idaho National Engineering Laboratory and the Savannah River Site. Naval SNF would be transported from naval shipyards to the Expended Core Facility and irradiated test specimens would be transported between the Expended Core Facility and offsite locations. Onsite transportation would relocate SNF from one facility to another for stabilization or storage.

Incident-Free Transportation-For the 1992/1993 Planning Basis alternative, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.14 to 0.45 over the 40-year period 1995 through 2035. These fatalities were the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The reason for a range of fatalities was due to two factors: (a) the option of using truck or rail transport for DOE SNF (see Appendix I) and (b) different SNF management options at the Savannah River Site (see Appendix C). Navy shipments would be made using a combination of truck or rail; DOE shipments were assumed to be made using 100 percent truck or 100 percent rail.

The estimated number of radiation-related latent cancer fatalities for transportation workers ranged from 0.029 to 0.11, the estimated number of radiation-related latent cancer fatalities for the general population ranged from 0.044 to 0.30, and the estimated number of nonradiological fatalities from vehicular emissions ranged from 0.045 to 0.071.

Onsite shipments of SNF were estimated to result in 0.0028 to 0.0036 fatality. Offsite shipments of SNF were estimated to result in 0.14 to 0.45 fatality. These fatalities were also the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

Transportation Accidents-The cumulative transportation accident risks over the 40-year operational period were estimated to be 0.0010 latent cancer fatality and 0.70 traffic fatality if all SNF were transported by truck. If all SNF were transported by rail, the corresponding risks were estimated to be 0.00035 latent cancer fatality and 0.73 traffic fatality.

The maximum reasonably foreseeable offsite transportation accident involves a rail shipment of special-case commercial SNF in a suburban population zone under neutral (average) weather conditions. The accident has a probability of occurrence of about 2.0 10-7 per year and would result in an estimated 7 latent cancer fatalities in the exposed population. For comparison, the same population would be expected to experience about 100,000 cancer fatalities from other causes. The probability of this accident occurring in an urban population zone would be less than 1 10-7 per year. In a rural population zone, the accident consequences would be estimated to be about 0.2 latent cancer fatalities.

Onsite transportation of SNF would occur under the 1992/1993 Planning Basis alternative at the Hanford Site, the Idaho National Engineering Laboratory, and the Savannah River Site. The maximum reasonably foreseeable accident for this alternative occurs at the Idaho National Engineering Laboratory, and the potential impacts would be the same as those described under the No Action alternative.

5.1.5 Regionalization Alternative

There are two alternatives under Regionalization: Regionalization 4A would relocate SNF according to fuel type; Regionalization 4B would relocate SNF according to location.

Under Regionalization 4A, certain types of SNF from other DOE sites, and SNF from university and other Government reactors, special-case commercial SNF, and foreign research reactor SNF would be transported to either the Idaho National Engineering Laboratory or Savannah River Site for storage. Existing research and development of technologies improving the safe and secure storage of SNF at DOE sites would continue, and new projects would commence. Naval SNF would be examined at the Expended Core Facility at the Idaho National Engineering Laboratory, then stored at the Idaho Chemical Processing Plant.

The implications of Regionalization 4A are essentially the same as those of the 1992/1993 Planning Basis alternative because there would be minor differences in the amounts of fuel transported to each destination under these alternatives (see Figure 5-4).

Under Regionalization 4B, however, two regional sites would be selected, and SNF would be moved to one site or the other. In the west, either the Hanford Site, Idaho National Engineering Laboratory, or Nevada Test Site would be the regional site; in the east, either the Savannah River Site or Oak Ridge Reservation would be designated. SNF stored or generated west of the Mississippi River would be transported to the Western Regional Site, and SNF stored or generated east of the Mississippi River would be transported to the Eastern Regional Site. An expended core facility would be built at either the Eastern or Western Regional Site (unless the Western Regional Site were the Idaho National Engineering Laboratory, in which case no new facility would be required). Research and development would be conducted at the regional sites.

Regionalization 4B affects more sites than Regionalization 4A. Only one site would have SNF management responsibility in the east and in the west; thus, SNF management activities would be phased out at those sites not selected as regional sites. If the Idaho National Engineering Laboratory were not selected as the Western Regional Site, the Expended Core Facility in Idaho would be closed, and a new facility would be built at either the Eastern or Western Regional Site. If the Oak Ridge Reservation were chosen as the Eastern Regional Site, SNF now at Savannah River would be transported to the Oak Ridge Reservation. This would require the development of new storage facilities at the Reservation. Some fuels might need to be stabilized before transport. If the Savannah River Site were selected as the Eastern Regional Site, there would be few differences between Regionalization 4B and Regionalization 4A except that an expended core facility might be built at the site. In the west, transport of Hanford SNF to another site would require stabilization of the N-Reactor fuels, the great majority of the SNF now stored there. Some Idaho National Engineering

Laboratory fuels would also require stabilization if they were transported to another site. New SNF management facilities would be required at any Western Regional Site selected because of the large volumes of SNF that would be received.

Figure 5-4. Summary of impacts for Regionalization 4A (by fuel type). (The maximum incremental change from baseline is illustrated in all graphs. Input data are summarized in Appendix K.)

This alternative would affect only the five major DOE sites. The environmental consequences at these sites are described below.

5.1.5.1 Socioeconomics.

Under Regionalization 4A, the socioeconomic impacts at the Idaho National Engineering Laboratory would be the same as those described for the 1992/1993 Planning Basis alternative described in Section 5.1.4.1. The peak employment under Regionalization 4A would be an additional 470 workers at the Hanford Site, approximately 3 percent above the 1995 baseline. Implementation of Regionalization 4A would have no socioeconomic consequences at either the Oak Ridge Reservation or the Nevada Test Site because this would result in no changes to existing operations at either site.

Impacts of Regionalization 4A on the naval sites would be the same as that described for the 1992/1993 Planning Basis alternative because naval SNF would be transported to the Expended Core Facility in Idaho for examination and storage at the Idaho National Engineering Laboratory.

If either the Hanford Site, Idaho National Engineering Laboratory, or Savannah River Site were not selected as a regional site under Regionalization 4B, there would be an eventual reduction in employment equal to existing employment for SNF management at these sites. This would add to the currently predicted loss of jobs at each of these sites. In the short term, additional jobs would be required to prepare SNF for transport offsite (see Figure 5-5). The closure of the Expended Core Facility at the Idaho National Engineering Laboratory, however, would lead to a short-term loss of jobs as well, increasing the rate of job loss at that site.

Sites that were selected as regional sites would have generally increased employment over baseline levels (see Figure 5-6). Site employment levels would also increase at whatever site an expended core facility were constructed (Figure 5-7). Employment at the Oak Ridge Reservation and Nevada Test Site would increase if these sites were chosen as the Eastern and Western Regional Sites. Operation of storage facilities at both the Oak Ridge Reservation and Nevada Test Site could ultimately result in the creation of approximately 500 jobs per year at both sites, a 3-percent increase above current site employment at Oak Ridge Reservation and a 6-percent increase above current site employment at the Nevada Test Site without the expended core facility or a 7- and 13-percent increase with an expended core facility, respectively (Figure 5-6). The peak annual employment from implementation of Regionalization 4B would be an additional 1,100 workers at the Nevada Test Site. The secondary impacts of increased employment at either the Oak Ridge Reservation or the Nevada Test Site could result in an increased housing demand. At the Nevada Test Site, overall socioeconomic impacts could be absorbed within the projected expansion of the local economy, infrastructure, public service, and real estate development. At the Oak Ridge Reservation, increased employment could result in increases in capital expenditures to meet the increased demand of housing, transportation, and educational facilities.

Figure 5-5. Summary of impacts for Regionalization 4B (by geography) if the site were not selected as the regional site. (The maximum incremental change from baseline is illustrated in all graphs. Input data summarized in Appendix K.)

Figure 5-6. Summary of impacts for Regionalization 4B (by geography) if sites were selected as a regional site and do not have the expended core facility. (The maximum incremental change from baseline is illustrated in all graphs. Input data are summarized in Appendix K.)

Figure 5-7. Summary of impacts for Regionalization 4B (by geography) if sites were selected as a regional site and have the expended core facility. (The maximum incremental change from baseline is illustrated in graphs. Input data are summarized in Appendix K.)

For the naval sites, implementing Regionalization 4B would have no socioeconomic consequences.

5.1.5.2 Utilities (Electricity).

As shown in Figure 5-4, implementing Regionalization 4A would have a similar impact on power consumption as the 1992/1993 Planning Basis alternative (compare Figures 5-3 and 5-4). There would be no effect on power consumption at the Oak Ridge Reservation, Nevada Test Site, or naval sites from the implementation of Regionalization 4A.

Figures 5-5, 5-6, and 5-7 illustrate the minimum and maximum change from baseline site power use from implementing Regionalization 4B with and without an expended core facility and if the site were not selected as the regional site. Regionalization at the Hanford Site or the Nevada Test Site could produce an impact on power consumption at these sites.

Figure 5-5 illustrates the impact on power consumption if a site were not selected as a regional site. The increase in electricity consumption at the Hanford Site and the Savannah River Site reflects the power required to prepare or process the SNF for transport as required. The decrease in power consumption at the Idaho National Engineering Laboratory would be from shutdown of the Expended Core Facility.

Figure 5-6 shows the minimum and maximum percent change, without an expended core facility, over baseline site power consumption if a site were selected as a regional center. At the Hanford Site and Savannah River Site, the power consumption increases slightly with the transport of naval fuel to the site. Regionalization at the Oak Ridge Reservation would result in a small (less than 3 percent) increase in electric power demand. The site electricity supply at each of these sites would be more than adequate. However, regionalization at the Nevada Test Site would increase power consumption about 13 percent above existing site usage and may require additional transmission lines or another substation at the site (see Appendices F and K).

Regionalization 4B with an expended core facility onsite is illustrated in Figure 5-7. The electricity requirements at each of the major DOE sites would increase with the addition of an expended core facility for examination of naval SNF. Power consumption at the Nevada Test Site would increase approximately 18 percent above baseline and about 40 percent at Hanford if the processing (figure maximum) option were selected. The storage only options (figure minimum) at the Hanford site would result in only a 3-percent increase in electricity consumption. The Nevada Test Site would require additional transmission lines or another substation to handle additional loads. The increased load could be handled at the Savannah River Site, and relatively minor increases could occur at the Idaho National Engineering Laboratory.

5.1.5.3 Materials and Waste Management.

Figures 5-4 through 5-7 illustrate the effects of implementing the different Regionalization alternatives: Regionalization 4A, Regionalization 4B with SNF transported offsite, Regionalization 4B without an expended core facility located at the selected site, and Regionalization 4B with an expended core facility located at the selected site. The annual average waste volumes generated from SNF management activities at a nonselected site would decrease over the next 10 years, but at the selected sites the annual generation rate of waste from SNF management activities would increase with implementation of the Regionalization alternative. The construction of an expended core facility at any site would also increase the annual volume of low-level waste generated.

The annual waste volumes generated from SNF management activities associated with Regionalization 4A are illustrated in Figure 5-4. The effects of Regionalization 4A would be similar to those described for the 1992/1993 Planning Basis alternative in Section 5.1.4.3 (see Figures 5-3 and 5-4).

Figure 5-5 illustrates the effect of not being selected as a regional center. In comparison to the Decentralization and 1992/1993 Planning Basis alternatives, the annual generation rate of high-level, transuranic, mixed, and low-level wastes would ultimately decrease at the affected site because the SNF inventory would be transported offsite. However, characterization and stabilization activities prior to transport would generate transient increases in waste volumes.

The effect of being selected as a regional center without a replacement expended core facility is illustrated in Figure 5-6. Implementation of this Regionalization 4B alternative would have similar effects at the Hanford Site and Savannah River Site as the 1992/1993 Planning Basis alternative. The Oak Ridge Reservation and Nevada Test Site would generate waste from SNF management activities under the alternative. Regionalization at either of these two sites would be expected to generate approximately 16 cubic meters (21 cubic yards) of transuranic waste and approximately 200 cubic meters (260 cubic yards) of low-level waste annually from operating an SNF management complex.

Figure 5-7 illustrates the effect on annual waste volume generation of being selected as a regional center with the addition of an expended core facility to examine naval SNF. The addition of the expended core facility would have no effect on the annual volume of high-level, transuranic, or mixed waste generated, but would increase the volume of low-level waste that would have to be managed at any site.

The effects from implementing either of the Regionalization alternatives at the naval sites would be the same as that described for the 1992/1993 Planning Basis alternatives in Section 5.1.4.3.

5.1.5.4 Radiological Impacts.

Radiological exposures to both workers and the public for Regionalization 4A would to be similar to the 1992/1993 Planning Basis alternative. These are not discussed further in this section. Figure 5-4 illustrates the potential latent cancer fatalities to the population within 80 kilometers (50 miles) from SNF operations at the major sites for Regionalization 4A.

Radiological exposures to both workers and the public for Regionalization 4B would to be similar to the 1992/1993 Planning Basis alternative if the Savannah River Site, Idaho National Engineering Laboratory, or Hanford Site were selected as regional sites. Figures 5-5, 5-6, and 5-7 illustrate the potential latent cancer fatalities to the population within 80 kilometers (50 miles) from SNF operations for Regionalization 4B if SNF is transported offsite, or if the site is selected as the regional site without and with the expended core facility, respectively.

For any of the Regionalization alternatives, the maximum estimated latent cancer fatalities in the general population from normal operations are estimated to be 7.6 10-3 per year.

SNF Facility Accidents-

Hanford Site. Accident risks under Regionalization 4A are the same as those for the Decentralization alternative. The selection of the Hanford Site as the regional site would not result in accident risks significantly different from those identified for the Decentralization alternative (Section 5.15 of Appendix A), although higher activity under this alternative would increase the annual frequency of accidents. The probability of the cask impact and fire accident scenario was estimated to be 7 in 1,000,000 if the Hanford Site were selected as a regional site.

Selecting a different site as the regional site would reduce the estimated accident risks from those identified for the Decentralization alternative because the existing wet storage facilities would be shut down and the amount of SNF handled at the dry storage facility would change slightly. The accident probability for the dry storage cask impact and fire was estimated to be 5 in 1,000,000 such that the estimated risk from this, the highest risk accident, would be 4.1 10-4 latent cancer fatalities in the general population per year of operation.

Idaho National Engineering Laboratory. While the consequences of potential SNF storage and handling accidents would be similar for all alternatives, the estimated frequency of handling accidents depends on the amount of SNF handled under the alternatives. For alternatives where all stored SNF is transported to another site, SNF storage and handling risks would be reduced to those associated with SNF generated at the Idaho National Engineering Laboratory research reactors. Under Regionalization 4A, the consequences and risks of accidents associated with SNF storage would be the same as described under the No Action alternative (Section 5.15, Appendix B). The consequences of fuel-handling accidents would be the same as described under the No Action alternative, but increased transporting and handling of SNF would result in a frequency of fuel-handling accidents about five times higher than for the No Action alternative (Slaughterbeck et al. 1995). Because of the increased frequency of fuel-handling accidents, risk to the public from fuel-handling accidents may exceed the risk from SNF storage accidents.

If the Idaho National Engineering Laboratory were selected as a regional site under Regionalization 4B, the highest consequences to the offsite population result from accidents involving stored SNF and would be the same as described under the No Action alternative (Section 5.15 of Appendix B). With the resumption of processing at the Idaho Chemical Processing Plant, the postulated accident with the highest consequence and risk to workers would be an inadvertent nuclear criticality during processing that has an estimated probability of 1 chance in 1,000 per year of operation. The estimated probability of a latent cancer fatality in a worker approximately 100 meters (330 feet) downwind of the accident would be 3.6 x 10-3, corresponding to an estimated risk to a worker of 3.6 x 10-6 latent cancer fatalities per year of operation. The consequences of fuel-handling accidents would be the same as described under the No Action alternative, but increased transporting and handling of SNF results in a frequency of fuel-handling accidents about 20 times higher than for the No Action alternative (Slaughterbeck et al. 1995). Because of the increased frequency of fuel-handling accidents, risk to the public from fuel-handling accidents may exceed the risk from SNF storage and processing accidents.

If the Idaho National Engineering Laboratory were not selected as a regional site under Regionalization 4B, the consequences and risks of accidents associated with SNF storage would be the same as described under the No Action alternative (Section 5.15 of Appendix B). The consequences of fuel-handling accidents would be the same as described under the No Action alternative, but increased transporting and handling of SNF would result in a frequency of fuel-handling accidents about nine times higher than for the No Action alternative (Slaughterbeck et al. 1995). Because of the increased frequency of fuel-handling accidents, risk to the public from fuel-handling accidents may exceed the risk from SNF storage accidents.

Savannah River Site. Accident risks under Regionalization 4A would be essentially the same as those for the 1992/1993 Planning Basis alternative. The accident frequency for the highest risk accident, a fuel assembly breach, would be expected to be about 0.44 fuel assembly breaches per year of operation with implementation of this alternative. The estimated risk of latent cancer fatalities to the general public, maximally exposed offsite individual, and co-located worker would be 3.7 10-3, 4.4 10-7, and 2.1 10-6 per year of operation, respectively.

The implementation of Regionalization 4B at the Savannah River Site, including the three options of dry storage, wet storage, and processing followed by dry storage, would not result in accidents significantly different from those identified for the same options under the Decentralization alternative (Section 5.15 and Attachment A of Appendix C). Because of an increase in the amount of SNF handled, however, the accident frequency for some accidents would increase.

Under Regionalization 4B, the accident frequency for the highest risk accident, a fuel assembly breach, would be expected to be about 0.41 fuel assembly breaches per year of operation with implementation of this alternative. This results in a proportional increase in risk to the general public and the workers. The estimated risk of latent cancer fatalities to the general public, maximally exposed offsite individual, and co-located worker would be 3.5 10-3, 4.1 10-7, and 2.0 10-6 per year of operation, respectively. With regionalization elsewhere, the highest risk accident would still be the fuel assembly breach with an estimated risk approximately the same as with the No Action alternative.

Naval Facilities. The accident risks associated with the implementation of the Regionalization alternative at sites other than the Idaho National Engineering Laboratory are presented in detail in Attachment F of Appendix D. That evaluation considered the accidents associated with operation of an expended core facility and wet and dry storage facilities at the Hanford Site, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site. Accidents evaluated were the same set of accidents identified for the Decentralization alternative. The maximum risk accidents, for either the general population and workers at sites where an expended core facility might be located if they are associated with an expended core facility, are discussed under the affected sites.

Oak Ridge Reservation. The Oak Ridge Reservation would not be affected by Regionalization 4A. The implementation of Regionalization 4B at the Oak Ridge Reservation would be expected to be similar to implementation of the Centralization alternative, except that less storage requirements would be needed. Section 5.15 (Part 3) of Appendix F indicates that the accident consequences would be similar for both alternatives and that it is reasonable to assume that the accident consequences and risks described for the Centralization alternative would envelop the Regionalization alternative.

A wide range of accident scenarios were considered, including accidents initiated by operational events, external hazards such as aircraft crashes, and natural phenomena such as earthquakes. The highest risk SNF-related accidents identified were (a) a fuel assembly breach as a result of dropping the assembly, objects falling on the assembly, or cutting into the fuel portion of the assembly, (b) a dropped fuel cask, (c) a severe impact that results in breach of a transport cask and fire, (d) an aircraft crash into the SNF dry storage facility, (e) an aircraft crash into the SNF dry cell facility, (f) a wind-driven missile impact into storage casks, and (g) and aircraft crash into a water storage pool.

The highest risk to the general population would be a fuel assembly breach, with an estimated frequency of 0.16 per year. General population consequences were estimated to be approximately 2.1 10-2 latent cancer fatalities per year. The estimated risk to the general population, taking into account the probability of occurrence of this accident, would be 3.4 10-3 latent cancer fatalities per year. The estimated probability of maximum latent cancer fatalities to the maximally exposed individual would be 6.0 10-6.

The dropped fuel cask accident has the maximum risk to workers with an estimated frequency of less than 1 in 10,000 per year. A worker downwind of the accident was estimated to receive a dose that corresponds to an estimated probability of 1.9 10-3 latent cancer fatalities. The estimated risk for a worker would be 1.9 10-7 latent cancer fatalities per year.

Workers in the immediate vicinity of the cask drop accident could receive very high doses; however, the doses would not result in a fatality. For that accident, workers could be expected to be very near the cask when it drops and receive both direct radiation as well as inhale airborne fission products. Workers would be expected to quickly evacuate the area and thus reduce their potential radiation exposure.

Nevada Test Site. The implementation of Regionalization 4B at the Nevada Test Site would also be expected to be similar to implementation of the Centralization alternative, except that storage requirements would be less. Section 5.15 (Part 2) of Appendix F indicates that the accident consequences would be similar for both alternatives and that it is reasonable to assume that the accident consequences and risks described for the Centralization alternative would envelop the Regionalization alternative.

A wide range of accident scenarios were considered for the Centralization alternative, which also apply to Regionalization 4B, including accidents initiated by operational events, external hazards such as aircraft crashes, and natural phenomena such as earthquakes. The highest risk SNF-related accidents identified for the Nevada Test Site were a fuel assembly breach (highest risk to the general public) and a dropped fuel cask (highest risk to workers).

The fuel assembly breach is the highest risk to the general population with an estimated frequency of 0.16 per year and an estimated offsite population dose corresponding to 6.6 10-4 latent cancer fatalities. The estimated risk to the general population, taking into account the probability of occurrence of this accident, would be 1.1 10-4 latent cancer fatalities per year. The potential dose to the maximally exposed offsite individual would correspond to a probability of a latent cancer fatality of 1.6 10-7.

The dropped fuel cask accident was the highest risk accident to workers with an estimated frequency of less than 1 in 10,000 per year. A worker approximately 100 meters (330 feet) downwind of the accident would have a probability of a latent cancer fatality of 1.9 10-3. The estimated risk to a worker would be 1.9 10-7 latent cancer fatalities per year of operation.

Workers in the immediate vicinity of the cask drop accident could receive very high doses; however, the doses would not result in a fatality. For that accident, workers could be expected to be very near the cask when it drops and receive both direct neutron and gamma radiation as well as inhale airborne fission products. Workers would be expected to quickly evacuate the area and thus reduce their potential radiation exposure.

Other Generator/Storage Locations. For Regionalization 4A and 4B, the accident risks would be expected to be similar to the accident risks under the No Action alternative.

5.1.5.5 Nonradiological Accidents.

The maximum reasonably foreseeable chemical accident at the Idaho Engineering National Laboratory, Savannah River Site, and other generator/storage locations would be similar to those described under the No Action alternative. An accident during the operation of a wet storage facility at the Hanford Site could release sulfuric acid and subject workers to fatalities or serious health effects.

Two independent accidents have been evaluated to describe the maximum reasonably foreseeable chemical accident during the operation of the expended core facility at each of its potential locations. Such a release could subject workers to chemical concentrations that could cause fatalities or serious health effects but would not subject the public to such concentrations except at potential locations on the Oak Ridge Reservation and adjacent to the Savannah River Site.

5.1.5.6 Transportation.

Regionalization 4A (by fuel type)-

Shipments. Under Regionalization 4A, the same SNF types would be transported as under the 1992/1993 Planning Basis alternative with differences occurring in the destinations of some SNF based on fuel type. Onsite shipments would relocate SNF for continued safe storage or stabilization.

Incident-Free Transportation. For Regionalization 4A, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.17 to 0.61 over the 40-year period 1995 through 2035. These fatalities represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The reason for a range of fatalities was due to two factors: (a) the option of using truck or rail transport for DOE SNF (see Appendix I), and (b) different SNF management options at the Savannah River Site (see Appendix C). Navy shipments would be made using a combination of truck and rail; DOE shipments were assumed to be made using 100 percent truck or 100 percent rail.

The estimated number of radiation-related latent cancer fatalities for transportation workers ranged from 0.031 to 0.15, the estimated number of radiation-related latent cancer fatalities for the general population ranged from 0.054 to 0.41, and the estimated number of nonradiological fatalities from vehicular emissions ranged from 0.052 to 0.084.

Onsite shipments of SNF were estimated to result in 0.0025 to 0.0034 fatalities. Offsite shipments of SNF were estimated to result in 0.17 to 0.61 fatalities. These fatalities also represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

Transportation Accidents. The cumulative transportation accident risks over the 40-year operational period were estimated to be 0.0011 latent cancer fatality and 0.77 traffic fatality if all SNF were transported by truck. If all SNF were transported by rail, the corresponding risks were estimated to be 0.00037 latent cancer fatality and 0.76 traffic fatality.

As in the 1992/1993 Planning Basis alternative, the maximum reasonably foreseeable offsite transportation accident involves a rail shipment of special-case commercial SNF in a suburban population zone under neutral (average) weather conditions. The accident has a probability of occurrence of about 2.8 10-7 per year, and the consequences are the same as those described under the 1992/1993 Planning Basis alternative.

Onsite transportation of SNF would occur under Regionalization 4A at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The maximum reasonably foreseeable accident for this alternative would occur at the Idaho National Engineering Laboratory, and the potential impacts would be the same as those described under the No Action alternative.

Regionalization 4B (by geography)-

Shipments. Under Regionalization 4B, the same SNF types would be transported as under the 1992/1993 Planning Basis alternative with differences occurring in the destinations of the SNF based on geographical considerations. Non-naval SNF originating from western United States locations or points of entry would be transported to the Idaho National Engineering Laboratory, Hanford Site, or Nevada Test Site. Non-naval SNF originating from eastern United States locations or points of entry would be transported to the Savannah River Site or Oak Ridge Reservation. Naval SNF would not be split on an east-west basis because the Navy would operate a facility for examining naval SNF at one of the DOE sites. Onsite shipments at major DOE sites may relocate SNF from one facility or another for continued safe storage or stabilization, if applicable.

Incident-Free Transportation. For the six Regionalization 4B alternatives, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.14 (Idaho National Engineering Laboratory and Oak Ridge Reservation alternative) to 0.90 (Nevada Test Site and Oak Ridge Reservation alternative). The other four alternatives would result in fatalities between these two alternatives. These fatalities were over the 40-year period 1995 through 2035 and represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The reason for a range of fatalities was due to two factors: (1) the option of using truck or rail transport for DOE SNF (see Appendix I), and (2) the six regionalization alternatives. Navy shipments would be made using a combination of truck or rail; DOE shipments were assumed to be made using 100 percent truck or 100 percent rail.

For regionalization at the Idaho National Engineering Laboratory and Oak Ridge Reservation, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.033, the estimated number of radiation-related latent cancer fatalities for the general population was 0.043, and the estimated number of nonradiological fatalities from vehicular emissions was 0.059.

For regionalization at the Nevada Test Site and Oak Ridge Reservation, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.21, the estimated number of radiation-related latent cancer fatalities for the general population was 0.60, and the estimated number of nonradiological fatalities from vehicular emissions was 0.091.

For regionalization at the Idaho National Engineering Laboratory and Oak Ridge Reservation, onsite shipments of SNF were estimated to result in 0.0025 fatalities. Offsite shipments of SNF were estimated to result in 0.13 fatalities. These fatalities also represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

For regionalization at the Nevada Test Site and Oak Ridge Reservation, onsite SNF shipments were estimated to result in 0.0023 fatalities. Offsite shipments of SNF were estimated to result in 0.90 fatalities. These fatalities also represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

Transportation Accidents. Cumulative accident risks for transportation by truck would range from 0.00090 latent cancer fatalities and 0.72 traffic fatalities for regionalization at the Idaho National Engineering Laboratory and Savannah River Site, to 0.0012 latent cancer fatalities and 1.0 traffic fatalities for regionalization at the Nevada Test Site and Oak Ridge Reservation. Cumulative accident risks for transportation by rail would range from 0.00024 latent cancer fatalities and 0.72 traffic fatalities for regionalization at the Idaho National Engineering Laboratory and Oak Ridge Reservation, to 0.00035 latent cancer fatalities and 0.91 traffic fatalities for regionalization at the Nevada Test Site and Oak Ridge Reservation.

As in the 1992/1993 Planning Basis alternative, the maximum reasonably foreseeable offsite transportation accident would involve a rail shipment of special-case commercial SNF in a suburban population zone under neutral (average) weather conditions. The accident has a probability of occurrence that ranges from about 2.7 10-7 per year for regionalization at the Hanford Site and Savannah River Site, to about 3.7 10-7 per year for regionalization at the Nevada Test Site and Savannah River Site. Accident consequences would be the same for each alternative and would be the same as those described under the 1992/1993 Planning Basis alternative.

Onsite transportation of SNF would occur under Regionalization 4B at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The maximum reasonably foreseeable accident for this alternative would occur at the Idaho National Engineering Laboratory, and the potential impacts would be the same as those described under the No Action alternative.

5.1.6 Centralization Alternative

Under this alternative, all stored and newly generated SNF would be transported to and stored at one of five sites: the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, or Nevada Test Site. SNF management activities at unselected sites would cease. All SNF-related research and development activities would be conducted at the selected site, and the expended core facility would also be located there.

The implications of this alternative would be similar to those of Regionalization 4B alternative for western sites, but if an eastern site were selected, considerably greater volumes of SNF would be stored there than under any other alternative because the site would receive fuels from the Hanford Site and the Idaho National Engineering Laboratory. Therefore, substantially larger storage facilities would be needed under this alternative than under any other. New facilities with the largest capacity for SNF would be built at the

Oak Ridge Reservation and Nevada Test Site because they do not now have the capacity to accept additional fuels and do not currently store significant volumes of SNF. The potential environmental consequences at these sites are described below.

5.1.6.1 Socioeconomics.

The Centralization alternative would result in the largest socioeconomic impact in terms of the number of direct jobs created (or lost) on a local basis by SNF management activities (see Figure 5-7). The change in site employment would range from a decrease of less than 3 percent of total site employment at the Idaho National Engineering Laboratory to a maximum increase of about 13 percent above existing site employment at the Nevada Test Site when an expended core facility were constructed at the site. The intensity of this impact at the major DOE sites would depend on (a) whether the SNF management programs used existing personnel or required workers to move into the region, and (b) future actions at each site competing for the available labor pool. Under Centralization if the site were selected, the peak in employment would occur at the Savannah River Site where an additional 1,700 workers would be required for the proposed SNF management activities, an increase of approximately 11 percent above the projected 1995 baseline. If the site were not selected, the peak in employment would be an additional 580 workers at the Hanford Site or approximately 3 percent above the projected 1995 baseline. If either the Hanford Site, Idaho National Engineering Laboratory, or Savannah River Site were not selected as a central site under the Centralization alternative, there would ultimately be a reduction in employment equal to existing employment for SNF management at these sites. This would add to the forecast loss of jobs at each of these sites. In the short term, additional jobs would be required to prepare SNF for transport offsite (see Figure 5-5). The closure of the Expended Core Facility at the Idaho National Engineering Laboratory, however, would lead to a long-term loss of jobs as well, increasing the rate of job loss at that site.

Sites selected as central sites would generally have increased employment over baseline levels (see Figure 5-6). This increased direct employment would also result in an indirect increase in employment in the surrounding communities. At the Oak Ridge Reservation, the associated population growth could result in increases in capital expenditures to meet the increased demand of housing, utilities, including electricity generation, wastewater treatment, and water, transportation, and education facilities. At the Hanford Site, centralization activities could strain the housing market and add to school-capacity concerns. For centralization at the Savannah River Site or the Idaho National Engineering Laboratory, DOE expects that potential impacts on the demand for community resources and services would be minimal. For centralization at the Nevada Test Site, there is a potential increase in housing demand. Overall socioeconomic impacts for centralization at the Nevada Test Site could be absorbed within the projected expansion of the local economy, infrastructure, public service, and real estate development.

5.1.6.2 Utilities (Electricity).

The effect on power consumption from implementing the Centralization alternative would be generally similar to that described for Regionalization 4B where the SNF is transported offsite or where the SNF is transported to the regional site except at the Savannah River Site.
Power consumption minimum increase would be about 8 percent over the site baseline usage at the Savannah River Site from the construction and operation of additional wet storage facilities under the

Centralization alternative. Figures 5-8 and 5-9 illustrate the Centralization impacts for the two cases: if a site were selected or not selected as the central site (compare with Figures 5-5 and 5-7). The impacts would be the same as those described in Section 5.1. Thus, for example, electric power requirements with centralization at the Nevada Test Site would be similar to Regionalization 4B at the Nevada Test Site with a replacement expended core facility also located at that site (Figure 5-6).

Under the Centralization alternative at Hanford, the power consumption would rise by approximately 3 percent if SNF were only stored and could rise as much as 40 percent if processing were required. While the increase in power required for processing appears large (as a percent of baseline) when compared to the Savannah River Site, much of the difference would be the result of a higher Savannah River Site baseline with power consumption.

5.1.6.3 Materials and Waste Management.

The Centralization alternative would have similar effects at the major DOE sites to those described in Section 5.1.5.3 for the Regionalization alternative (see Figures 5-5 and 5-7). If a site were not selected as the central site, the annual volume of waste generated from SNF management activities would ultimately decrease; however, transient activities to stabilize and package the fuel could be substantial. The site selected as the central site would increase the annual volume of wastes generated from SNF management activities. The increase in waste would not necessarily be proportional to the larger amount of SNF being managed onsite because the originating sites would characterize and can their fuel before transport so it could be placed directly into storage at the receiving site. The waste volumes would be generated from transferring fuel from water pools at some sites, characterizing and canning small amounts of new fuel, and operating the expended core facility. Figures 5-8 and 5-9 show the effects of not being selected as well as being selected as the central site for SNF management activities.

Figure 5-8. Summary of impacts for the Centralization option if sites were not selected as a central site. (The maximum incremental change from baseline is illustrated in graphs. Input data are summarized in Appendix K.)

Figure 5-9. Summary of impacts for the Centralization option if sites were selected as a central site and have an expended core facility. (The maximum incremental change from baseline is illustrated in graphs. Input data are summarized in Appendix K.)

5.1.6.4 Radiological Impacts.

For the Centralization alternative, the radiological impacts from both normal operations and accidents at both the originating site and the central storage site would be expected to be low and similar in magnitude. Accident analysis for both existing and proposed SNF interim storage facilities indicates that the probabilities of accidents with the potential for significant impacts would be extremely low.

Figure 5-7 illustrates the estimated latent cancer fatalities among the population within 80 kilometers (50 miles) from SNF operations at each of the major sites. For each major site, this figure includes the potential impacts associated with site SNF operations with centralization at another site, as well as with centralization at that site.

Accident risks from SNF activities would be principally because of handling and storage activities and, therefore, would be expected to be similar for each of the centralization sites. The principal differences would be due to activities at the existing SNF sites necessary to prepare the SNF for transport to the central site.

SNF Facility Accidents-

Hanford Site. The implementation of the Centralization alternative at the Hanford site would be expected to result in accident risks for some accidents slightly different from those identified for the Decentralization alternative (Section 5.15 of Appendix A). The amount of SNF handled at the dry storage facility would be greater, resulting in an increase in the accident probability for the dry storage cask impact and fire to approximately 8 in 1,000,000. The estimate of risk from this, the highest risk accident to the general population, would be 6.5 10-4 latent cancer fatalities in the general population per year of operation. The corresponding risk to an individual worker would be 7.5 10-7 potential latent cancer fatalities per year of operation.

Implementation of the Centralization alternative (or Regionalization 4B) elsewhere reduces the estimates of accident risks from those identified for the Decentralization alternative because the existing storage facilities would be shut down and the amount of SNF handled at the site decreases slightly. The accident probability for the dry storage cask impact and fire would be expected to decrease slightly, to approximately 5 in 1,000,000. This yields an estimated accident risk to the general population of 4.1 10-4 latent cancer fatalities per year of operation. The corresponding highest risk accident to a worker would be 4.75 10-7 potential latent cancer fatalities per year of operation.

Idaho National Engineering Laboratory. The implementation of the Centralization alternative at the Idaho National Engineering Laboratory is estimated in Section 5.15 of Appendix B to result in additional accident scenarios and accident risks from those identified for the No Action alternative due to the assumed resumption of chemical processing of SNF at the Idaho Chemical Processing Plant. The consequences and risks from SNF-related accidents would be the same as Regionalization 4B if the Idaho National Engineering Laboratory is selected as a regional site.

The implementation of the Centralization alternative at a site other than the Idaho National Engineering Laboratory would result in potential accident consequences and risks the same as the Regionalization 4B when the Idaho National Engineering Laboratory is not selected as a regional site.

Savannah River Site. The implementation of the Centralization alternative at the Savannah River Site, including the three options of dry storage, wet storage, and processing followed by dry storage, is assessed in Section 5.15 and Attachment A of Appendix C to result in accidents not significantly different from those identified for the same options under the Decentralization alternative. Because of an increase in the amount of SNF handled, however, the accident frequency for some accidents would increase.

The accident frequency for the highest risk accident, a fuel assembly breach, would be expected to be about 0.84 fuel assembly breaches per year of operation with implementation of this alternative. The estimated risk of latent cancer fatalities to the general public, maximally exposed offsite individual, and co-located worker would be 7.2 10-3, 8.4 10-7, and 4 10-6 per year of operation, respectively. With centralization elsewhere, the highest risk accident would still be the fuel assembly breach with an estimated risk approximately the same as with the No Action alternative.

Oak Ridge Reservation. The accident risks associated with implementation of the Centralization alternative at the Oak Ridge Reservation are presented in detail in Section 5.15 (Part 3) of Appendix F. These accident risks are summarized under Regionalization 4B.

Nevada Test Site. The accident risks associated with implementation of the Centralization alternative at the Nevada Test Site are presented in detail in Section 5.15 (Part 2) of Appendix F. These accident risks are summarized under Regionalization 4B.

Other Generator/Storage Locations. The accident risks under the Centralization alternative would be expected to be the same as the accident risks under the No Action alternative.

5.1.6.5 Nonradiological Accidents.

Abnormal operational events could result in the release of toxic or hazardous substances from the centralized facility or from SNF management facilities at the other storage/generator sites prior to the shipment of SNF to the central site. The events that would be expected to exceed exposure guidelines would be similar to those described under the 1992/1993 Planning Basis alternative.

Two independent accidents have been evaluated to describe the maximum reasonably foreseeable chemical hazard during the operation of the expended core facility at each of its potential locations. Such a release could subject workers to chemical concentrations that would exceed the Emergency Response Planning Guideline value but would not subject the public to such concentrations except at potential locations on the Oak Ridge Reservation and adjacent to the Savannah River Site.

5.1.6.6 Transportation.

Shipments-Under the Centralization alternative, all stored and newly generated SNF would be transported to one of five sites: the Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, or Nevada Test Site.

Incident-Free Transportation-For the five Centralization alternative sites, the incident-free transportation of SNF was estimated to result in total fatalities that ranged from 0.21 (centralization at the Oak Ridge Reservation) to 1.7 (centralization at the Savannah River Site). These fatalities were over the 40-year period 1995 through 2035 and represent the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

The range of fatalities was due to two factors: (a) the option of using truck or rail transport for DOE SNF (see Appendix I) and (b) the five centralization options. Navy shipments would be made using a combination of truck and rail; DOE shipments were assumed to be made using 100 percent truck or 100 percent rail.

For centralization at the Oak Ridge Reservation, the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.050, the estimated number of radiation-related latent cancer fatalities for the general population was 0.073, and the estimated number of nonradiological cancer fatalities from vehicular emissions was 0.083.

For centralization at the Savannah River Site the estimated number of radiation-related latent cancer fatalities for transportation workers was 0.43, the estimated number of radiation-related latent cancer fatalities for the general population was 1.2, and the estimated number of nonradiological fatalities from vehicular emissions was 0.11.

For centralization at the Oak Ridge Reservation, onsite shipments of SNF were estimated to result in 0.0023 fatalities. Offsite shipments of SNF were estimated to result in 0.20 fatalities. These fatalities were also the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

For centralization at the Savannah River Site, onsite shipments of SNF were estimated to result in 0.0035 fatalities. Offsite shipments of SNF were estimated to result in 1.7 fatalities. These fatalities were also the sum of the estimated number of radiation-related latent cancer fatalities and the estimated number of nonradiological fatalities from vehicular emissions.

Transportation Accidents-Cumulative accident risks for transportation by truck would range from 0.0048 latent cancer fatalities and 1.0 traffic fatalities for centralization at the Idaho National Engineering Laboratory, to 0.0020 latent cancer fatalities and 1.44 traffic fatalities for centralization at the Savannah River Site. Cumulative accident risks for transportation by rail would range from 0.0013 latent cancer fatalities and 0.95 traffic fatalities for centralization at the Idaho National Engineering Laboratory, to 0.0014 latent cancer fatalities and 1.19 traffic fatalities for centralization at the

Nevada Test Site.

For centralization at either the Hanford Site or Idaho National Engineering Laboratory, the maximum reasonably foreseeable offsite transportation accident would involve a rail shipment of special-case commercial SNF in a suburban population zone under neutral (average) weather conditions. The accident has a probability of occurrence of about 5 10-7 per year and the consequences would be the same as those described under the 1992/1993 Planning Basis alternative.

For centralization at the Oak Ridge Reservation or the Nevada Test Site, the maximum reasonably foreseeable offsite transportation accident involves a rail shipment of special case commercial SNF in an urban population zone under neutral (average) weather conditions. The accident has a probability of occurrence of about 1 10-7 per year and could result in an estimated 36 latent cancer fatalities in the exposed population for Oak Ridge Reservation; for the Nevada Test Site, the accident would result in approximately 36 latent cancer fatalities. For comparison, the same population would be expected to experience about 540,000 cancer fatalities from other causes. The probability of this accident occurring under stable (worst-case) weather conditions is less than 1 10-7 per year for urban and suburban zones; the probability of occurrence is 5.7 10-7 per year if the accident occurred in a rural population zone and could result in an estimated 2 latent cancer fatalities.

For centralization at the Savannah River Site, the bounding offsite transportation accident would involve a rail shipment of commercial SNF in a suburban population zone under stable (worst-case) weather conditions. The accident has a probability of occurrence of about 1.2 10-7 per year and could result in an estimated 55 latent cancer fatalities in the exposed population. For comparison, the same population would be expected to experience about 42,000 cancer fatalities from other causes. The probability of this accident occurring in an urban population zone is less than 1 10-7 per year. In a rural population zone, the accident consequences would be approximately 3 percent of the suburban zone consequences.

Onsite transportation of SNF would occur under the Centralization alternative at the Hanford Site, Idaho National Engineering Laboratory, and Savannah River Site. The bounding accident among the three sites occurs at the Idaho National Engineering Laboratory, and the potential impacts would be the same as those described under the No Action alternative.

Table 5-2 summarizes the comparison of incident-free transportation fatalities for each of the SNF management alternatives. Table 5-3 provides the comparison of transportation accident risks for each of the SNF management alternatives.

Table 5-2. Comparison of incident-free transportation total fatalities for alternatives over the 40-year period.

	Minimum(a,b) total fatalities	Maximum(b,c) total fatalities
No Action	0.0089	0.0089
Decentralization	0.12 to 0.15	0.35 to 0.38
1992/1993 Planning Basis	0.14	0.45
Regionalization 4A (fuel type)	0.17	0.61
Regionalization 4B (geography)		
Idaho National Engineering Laboratory and Savannah Site	0.15 to 0.17	0.51 to 0.53
Idaho National Laboratory and Oak Ridge Reservation	0.14 to 0.15	0.53 to 0.54
Hanford Site and Savannah River Site	0.17	0.55 to 0.56
Hanford Site and Oak Ridge Reservation	0.15	0.57
Nevada Test Site and Savannah River Site	0.19	0.88
Nevada Test Site and Oak Ridge Reservation	0.17	0.90
Centralization		
Hanford Site	0.23	1.3
Idaho National Engineering Laboratory	0.21	1.1
Savannah River Site	0.26	1.7

Oak Ridge Reservation	0.21	1.6
Nevada Test Site	0.26	1.6

---

a. The minimum total fatalities would be associated with transport of DOE fuel by rail; naval SNF shipments would be by both truck (onsite) and rail (offsite).

b. Total fatalities were calculated for the 40-year period 1995 through 2035 and were the sum of the estimated number of radiation-related latent cancer fatalities for workers and the general population and the estimated number of nonradiological fatalities from vehicle emissions.

c. The maximum total fatalities would be associated with transport of DOE fuel by truck, naval SNF shipments would be by both truck (onsite) and rail (offsite).

Table 5-3. Comparison of estimated transportation accident risks for alternatives over the 40-year period.

	Truck Accident Risks(a)		Rail Accident Risks(a)	
Alternative	Latent cancer fatalities	Traffic fatalities	Latent cancer fatalities	Traffic fatalities
No Action	4.1 X 10^-6	0.047	4.1 10-6	0.047
Decentralization(b)	0.00085 to 0.00090	0.20 to 1.01	0.00029 to 0.00034	0.26 to 1.07
1992/1993 Planning Basis	0.0010	0.70	0.00035	0.73

---

a. Assumes SNF shipments would be 100 percent by truck or 100 percent by rail, except for naval SNF shipments that would be by both truck (onsite) and rail (offsite).

b. Range of values in each column for the Decentralization alternative reflects the different fuel examination options for naval SNF.

5.2 Issues Not Discussed In Detail

This section discusses potential impacts for issues that are not discussed in detail because they are small and do not distinguish among alternatives, but about which the public may have general interest. The discussion for each discipline generally concentrates on sites and alternatives that have the largest expected impacts, demonstrating that the environmental consequences for that discipline are not of sufficient importance to be given strong consideration in the programmatic decisionmaking process.

5.2.1 Land Use

The proposed alternatives would not result in major impacts on land use at either the DOE or the naval sites. The largest amount of land that would be disturbed at any of the DOE sites would be 53 hectares (130 acres) at the Hanford Site. This would occur under the Centralization alternative and would take less than 0.5 percent of the land at that site. Less than 6.5 hectares (16 acres) of land would be required at the naval sites for the No Action alternative for the storage of SNF on railcars, and no additional land outside of the existing sites would be required. At all SNF sites, new facilities would be located near existing facilities or new facilities would be built on previously disturbed or industrialized land. Additional land might be required for infrastructure and buffer zones if a new SNF management facility is required. Because less than 0.5 percent of the land at any of the DOE sites would be needed and the current land we at the naval sites would not change, land use was determined not to be a discriminating factor (discriminator) among sites or alternatives and is not considered further in this volume, Detail on land we impacts is presented in Appendices A through F. The EIS does not explicitly consider land that is currently used for SNF operations or land that might or might not be made available for other uses under some alternatives.

5.2.2 Cultural Resources

Cultural, archaeological, historic, and architectural resources are defined as prehistoric and historic sites, districts, structures, and evidence of human use that are considered important to a culture, subculture, or a community for scientific, traditional, religious, or other reasons.

Most of the major DOE sites and some of the naval sites contain areas of archaeological, cultural, or historical interest. Direct impacts to archaeological resources would be associated with ground disturbance activities. Indirect impacts would result from improved visitor access, changes in land status, or other actions that would limit future scientific investigation. Although the major DOE sites have not been surveyed completely, the locations for the construction of proposed new facilities have generally been evaluated for their cultural importance. No known cultural resources would be affected by construction under any of the proposed alternatives. Specific surveys would be conducted before beginning any construction to determine the impacts to cultural resources. As described in Section 5.7.3, if cultural resources (for example, prehistoric or historic artifacts) were encountered during construction, earth-moving activities would stop and the State Historic preservation officer would be contacted immediately. If Native American or Native Hawaiian resources were to be involved, their leaders would also be contacted. Impacts to cultural resources were determined not to be an important discriminator among sites and alternatives; therefore, they are not considered further in this chapter. Details on cultural impacts are given in Appendices A through F.

5.2.3 Aesthetic and Scenic Resources

At all DOE sites, any proposed new SNF management facilities would be located far from areas with public access. Where new facilities would be visible to the public, similar facilities are already visible. At naval sites, SNF storage locations would be located at existing industrial facilities. Aesthetic and scenic resources would not be significantly affected by SNF management activities and are not considered further in this chapter. Discussion of impacts on aesthetic and scenic resources are contained in Appendices A through F.

5.2.4 Geologic Resources

None of the sites has known significant geologic resources that would be affected by the alternatives. Except for the potential existence of gold, tungsten, and molybdenum at the Nevada Test Site, geologic resources at the candidate sites consist of surficial sand, gravel, or clay deposits that have low economic value. The alternatives that involve constructing new facilities would result in disturbing or extracting surface deposits to construct the facilities. New construction would increase the use of surface deposits (that is, sand and gravel deposits), but because of the large volume of these materials on the sites, the impact is expected to be small.

All the major DOE sites have experienced earthquakes; however, they are located in areas with low to moderate seismic potential with respect to more seismically active areas in the United States (Algermissen et al. 1982, 1990). Because any new facility would be constructed to meet current seismic design criteria for a given area, seismic concerns are not a discriminating factor among sites. Details on site geology are provided in Appendices A through F.

5.2.5 Air Quality

SNF management activities under some alternatives would result in slightly increased releases of pollutants to the atmosphere. At the major DOE sites, the projected emissions from SNF management activities would not contribute to nonattainment of state or Federal standards. There would be no impact on nonradiological ambient air quality at the naval sites (Appendix D). Construction activities at several different sites are expected to cause short-term, minor increases in fugitive dust emissions, but the use of standard dust suppression techniques would be expected to minimize this problem. These particulate emissions could temporarily affect visibility in localized areas but would not cause nonattainment of state or Federal standards. Because SNF management activities would not be expected to cause either radiological or nonradiological air quality impacts to exceed state or Federal standards at any site for any alternative considered, or to significantly affect air quality in any other respect, air quality impacts are not discussed further in this chapter. The potential radiological impacts on health are discussed in Section 5.1. The computer models used for evaluating air quality impacts, and detailed results are discussed in Appendices A through F.

5.2.6 Water Resources

The proposed alternatives would have small impacts on water resources at each of the candidate sites. Compared with existing activities at all proposed SNF sites, additional water consumption would be minor and would relate primarily to the increased demand of a larger work force because SNF water pools use recycled water. The maximum increase of water usage over baseline at any candidate site would be approximately 5 percent. There would be net increases in employment at the Oak Ridge Reservation, and the Nevada Test Site; however, water resources would not be expected to be appreciably affected under any alternative. Nevertheless, at the Nevada Test Site, where available water is limited, a cumulative water supply impact is possible. The effects of groundwater withdrawal from the Frenchman Flat hydrographic area at the Nevada Test Site to support a proposed SNF facility on groundwater yields are unknown and require additional study. The Frenchman Flat hydrographic area is part of the Ash Meadows sub-basin whose perennial yield has greatly exceeded its annual water withdrawals. Some potential also exists for minor, short-term impacts of sedimentation during construction at the Oak Ridge Reservation and the Savannah River Site.

Storing SNF in water pools creates a potential for radiological groundwater contamination through undetected leaks or accidents that breach containment systems. Releases to groundwater caused by accidental minor breaches of leak containment systems are very small compared with accidental minor releases, which are presented in Appendices A through F under Occupational and Public Health and Safety. Water resources are discussed in detail in Appendices A through F.

5.2.7 Ecological Resources

The major DOE sites under consideration are located on large reservations that are predominantly "natural." The naval sites, on the other hand, are generally much smaller with significant industrial infrastructure. Similarly, the majority of the other generator and storage sites are in urban or suburban settings, where natural flora and fauna are limited to species that have developed a tolerance to human activities. Therefore, the largest impacts to ecological resources are expected to occur at the five major DOE sites where undisturbed or semi-disturbed natural areas could be converted to industrial activity. Under any of the alternatives involving the construction of new facilities at DOE sites, individuals or small populations of some wildlife species may be disturbed, displaced, or destroyed.

The development of new DOE facilities would affect some natural habitats. The size of the areas affected would be small in relation to the size of the sites and the size of remaining natural habitats. The type of habitats affected would vary but would be typical of the regional area in which the sites are located. The habitat losses would probably not affect any threatened or endangered species or critical habitats with the possible exception of the proposed facilities at the Nevada Test Site and the Hanford Site. At the Nevada Test Site, the proposed SNF facilities could be constructed within the range of the desert tortoise, a federally listed threatened species. At the Hanford Site, construction related to SNF management could result in a habitat loss up to 28 hectares (70 acres) for Federal and state-listed candidate species (for example, loggerhead shrike, sage sparrows, burrowing owls, pygmy rabbits). As described in Section 5.7.7, mitigation plans would be developed in consultation with the appropriate agencies if any threatened or endangered species were identified on the project site. Habitat fragmentation is not expected because new facilities would be constructed adjacent to existing facilities. Because minor impacts to ecological resources would occur at all sites for all alternatives involving construction, ecology was not considered a significant discriminator among sites and, therefore, is not discussed further in this chapter. Appendices A through F present a detailed discussion of ecological impacts.

5.2.8 Noise

The construction of SNF management facilities at any of the sites would generate noise levels consistent with light industrial activity. However, at the major DOE sites, noise generated onsite does not propagate offsite at levels that would affect the general population. Noise at the naval sites is primarily from truck and car traffic, shiploading, and diesel-powered equipment. Noise impact analyses at the naval sites indicate that noise from construction or operation of facilities would not cause the ambient noise levels to exceed U.S. Environmental Protection Agency or state guidelines.
Construction would occur at the naval sites under the No Action and Decentralization alternatives.
Noise impacts would be expected to be comparable at the major DOE sites for all alternatives except for the No Action alternative, which does not involve construction of new facilities. Because these new facilities would be located in industrialized areas, however, no impacts are expected. Because noise impacts would be minor and do not differentiate among the sites or the alternatives, they are not considered further in this chapter. Details on the noise impact analyses are provided in

Appendices A through F.

5.2.9 Utilities and Energy

New facilities (or the restarting of idle facilities) would result in increased demands on water, power, and sewage. The greatest resource requirements would result from the implementation of the Centralization alternative. Based on available data, the increased water usage would range from less than 1 percent at the Idaho National Engineering Laboratory to a maximum of less than 5 percent above existing site usage at the Savannah River Site. Electricity requirements are discussed in Section 5.1. The increase in sewage generation resulting from implementation of the alternatives would range from less than 1 percent at the Idaho National Engineering Laboratory to a maximum of 9 percent at the Savannah River Site. A central sewage treatment system would have to be constructed for the SNF facilities at the Nevada Test Site under the Regionalization and Centralization alternatives if the Nevada Test Site were selected as a regional or central site. The existing system capacities at all sites could manage the estimated changes in utility usage rates for water. Appendices A through F provide details on utilities and energy consumption.

5.3 Cumulative Impacts

A cumulative impact on the environment results from the incremental impact of the action when added to other past, present, and reasonably foreseeable actions. "Other" actions include DOE projects at the potentially affected sites not related to SNF management, as well as projects proposed by other Government agencies, private businesses, or individuals. This type of an assessment is important because significant cumulative impacts can result from several smaller actions that by themselves do not have significant impacts. The programmatic cumulative impacts from the implementation of the DOE SNF Management Program are discussed in Section 5.3.1. The site-specific cumulative impacts are described in Section 5.3.2.

5.3.1 Programmatic Cumulative Impacts

On a nationwide basis, the implementation of any of the SNF Management Program alternatives would not be expected to significantly contribute to cumulative impacts. There would be a small change in regional employment, little use of nonrenewable resources, low radiological emissions, and a low rate of radioactive waste generation. Under most alternatives, subalternatives, and options, the activities required for SNF management would be very small in comparison to other non-SNF-related activities already underway at almost all sites where SNF would be stored. Even in those alternatives where there would be large changes in nonrenewable resource use at one or more sites (Regionalization by geography or Centralization), on a national scale, increases at the selected regional or central site would be compensated for by changes at nonselected sites, so the net change is very small.

Reasonably foreseeable projects that could contribute to cumulative impacts are identified for each of the DOE and naval sites in Appendices A, B, C, D, and F. For the major DOE sites, these projects are primarily associated with environmental restoration and waste management activities, one of the priorities being given to site management, and are being covered by the Waste Management Programmatic EIS and site-specific EISs. It is expected that SNF management activities would have consistently smaller impacts than the environmental restoration and waste management activities, and that the overall impact of SNF management would not contribute significantly to cumulative impacts on either a regional or a nationwide basis.

The transport of DOE and naval SNF over highways and railways is only one of the sources of radiological dose to the general public. The potential transport of commercial SNF for disposal in a repository, assumed to be in Nevada for purposes of analysis, the proposed transport of transuranic wastes to the Waste Isolation Pilot Plant in New Mexico, and the expected transport of radioisotopes used in medicine and other activities all would contribute to public exposures. Available historical data and projected future doses are summarized in Appendix I.

During analysis, the potential for significant cumulative impacts to other resources was considered; none were found. Cumulative impacts are described qualitatively because programmatic considerations do not require detailed information that depends on specific facility location or design. More detailed cumulative effects analysis will be performed for any actions that are proposed in the course of implementing programmatic SNF management decisions.

5.3.2 Site-Specific Cumulative Impacts

All of the sites contain facilities unrelated to SNF that may continue to operate throughout the duration of the SNF interim management program (approximately 40 years). Impacts from both construction and operation of SNF facilities would be cumulative with the impacts of existing and planned facilities or actions such as environmental restoration and waste management activities unrelated to SNF. Cumulative effects involving site-specific projects that are planned to occur simultaneously with SNF management activities at the major DOE sites are discussed in the site appendices. Not all planned facilities were factored into the assessment of cumulative impacts pending funding approval or resolution of DOE policy issues.

The following sections discuss cumulative impacts to those environmental resources identified in Appendices A through F. During analysis, the potential for significant cumulative impacts to other environmental resources (that is, geologic resources, aesthetic and scenic resources, and cultural resources) was evaluated; none were found.

5.3.2.1 Land Use.

Implementation of any of the SNF alternatives at the major DOE sites would have a minimal cumulative impact with respect to either the available land onsite or to the continued mission of the sites. The largest proportion of any site that would be required for all sitewide activities is less than 1 percent of the total site area.

5.3.2.2 Socioeconomics.

Depending on the economic status and outlook for an area, SNF activities coupled with other actions have the potential to strain or overburden the socioeconomic resources of certain areas, particularly if either the Regionalization or Centralization alternatives were selected with an expended core facility located at the site. For example, these cumulative effects could contribute to housing shortages, the need for additional schools, and increased demand for utilities and transportation.

Each site is anticipating an overall decline in site employment over the next few years; therefore, the existing work force could be reassigned to SNF management activities. However, it was assumed that the construction activities associated with the proposed SNF management alternatives would require the in-migration of construction workers. Although these construction activities are short-term with a duration of a few years, when addressed cumulatively with other reasonably foreseeable activities, there could be a socioeconomic impact in the communities surrounding the Hanford Site, Nevada Test Site, and Oak Ridge Reservation. For example, at the Hanford Site cumulative employment, housing requirements, and needs for schools would increase up to 1 percent over those based on present Hanford employment for SNF management activities only.

Impacts to socioeconomic resources associated with the implementation of proposed SNF actions at the Idaho National Engineering Laboratory, Savannah River Site, naval sites, and other generator sites are not expected to be sufficient to have a cumulative effect on the regional social infrastructure within each site's region of influence.

5.3.2.3 Air Quality.

The available data in Appendices A through F indicate that the cumulative air emissions from the Savannah River Site, Idaho National Engineering Laboratory, and naval sites, including those from the proposed SNF management alternatives, would not exceed the limits for nonradioactive air pollutants and would not threaten to exceed the limits for nonradioactive pollutants or the 40 CFR Part 61 limit of 0.01 rem (10 millirem) per year for radioactive emissions.

5.3.2.4 Water Resources.

Based on data available in Appendices A through F, the implementation of any of the SNF alternatives at the major DOE sites would result in minimal cumulative impacts to water resources under normal operations. The proposed SNF facilities and related management operations are designed to generate no liquid releases of wastewater to the subsurface or water resources containing radiological constituents or hazardous chemicals. The facilities would be constructed using state-of-the-art technologies, including secondary containment and leak detection and water balance monitoring equipment. Liquid effluent discharges from SNF activities will be monitored for the presence of radioactive and chemical constituents and determined suitable for land disposal as required under Federal and State regulations.

Water usage from SNF activities would also have a small cumulative effect on overall quantities of water available at the major DOE sites. The maximum increase over baseline water use would be approximately 5 percent for any of the proposed locations.

5.3.2.5 Biotic Resources.

Construction of the proposed SNF facilities in addition to other planned activities could disturb as much as 9 hectares (24 acres) of terrestrial habitat at the Hanford Site and as much as 13 hectares (31 acres) of previously disturbed land at the Idaho National Engineering Laboratory. No impacts to biotic resources would be expected at the Savannah River Site or Oak Ridge Reservation. However, construction activities at the Nevada Test Site and Hanford Site could result in habitat loss for either Federal and state candidate species or federally listed threatened species. For example, at the Hanford Site the Cumulative impact from planned activities including construction related to SNF management could result in habitat loss for Federal and state candidate species (for example, loggerhead shrike, sage sparrows, burrowing owls, pygmy rabbits). At the Nevada Test Site, the proposed SNF facilities would be constructed within the range of the desert tortoise, a federally listed threatened species. Therefore, the proposed SNF management activities in addition to other planned actions could result in a small cumulative loss of habitat for the desert tortoise.

5.3.2.6 Occupational and Public Heath.

The sources of radiation exposure to individuals consist of natural background radiation from cosmic, terrestrial, and internal body sources; medical radiation; and radiation from manmade sources, including consumer and industrial products, nuclear facilities, and weapons test fallout. At the Savannah River Site, for example, natural background radiation contributes about 82 percent of the dose received by an average member of the population within 80 kilometers (50 miles) of the site, medical exposure accounts for 15 percent of the annual dose, and the combined doses from weapons test fallout, consumer and industrial products, and air travel account for approximately 3 percent. DOE nuclear facilities at the Savannah River Site account for less than 0.1 percent of the total radiation exposure.

The radiological impacts from SNF management operations are exposures to both workers and the general public from normal operations and the risk of additional radiation exposures due to accidents. The major concerns with these exposures are whether the doses are sufficient to cause immediate harm and bow much they will increase the probabilities, among the exposed population, of latent cancer fatalities, nonfatal cancers, and genetic effects. Of further concern is that these SNF management-related exposures are in addition to those exposures and risks affecting the same workers and members of the general public from other sources. The cumulative impact of both the SNF-related increment and other possible sources is also a concern.

Cumulative Impacts to the General Public-The principal regulatory limit affecting emissions from DOE and naval sites is the Clean Air Act standard (40 CFR Part 61, Subpart H for DOE; Subpart I for the Navy) for airborne radionuclide emissions from DOE facilities.

This rule limits airborne emissions to those amounts that would not cause any member of the public to receive in any year an effective dose equivalent of more than 0.01 rem (10 millirem) per year. Implementation of any of the alternatives at any of the sites is not expected to result in normal releases exceeding this limit. The naval sites have demonstrated to the U.S. Environmental Protection Agency that, at 0.0001 rem (0.1 millirem) per year, they are at 1 percent of the limit and operation of SNF management facilities is not expected to change that conclusion. Data available for each of the sites (see Appendices A through F) indicate that over the 40-year planning period, the cumulative radioactive emissions from the existing, the potential SNF management activities, and reasonably foreseeable future site activities at any of the sites would not be expected to result in an additional latent cancer fatality among the general population surrounding the site, except for the Oak Ridge Reservation. With centralization at the Oak Ridge Reservation, operation of the proposed SNF management facilities over their expected 40-year lifetimes is estimated to result in a total population dose of approximately 2,500 person-rem. This equates to approximately two latent cancer fatalities over the period.

Cumulative Impacts on the Site Work Force - The cumulative impact of selection of either of the alternatives coupled with the existing and reasonably foreseeable actions has the potential to increase the radiological exposure to workers at the sites transporting and receiving the SNF. For both the transporting and receiving sites, the routine exposure to the workers is expected to increase because much of the dose to the workers is associated with SNF handling operations.

Because occupational worker exposures are easily monitored and controlled to levels a factor of 10 or more below the current standards, the overall average exposure per worker is expected to remain approximately constant at each of the SNF transporting and receiving sites with each of the alternatives. However, with options that involve more SNF activities, the number of SNF-related workers is expected to increase, thus increasing the collective radiation dose to the site work force.

As reported in Appendices A through F and summarized in Appendix K, the increases in collective dose to the work force varies from site to site and with the alternatives. At the Oak Ridge Reservation, for example, the increases due to SNF-related actions range to 3,200 person-rem over the 40-year planning period. The maximum SNF-related increase is equivalent to approximately one additional latent cancer fatality among the workforce.

5.3.2.7 Transportation.

Radiological Impacts - Table 5-4 summarizes the existing and reasonably foreseeable actions assessed to determine the cumulative impact for transportation for the SNF alternatives. The cumulative radiological impacts of incident-free transportation of SNF are presented in terms of radiation-related latent cancer fatalities. These results are summarized in Table 5-5 and more details are contained in Appendix I. Over the 93-year period from 1943 through 2035, the total number of radiation-related latent cancer fatalities was estimated to be 290, or approximately three latent cancer fatalities per year. General transport of radioactive material accounted for about 90 percent of these radiation-related latent cancer fatalities. The radiation-related latent cancer fatalities would be indistinguishable from other cancer fatalities and would be 0.001 percent of the total number of cancer fatalities that would be expected to occur. The radiation-related latent cancer fatalities associated with the alternatives evaluated in this EIS would be 5 x 10^-6 percent of the total number of cancer fatalities that would be expected to occur.

Traffic Accident Impacts - Fatalities involving the transport of radioactive materials for 1971 through 1993 were surveyed based on data in the Radioactive Material Incident Report database. This database contains information on radioactive materials transportation incidents

Table 5-4. Other activities included for assessment of cumulative impacts for transportation.

Activity	Description
Existing activities:	

Historical shipments	Historical shipments of SNF, Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site
General transportation	Nationwide transport of radioactive materials for medical, industrial, fuel cycle, and disposal purposes
Reasonably foreseeable activities:	
Geologic repository	Shipments of commercial SNF and defense high-level waste to the geologic repository at Yucca Mountain, Nevada
Waste Isolation Pilot Plant	Shipments of transuranic waste to the Waste Isolation Pilot Plant at Carlsbad, New Mexico (including a 5-year Test Phase and 20-year Disposal Phase)
Submarine reactor compartments	Shipments of reactor compartments from Puget Sound Naval Shipyard to Hanford
Return of isotope capsules	Shipments of cesium-137 isotope capsules to the Hanford Site
Uranium billets	Shipment of low-enriched uranium billets from the Hanford Site to the United Kingdom

Table 5-5. Summary of transportation radiological cumulative impacts.

Category of shipment(a)	Occupational latent cancer fatalities	General population latent cancer fatalities
Projected SNF shipments for all alternatives		
Truck	0.00060 to 0.40	0.00017 to 1.2
Train	0.00060 to 0.060	0.00017 to 0.085
Historical SNF(b)	0.080	0.055
General transportation (1943 to 2035)(c)	120	140
Reasonably foreseeable actions(d)		
Truck	4.4	25
Train	0.33	0.85
Total cancer fatalities(c)	130	160

---

a. See Table 54 and Appendix I for more details.
b. Shipments to Hanford Site, Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site. Includes transport of naval SNF to the Idaho National Engineering Laboratory.
c. Shipments are a combination of truck and train.
d. Shipments to the geologic repository, the Waste Isolation Pilot Plant, and shipments of submarine reactor compartments, isotope capsules, and uranium billets
e. Numbers may not sum due to rounding.

and accidents from the U.S. Department of Transportation, U.S. Nuclear Regulatory Commission, DOE, state radiation control offices, and media coverage. From 1971 through 1993, 21 traffic accidents involving 36 fatalities have occurred. These fatalities resulted from traffic accidents and were not associated with the radioactive nature of the cargo. No radiological fatalities because of transportation accidents have ever occurred in the United States. During the same time period, over 1,000,000 persons were killed in traffic accidents in the United States.

For the alternatives evaluated in this EIS, about one traffic accident fatality was estimated to occur. During the 40-year time period from 1995 through 2035 evaluated in this EIS, approximately 1,600,000 persons would be killed in traffic accidents in the United States.

5.3.2.8 Energy/Utilities.

Under certain SNF management alternatives, energy or utility requirements for SNF management in combination with other present for future projects, could stress or exceed the existing capacity at a site. The existing energy and capacity would be adequate for the SNF management alternatives at all sites with the possible exception of the Hanford Site and the Nevada Test Site.

If all SNF were transported to the Hanford Site under the Centralization alternative, then existing utilities, including water mains, power lines, sewage facilities, and telephone lines, would need to be extended to the project area. If the Centralization alternative was implemented in addition to other power-intensive activities (for example, operating a vitrification plant), existing capacity might be inadequate based on current consumption.

If the Centralization alternative were implemented at the Nevada Test Site, additional transmission lines might need to be constructed. In addition, a sewage treatment facility for the SNF management facility would have to be constructed at the Nevada Test Site if SNF management activities were implemented under the Regionalization and Centralization alternatives. Water supplies at the Nevada Test Site have been developed from local groundwater sources within the Ash Meadows Sub-basin. Existing withdrawals of groundwater from this sub-basin may have already exceeded its localized perennial yield (Appendix F). SNF management facilities at this site may result in the need for additional water.

5.3.2.9 Waste Generation.

Waste volumes generated from SNF management activities depend on the alternative chosen. In general, the Regionalization and Centralization alternatives at the Idaho National Engineering Laboratory, and the alternatives at the Savannah River Site involving processing, would result in the largest cumulative impact on waste generation. Under some options, the total increase in waste generation could be four times the current facility baseline and require the construction of additional facilities.

To evaluate the adequacy of existing storage capacity, waste volumes generated from the SNF management alternatives were compared with current generation rates at the major DOE sites. At the Navy sites, the rate of low-level waste generation would be small and not stress existing capacity. No mixed, transuranic, or high-level waste would be generated from SNF activities at the Navy sites (Appendix D).

At the major DOE sites, increased low-level waste generated from SNF management activities would range from about 1 percent above baseline generation rates at the Oak Ridge Reservation to approximately four times above baseline at the Savannah River Site for centralization and processing options, respectively. Adequate storage capacity exists at all sites except at the Idaho National Engineering Laboratory, where beyond the year 2005 low-level waste storage capacity may be strained (Appendix B).

The increased volume of transuranic waste that could be generated from SNF management activities could exceed 100 percent above baseline at the Idaho National Engineering Laboratory, Savannah River Site, Oak Ridge Reservation, and Nevada Test Site based on centralization and processing options. This percentage is high at both Nevada Test Site and the Oak Ridge Reservation because neither of these sites is currently generating transuranic waste and because both sites have projected that future transuranic waste volumes will only be produced by SNF management activities. However, adequate storage capacity exists at both sites.

The volume of high-level waste generated from SNF management activities has been estimated to range from approximately 21 percent to greater than 100 percent above current site baseline generation rates at the Idaho National Engineering Laboratory and the Savannah River Site, respectively. Again, the percentage is high at the Savannah River Site because essentially no high-level waste is currently being generated onsite, but with processing approximately 2 cubic meters per year of high-level waste could be generated. Adequate storage capacity exists at the sites. No high-level waste would be generated at either the Nevada Test Site or the Oak Ridge Reservation.

5.4 Adverse Effects That Cannot Be Avoided

Adverse impacts would result, no matter the alternative, from radiation exposure associated with maintaining facilities that are at or near the end of their design life, until completion of the construction of new facilities. However, these exposures would be kept within applicable regulatory requirements and other applicable guidelines and would be controlled to levels that are as low as reasonably achievable. Implementation of any alternative except the No Action alternative would increase the volume of radioactive waste, in particular, low-level waste generated at the major DOE sites. Under the action-based alternatives, where SNF is transported to other sites, there would be a small increased potential for exposure to the general population when the SNF is in transit.

Under the No Action alternative, there would be several adverse effects that could not be avoided. These include the continuation of the environmentally degraded state of the three major DOE sites because existing facilities would deteriorate further. Naval and research reactor SNF would be stored near population centers, potentially increasing the consequences of an SNF handling or management accident. This alternative also presents a greater personnel requirement for managing SNF interim storage facilities. (Under other alternatives, the apparently higher personnel requirement would be for additional management activities that would not be done under the No Action alternative - they are not just related to storage facilities.) In addition, the shutdown of research reactors that could not store SNF onsite would result in the loss of several hundred reactor operator and research positions.

Under Regionalization 4B and Centralization alternatives, one or more major DOE sites would transport all its SNF to another major DOE site, the facilities at the transport sites would be shut down, and facilities at the receiving site(s) would be built. This would cause the relocation of many jobs associated with SNF management and duplicate some existing facilities. While new facilities are generally required at each DOE site under many alternatives, there are existing facilities that can be used for storage at major sites that would be shut down prior to the end of their useful design life.

The construction and operation of any of the facilities under consideration for storage of SNF would result in some adverse impacts to the environment. Although location-dependent, changes in project design and other measures (for example, sound engineering practices during construction) would eliminate, avoid, or minimize these impacts. In general, most of the adverse impacts would be of short duration and would result from the construction of proposed facilities. For example, noise, atmospheric emissions, fugitive dust, sediment runoff, and solid waste would be expected to increase during construction. Section 5.7 discusses potential mitigation measures that could be used to control or minimize impacts to the environment. See Appendices A through F for site-specific discussion on adverse effects that cannot be avoided.

5.5 Relationship Between Short-Term Use of the Environment

and the Maintenance and Enhancement of Long-Term Productivity

The implementation of any of the SNF management alternatives would cause some adverse impacts to the environment and permanently commit certain resources. This section describes the relationship between short-term influences from the implementation of an SNF management alternative and the associated long-term effects.

The proposed alternatives for SNF management would require the short-term use of multiple resources; for example, energy, materials of construction, and labor to achieve the objective of safely securing SNF to minimize the risk to workers, to the public, and to the environment. For example, if no action were taken, degradation of the fuel and SNF facilities would occur with the potential for releases to the environment. Releases to the environment could contaminate land near the point of storage, thereby reducing the potential future use. By consolidating and containing the SNF at specific locations, the potential for impacting the environment would be reduced at the other locations. After the implementation of a comprehensive SNF management strategy, those areas currently used for SNF management could be released to allow other productive use, such as for research or technology development.

The premature shutdown of research reactors due to a lack of sufficient SNF interim storage space under the No Action alternative could have an impact upon the national and regional communities in which they are located. Most of these reactors are the only regional source of radiopharmaceuticals and often they are important centers of medical and biological research. The sites where these reactors are located, many of them universities, are unique training facilities for students in many fields of research and development: materials science, environmental science, physics, biology, and electronics.

In the medical arena, research reactors have proven to be vital to cancer therapy, diagnostic imaging, studies of the biological effects of radiation, and other important medical applications.

Demand for medically important radioisotopes would not decrease merely because the source was shut off. The continued demand for radioisotopes would be met by placing orders with remaining reactors, which may be farther away from the place where they are needed. Many medically important isotopes (for example, iodine-131) have such short half-lives that the amount transported must include enough to allow for radioactive decay during shipment. Therefore, shutdown of reactors would result in the need to produce and transport larger quantities of radiopharmaceuticals.

Shutdown of research reactors could produce an impact on commercial enterprises that are engaged in the doping of silicon crystals through neutron irradiation. The doped silicon chips are widely used in electronic components such as the computers used in automobile engines.

Graduates trained at these facilities contribute to a wide variety of nuclear industries and to Government agencies involved with (a) monitoring nuclear technology, for example, regulatory agencies, Federal and international inspections, (b)hardware for inspections, and (c) remote monitoring.

Development of new SNF interim management facilities would commit lands to those uses from the time of construction through cessation of operations. At that time, these facilities could be converted to other uses or decontaminated, decommissioned, and the site restored to its original land use. Existing SNF management facilities could also be converted to other uses or the lands restored following their decommissioning.

See Appendices A through F for site-specific discussions on the relationship between short-term use of the environment and the maintenance and enhancement of long-term productivity.

5.6 Irreversible and Irretrievable Commitment of Resources

The irreversible and irretrievable commitment of resources resulting from the construction and operation of SNF management facilities would involve materials that could not be recovered or recycled, or resources that would be consumed or reduced to unrecoverable forms. For example, the construction and operation of an SNF facility at any of the locations under consideration would consume irretrievable amounts of electrical energy, fuel, construction materials, and miscellaneous chemicals. Some construction materials are recyclable and, therefore, should not be considered irreversible and irretrievable commitments of resources. Furthermore, some of the resources would be irretrievable because of the nature of the commitment or the cost of reclamation. For example, human resources used for the construction and operation of the proposed SNF facilities would be irretrievably lost since these resources would be unavailable for use in other work activity areas. On the whole, however, SNF management is not particularly resource intensive. See Appendices A through F for site-specific discussions on irreversible and irretrievable commitments of resources.

5.7 Potential Mitigation Measures

This section summarizes measures that D0E(a) could implement to avoid or reduce impacts to the environment. Possible mitigation measures are generally the same for all alternatives and are summarized by resource category below. Although the environmental effects described in Sections 5.1 through 5.3 may not require mitigation, the range of potential mitigation actions is described below. For all sites, impacts to land use and aesthetic and scenic resources would be small; therefore, mitigation measures for these attributes would not be required.

5.7.1 Pollution Prevention

Implementation of the SNF management alternatives would generate waste with the potential for releases to air and water. To control both the volume and toxicity of waste generated and to reduce impacts on the environment, pollution prevention practices would be implemented.

DOE is responding to Executive Order 12856, Federal Compliance with Right to Know Laws and Pollution Prevention Requirements, and associated DOE orders and guidelines by reducing the use of toxic chemicals; improving emergency planning, response, and accident notification; and encouraging the development and use of clean technologies and the testing of innovative pollution prevention technologies. Pollution prevention programs have been implemented at each site. Program components include waste minimization, source reduction and recycling, and procurement practices that preferentially procure products made from recycled materials. Portions of the pollution prevention program have been implemented at the existing DOE and naval sites for nearly 10 years. For example, the waste minimization program at the Savannah River Site has decreased the amount of all waste types generated by material substitutions.

Implementation of the pollution prevention plans minimizes the amount of waste generated during SNF management activities.

5.7.2 Socioeconomics

The SNF management alternatives would require additional workers for construction, stabilization, monitoring, and maintenance of SNF. This would produce a socioeconomic effect depending on the available site work force, regional labor pool, and community infrastructure. Minor socioeconomic impacts would be expected from implementation of the SNF management alternatives; the mitigation measures described below could be used to further minimize the effect on the community.

Construction and operation-related impacts resulting from increased labor and capital requirements could be reduced by coordinating with local communities and county planning agencies. Effective planning would address changes in community services, housing, infrastructure, utilities, and transportation. DOE would coordinate, in an appropriate manner, with the local and regional planning agencies to address impacts on the work force and community infrastructure. This could be facilitated through the development of citizen advisory boards. The timing of certain activities that have been proposed to proceed concurrently could also be adjusted to minimize socioeconomic impacts.

---

a. Because this is an EIS issued by the DOE, it contains language concerning compliance with applicable environmental requirements, taking appropriate mitigative measures to reduce environmental impacts, and other matters phrased in the context of DOE as the party taking the actions. As a cooperative agency, and because Navy sites are also evaluated in this EIS, the Navy will also assure compliance with applicable environmental requirements and take other appropriate measures for its facilities in a consistent and appropriate fashion.

5.7.3 Cultural Resources

Impacts to cultural resources could occur during construction and earth-moving activities associated with the SNF management alternatives. Areas of proposed ground disturbance would be assessed for the potential to contain important archaeological and paleontological resources. Each DOE operations office is responsible for establishing and maintaining mitigation agreements including actions to be taken in the event of discovery of archaeological resources or human remains during construction. These agreements will be negotiated with their potentially affected tribes and state historic preservation officers. These agreements would be referenced in future site-specific National Environmental Policy Act documentation when appropriate. An example of a possible mitigation measure for archaeological resources would be avoidance or data recovery prior to construction. Other measures would be necessary to mitigate potential impacts to values of Native American or Native Hawaiian populations, including involvement in the selection of a mitigation strategy for impacts to archaeological sites, spiritual geographical features, and land use. This could include the SNF Program's participation in liaison programs to understand Native American or Native Hawaiian concerns.

For paleontological resources, assessments could include literature searches, surface surveys, and consultation with recognized paleontological experts in the region or limited test excavations in geologically similar disturbed areas. If significant paleontological resources were identified, a mitigation plan for recovery, stabilization, and caring of the resources would be implemented before construction.

For example, at the Hanford Site, certain site activities would have the potential to adversely affect prehistoric archaeological sites. In this case, the specific activity plans would be reviewed to determine potential effects before initiation of activities. The activity will then be designed to avoid these sites. If avoidance of these sites would not be possible, mitigation measures would be developed in conjunction with the appropriate state agencies and Native American tribes.

To avoid impacts during operation such as unauthorized artifact collection, workers could be educated through programs and briefing sessions to inform personnel of applicable laws and regulations for site protection. These educational programs would stress the importance of cultural resources and specifics of the laws and regulations for site protection.

5.7.4 Soils

Soils could be affected from implementation of the SNF management alternatives if there were leaks or a release to soils as a result of SNF activities. DOE would appropriately remediate any soils contaminated from SNF management activities.

5.7.5 Air Resources

Certain actions under the SNF management alternatives would impact air quality. For example, the construction of new facilities could negatively impact air quality through the emission of fugitive dusts and from pollutants from diesel- and gasoline-powered equipment. The increase in offsite ambient levels would be small because of the large distance to the nearest public access, and use of the mitigation measures described below would further minimize the potential impact.

DOE would meet applicable regulations regarding the maintenance of air quality from both radiological and nonradiological emission sources. DOE does not foresee impacts to air quality from SNF management that would warrant measures beyond those employed consistent with good construction, engineering, and operations, and management practices.

5.7.6 Water Resources

The implementation of some of the SNF management alternatives would require larger volumes of water for the stabilization of SNF. DOE would control water consumption through the appropriate application of water recycling, water conservation measures and equipment, stormwater catchment basins, and worker training programs. Constant process monitoring and mass-balance and design to current standards, including double-wall confinement of all vessels and piping, would be included in design and operating standards by DOE to limit potential operational releases from a SNF processing or storage facility to essentially zero.

5.7.7 Ecological Resources

Implementation of the SNF management alternatives could impact terrestrial resources, wetlands, aquatic resources, and threatened and endangered species either directly by earth-moving activities that disturb habitat or indirectly through construction activities that result in increased runoff into wetlands or aquatic environments.

To avoid potential impacts to endangered, candidate, or state-identified sensitive species, preconstruction surveys would be completed to determine the presence of these species or their habitat. If protected species or primary habitat for these species are located near or within an area to be disturbed, DOE would evaluate the project design and other program activities to determine if modifications would avoid negative impacts. DOE would consult with the U.S. Fish and Wildlife Service to develop the most appropriate action-specific mitigation measures.

Wetland habitat would be delineated in accordance with applicable U.S. Army Corps of Engineers procedures and wetlands located near proposed activities would be avoided. However, if avoidance were not possible, specific mitigation measures could be developed in consultation with the U.S. Army Corps of Engineers. For example, mitigation could include construction of new wetland acreage equivalent to the acreage of disturbed wetland habitat or enhancement of existing wetland habitat at another location onsite.

5.7.8 Noise

Construction and operation from SNF management would result in the generation of noise consistent with light industrial activity. DOE does not foresee noise impacts from SNF management that would warrant mitigation measures beyond those employed consistent with good construction engineering, operational, and management practices.

Noise impacts to the public and other noise-sensitive receptors could be reduced by providing noise buffer areas between sources and receptors, constructing noise walls and other attenuation structures, and limiting the emissions to daytime periods.

5.7.9 Traffic and Transportation

The number of workers in SNF management activities under some of the alternatives would add to the current work force and to additional commuting traffic. At sites with increasing traffic concerns, roads could be widened with the addition of lanes or implementation of traffic demand management. DOE would also consider using high-occupancy vehicles (such as vans or buses), implementing car-pooling or ride-sharing programs, or staggering schedules to reduce the potential for increased traffic congestion. See Section 5.7.12 for discussion of transportation accident mitigation.

5.7.10 Occupational and Public Health and Safety

Implementation of the SNF management alternatives would increase the potential for radiation exposure either through direct exposure or through air emissions. Although these effects are small, as discussed in Section 5.2, the as low as reasonably achievable principle would be used for controlling radiation exposure of workers and the public. Pollution prevention practices would be implemented to avoid or reduce production of potentially harmful substances. Waste minimization would be practiced to reduce the toxicity and volume of secondary wastes to be managed. Furthermore, sites would update their current worker training, emergency planning, emergency preparedness, and emergency response programs as needed to address new SNF management actions for the protection of both workers and the public.

5.7.11 Site Utilities and Support Services

The SNF management alternatives would put increased demands on utilities at the sites. Under certain alternatives, additional transmission lines or substations may need to be added to the infrastructure and, at the Nevada Test Site, a sewage treatment facility for the SNF management facility would need to be constructed. However, DOE would reduce the need for certain utilities (such as water and electricity) through the implementation of resource conservation, pollution prevention, and energy efficiency measures.

5.7.12 Accidents

The potential exists for an accident associated with either the handling or transportation of SNF with the consequence being a significant release of radioactive or other hazardous materials to the environment. Although the probability is very small, as discussed in Section 5.2, each of the locations considered for SNF management have emergency action plans and equipment to respond to accidents and other emergencies to limit the magnitude of potential impacts from any accident. These plans include training of workers, local emergency response agencies (such as fire departments), and the public; communication systems and protocols; readiness drills; and mutual aid agreements. The plans would be updated to cover any new SNF facilities and activities. DOE would coordinate activities with state and local agencies to establish and implement an appropriate emergency response training program for potential accidents.

5.8 Environmental Justice

In February 1994, Executive Order 12898, titled Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations (FR 1994), was released to Federal agencies. This order directs Federal agencies to incorporate environmental justice as part of their missions. As such, Federal agencies are specifically directed to identify and address, as appropriate, disproportionately high and adverse human health or environmental effects of their programs, policies, and activities on minority populations and low-income populations. Appendix L of this EIS provides an assessment of the areas surrounding the 10 sites under consideration for the management of SNF under all programmatic alternatives considered in this volume. Because DOE is still in the process of developing guidance, the approach used in this analysis might depart somewhat from the guidance eventually issued.

The overall review indicated that the potential impacts calculated for each discipline under each of the alternative sites considered for the management of all or some portion of DOE SNF (or naval SNF only) present no significant risk and do not constitute a reasonably foreseeable adverse impact to the surrounding population. This includes both the impacts of facility operations and the transport of SNF, and the risk of reasonably foreseeable accident scenarios postulated for both, all of which are small. Therefore, the impacts of the programmatic management of DOE SNF under all alternatives evaluated in this EIS do not constitute a disproportionately high and adverse impact on any particular segment of the population, minorities or low-income communities included.

Characterization of the numbers and location of minority and low-income populations is dependent on how these populations are defined and what assumptions are used in conducting the analysis. As discussed in Appendix L, at the time this EIS and the Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel (Draft FRR SNF EIS) were prepared, the Federal Interagency Working Group on environmental justice had not issued final guidance on the definitions of minority and low-income populations, or the approach to be used in analyzing environmental justice, as directed by the Executive Order (FR 1994). Final internal DOE guidance on environmental justice also has not been adopted. As a result, both the definitions and assumptions used by and within agencies for conducting environmental justice analyses can vary and the resulting demographic results can differ on a case-by-case basis. For example, this EIS and the Draft FRR SNF EIS present demographic characterizations derived from the same United States Census Bureau database, but these documents used different definitions and assumptions. Several of the same candidate interim SNF management sites were evaluated in both documents. As discussed in Appendix L, variations in these definitions and assumptions led to differences in the characterization of minority and low-income populations surrounding these potential interim SNF management sites. Nevertheless, although the characterizations differ, the impacts resulting from the proposed action under all alternatives present no significant risk to the population as a whole. Therefore, no disproportionately high and adverse effects would be expected for any particular segment of the population, including minority and I low-income populations, regardless of which set of definitions and assumptions were applied.

6. LIST OF PREPARERS

This EIS was prepared under the supervision of the DOE Idaho Operations Office. The organizations and individuals who contributed to the preparation of this document are listed below accompanied by each person's project role and level of experience and training. Table 6-1 at the end of this section summarizes, for each contributor, the chapters of the EIS for which inputs were prepared.

U.S. Department of Energy Idaho Operations Office

Thomas L. Wichmann, Manager EIS, U.S. DOE
U.S. Naval Nuclear Propulsion Program Graduate
Light Water Breeder Reactor/Expended Core Facility Project Officer
S1W Naval Nuclear Reactor Prototype Project Officer
Years of Experience: 25
EIS Project Manager

Kathleen B. Whitaker, Public Affairs Specialist
BA, 1973, English, University of Utah
Years of Experience: 17
EIS Stakeholder Involvement Manager

Robert C. Stump, Environmental Engineer
BS, 1987, Environmental Engineering, Montana Tech.
Years of Experience: 7
FEIS Volume 1 Manager
John E. Medema, Health Physicist
BS, Biology, Central Michigan University
MS, Biology, Central Michigan University
Years of Experience: 15
Volume 2 Manager
Analytical Lead-Spent Nuclear Fuel and Materials and Waste Management

Mary V. Willcox, Physical Scientist
BS, 1990, Chemistry, University of New Mexico
Years of Experience: 5
EIS Technical Sections Manager

Peter J. Dirkmaat, Senior Engineering Adviser
BS, Electrical Engineering, Calfornia State College, Long Beach
MS, Nuclear Engineering, Stanford University
Years of Experience: 30
Review, Approval, and Decision Process
Vicki L. Johnson, General Engineer
AS, 1984, Mechanical Engineering, Olympic College
EIT, 1987, State of Washington
DoD Nuclear Fluid Systems Mechanical Engineering Qualification
Years of Experience: 16
DEIS Volume 1 Manager
Robert Brown, PE, General Engineer
BS, Electrical Engineering
MA, Business Administration
Years of Experience: 24
Analytical Lead-Utilities and Energy

Robert Creed, Jr., PG, Physical Scientist/Geologist
AS, 1980, Geology, Santa Barbara City College
AS, 1980, Geoscience Technology, Santa Barbara City College
BA, 1983, Earth Sciences, University of California, Santa Cruz
Years of Experience: 7
Analytical Lead-Geology and Water Resources

Denise M. Glore, Attorney
BA, 1978, Geography and Anthropology, University of New Mexico
MS, 1980, Biology, University of New Mexico
JD, 1985, University of New Mexico
Years of Experience: 15
FEIS Analytical Lead - Consultations, Laws, Requirements
Jan Hagers, General Engineer
BS, 1968, Mechanical Engineering, North Carolina State University

MBA, 1974, College of William and Mary
Years of Experience: 27
Analytical Lead - Environmental Justice
John A. Herritt, Health Physicist
BS, 1968, Physics, Pennsylvania State University
MS, 1976, Nuclear Physics, Pennsylvania State University
Years of Experience: 13
Analytical Lead-Occupational Health and Safety

Mark W. Howard, Packaging and Transportation Program Manager
BS, 1989, Mechanical Engineering, University of Idaho
Years of Experience: 6
Analytical Lead-Traffic and Transportation, Transportation Accidents

Mary McKnight, Attorney
BA, 1982, Communications, University of Nebraska
JD, 1989, Creighton University
Years of Experience: 6
DEIS Analytical Lead-Consultations, Laws, and Requirements
Paul Martin, Environmental Protection Specialist
BA, English
BS, Wildlife
Years of Experience: 21
Analytical Lead-Land Use

William A. Owca, General Engineer
BS, 1974, Biology, Creighton University
BS, 1977, Engineering, University of Iowa
MS, 1980, Mechanical Engineering, University of Nebraska
Years of Experience: 15
Volume 1 Decision Process
Mark S. Pellechi, PE, Nuclear Engineer
BS, 1979, Nuclear Engineering, Polytechnic Institute of New York
Years of Experience: 16
Analytical Lead-Accident Analysis

Ralph W. Russell, Environmental Engineer
BS, 1970, Chemical Engineering, Texas A&M University
Years of Experience: 18
Analytical Lead-Air Resources, Air Quality

Roger Twitchell, Physical Scientist
BS, 1977, Botany, Weber State College
Years of Experience: 18
Analytical Lead-Cultural Resources, Ecological Resources

C. Brooks Weingartner, Environmental Engineer
BS, 1988, Geological Engineering, Montana Tech.
MS, 1991, Environmental Engineering, Montana Tech.
Years of Experience: 4

7. CONSULTATIONS, LAWS, AND REQUIREMENTS

7.1 Laws and Requirements

This section identifies and summarizes the major laws, regulations, executive orders, and DOE orders that may apply to the programmatic alternatives for SNF.

Section 7.1.1 discusses the major Federal statutes that impose environmental protection and compliance requirements upon DOE. In addition, there may be other Federal, state, and local measures applicable to the SNF Management Program because Federal law delegates enforcement or implementation authority to state or local agencies. These state- and local-specific requirements are addressed in the site-specific appendices. Section 7.1.2 addresses environmentally-related presidential executive orders that clarify issues of national policy and set guidelines under which Federal agencies, including DOE, must act. DOE implements its responsibilities for protection of public health, safety, and the environment through a series of departmental orders that are mandatory for operating contractors of DOE facilities. Section 7.1.3 discusses those DOE orders related to environmental, health, and safety protection. Hazardous and radioactive materials transportation regulations are summarized in Section 7.1.4.

7.1.1 Federal Environmental Statutes and Regulations

National Environmental Policy Act of 1969, as amended (42 USC -4321 et seq.) The National Environmental Policy Act establishes a national policy promoting awareness of the environmental consequences of the activity of humans on the environment and promoting consideration of the environmental impacts during the planning and decisionmaking stages of a project. The National Environmental Policy Act requires all agencies of the Federal Government to prepare a detailed statement on the environmental effects of proposed major Federal actions that may significantly affect the quality of the human environment.

This EIS has been prepared in response to these National Environmental Policy Act requirements and policies. It discusses reasonable alternatives and their potential environmental consequences of proposed SNF activities at various locations in the country and has been prepared in accordance with the Council on Environmental Quality Regulations for implementing the procedural provisions of the National Environmental Policy Act Implementing Procedures (40 CFR Parts 1500 through 1508) and DOE National Environmental Policy Act Implementing Procedures (10 CFR Part 1021).

Atomic Energy Act of 1954, as amended (42 USC -2011 et seq.). The Atomic Energy Act of 1954 authorizes DOE to establish standards to protect health or minimize dangers to life or property with respect to activities under its jurisdiction. Through a series of DOE orders, DOE has established an extensive system of standards and requirements to ensure safe operation of its facilities.

The Atomic Energy Act and the Reorganization Plan No. 3 of 1970 [5 USC (app. at 1343)] and other related statutes gave the U.S. Environmental Protection Agency responsibility and authority for developing generally applicable environmental standards for protection of the general environment from radioactive material. The U.S. Environmental Protection Agency has promulgated several regulations under this authority, among which are the Environmental Radiation Protection Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Wastes, at 40 CFR Part 191.

Nuclear Waste Policy Act of 1982, as amended, (42 USC -10101-10270). The Act authorizes the Federal agencies to develop a geologic repository for the permanent disposal of SNF and high-level radioactive waste. The Act specifies the process for selecting a repository site and constructing, operating, closing, and decommissioning the repository. The Act also establishes programmatic guidance for these activities.

Clean Air Act, as amended (42 USC -7401 et seq.). The Clean Air Act, as amended, is intended to "protect and enhance the quality of the Nation's air resources so as to promote the public health and welfare and the productive capacity of its population." Section 118 of the Clean Air Act, as amended, requires that each Federal agency, such as DOE, with jurisdiction over any property or facility that might result in the discharge of air pollutants, comply with "all Federal, state, interstate, and local requirements" with regard to the control and abatement of air pollution.

The Act requires the U.S. Environmental Protection Agency to establish National Ambient Air Quality Standards as necessary to protect public health, with an adequate margin of safety, from any known or anticipated adverse effects of a regulated pollutant (42 USC -7409). The Act also requires establishment of national standards of performance for new or modified stationary sources of atmospheric pollutants (42 USC -7411) and requires specific emission increases to be evaluated so as to prevent a significant deterioration in air quality (42 USC -7470). Hazardous air pollutants, including radionuclides, are regulated separately (42 USC -7412). Air emissions are regulated by the U.S. Environmental Protection Agency in 40 CFR Parts 50 through 99. In particular, radionuclide emissions and hazardous air pollutants are regulated under the National Emission Standard for Hazardous Air Pollutants Program (see 40 CFR Part 61 and 40 CFR Part 63).

Safe Drinking Water Act, as amended [42 USC -300 (F) et seq.]. The primary objective of the Safe Drinking Water Act, as amended, is to protect the quality of the public water supplies and all sources of drinking water. The implementing regulations, administered by the U.S. Environmental Protection Agency unless delegated to the states, establish standards applicable to public water systems. They promulgate maximum contaminant levels, including those for radioactivity, in public water systems, which are defined as public water systems that serve at least 15 service connections used by year-round residents or regularly serve at least 25 year-round residents. Safe Drinking Water Act requirements have been promulgated by the U.S. Environmental Protection Agency in 40 CFR Parts 100 through 149. For radionuclides, the regulations in effect now specify that the average annual concentration of beta particle and photon radioactivity from manmade radionuclides in drinking water shall not produce an annual dose equivalent to the total body or any internal organ greater than 0.004 rem (4 millirem)/year. The maximum contaminant level for gross alpha particle activity is 15 picocuries per liter. The U.S. Environmental Protection Agency proposed revisions to limits on regulating radionuclides July 18, 1991. The proposed rule has not been finalized. For purposes of analysis, however, the more conservative standards were used. Other programs established by the Safe Drinking Water Act include the Sole Source Aquifer Program, the Wellhead Protection Program, and the Underground Injection Control Program.

Clean Water Act, as amended (33 USC -1251 et seq.). The Clean Water Act, which amended the Federal Water Pollution Control Act, was enacted to "restore and maintain the chemical, physical and biological integrity of the Nation's water." The Clean Water Act prohibits the "discharge of toxic pollutants in toxic amounts" to navigable waters of the United States. Section 313 of the Clean Water Act, as amended, requires all branches of the Federal Government engaged in any activity that might result in a discharge or runoff of pollutants to surface waters to comply with Federal, state, interstate, and local requirements.

In addition to setting water quality standards for the Nation's waterways, the Clean Water Act supplies guidelines and limitations for effluent discharges from point-source discharges and provides authority for the U.S. Environmental Protection Agency to implement the National Pollutant Discharge

Elimination System permitting program. The National Pollutant Discharge Elimination System program is administered by the Water Management Division of the U.S. Environmental Protection Agency pursuant to regulations in 40 CFR Part 122 et seq. Idaho has not applied for National Pollutant Discharge Elimination System authority from the U.S. Environmental Protection Agency. Thus, all National Pollutant Discharge Elimination System permits required for the Idaho National Engineering Laboratory are obtained by DOE through the U.S. Environmental Protection Agency Region 10 (40 CFR Part 122 et seq.).

Sections 401 and 405 of the Water Quality Act of 1987 added Section 402(p) to the Clean Water Act. Section 402(p) requires that the Environmental Protection Act establish regulations for issuing permits for stormwater discharges associated with industrial activity. Stormwater discharges associated with industrial activity are permitted through the National Pollutant Discharge Elimination System. General Permit requirements are published at 40 CFR Part 122.

Resource Conservation and Recovery Act, as amended (42 USC -6901 et seq.). The treatment, storage, or disposal of hazardous and nonhazardous waste is regulated under the Solid Waste Disposal Act, as amended by the Resource Conservation and Recovery Act and the Hazardous and Solid Waste Amendments of 1984. Pursuant to Section 3006 of the Act, any state that seeks to administer and enforce a hazardous waste program pursuant to the Resource Conservation and Recovery Act may apply for U.S. Environmental Protection Agency authorization of its program. The U.S. Environmental Protection Agency regulations implementing the Resource Conservation and Recovery Act are found in 40 CFR Parts 260 through 280. These regulations define hazardous wastes and specify hazardous waste transportation, handling, treatment, storage, and disposal requirements.

The regulations imposed on a generator or a treatment, storage, and/or disposal facility vary according to the type and quantity of material or waste generated, treated, stored, and/or disposed of. The method of treatment, storage, and/or disposal also impacts the extent and complexity of the requirements (see also Section 7.2.5).

Comprehensive Environmental Response, Compensation, and Liability Act, as amended (42 USC -9601 et seq.). The Comprehensive Environmental Response, Compensation, and Liability Act, as amended, provides a statutory framework for the cleanup of waste sites containing hazardous substances and-as amended by the Superfund Amendments and Reauthorization Act-provides an emergency response program in the event of a release (or threat of a release) of a hazardous substance to the environment. Using the Hazard Ranking System, Federal and private sites are ranked and may be included on the National Priorities List. The Comprehensive Environmental Response, Compensation, and Liability Act, as amended, requires such Federal facilities having such sites to undertake investigations and remediation as necessary. The Act also includes requirements for reporting releases of certain hazardous substances in excess of specified amounts to state and Federal agencies.

Emergency Planning and Community Right-to-Know Act of 1986 (42 USC -11001 et seq.) (also known as "SARA Title III"). Under Subtitle A of this Act, Federal facilities, including those owned by DOE, provide various information (such as inventories of specific chemicals used or stored and releases that occur from these sites) to the State Emergency Response Commission and to the Local Emergency Planning Committee to ensure that emergency plans are sufficient to respond to unplanned releases of hazardous substances. Implementation of the provisions of this Act began voluntarily in 1987, and inventory and annual emissions reporting began in 1988 based on 1987 activities and information. DOE also requires compliance with Title III as matter of Agency policy. The requirements for this Act were promulgated by the U.S. Environmental Protection Agency in 40 CFR Parts 350 through 372.

Toxic Substances Control Act (15 USC -2601 et seq.). The Toxic Substances Control Act provides the U.S. Environmental Protection Agency with the authority to require testing of chemical substances, both new and old, entering the environment, and regulates them where necessary. The law complements and expands existing toxic substance laws such as -112 of the Clean Air Act and -307 of the

Clean Water Act. The Toxic Substances Control Act came about because there were no general Federal regulations for the potential environmental or health effects of the thousands of new chemicals developed each year before they were introduced into the public or commerce. The Toxic Substances Control Act also regulates the treatment, storage, and disposal of certain toxic substances, specifically polychlorinated biphenyls, chlorofluorocarbons, asbestos, dioxins, certain metal-working fluids, and hexavalent chromium. The asbestos regulations under the Toxic Substances Control Act were ultimately overturned. However, regulations pertaining to asbestos removal, storage, and disposal are promulgated through the National Emission Standard for Hazardous Air Pollutants Program (40 CFR Part 61, Subpart M). For chlorofluorocarbons, Title VI of the Clean Air Act Amendments of 1990 requires a reduction of chlorofluorocarbons beginning 1991, and prohibits production beginning 2000.

Pollution Prevention Act of 1990 (42 USC -13101 et seq.). The Pollution Prevention Act of 1990 establishes a national policy for waste management and pollution control that focuses first on source reduction, followed sequentially by environmentally safe recycling, treatment, and lastly, disposal. Disposal or releases to the environment should only occur as a last resort. In response, DOE has committed to participation in the Superfund Amendments and Reauthorization Act Section 313, U.S. Environmental Protection Agency 33/50 Pollution Prevention Program. The goal, for facilities already involved in Section 313 compliance, is to achieve a 33 percent reduction in the release of 17 priority chemicals by 1997, from a 1993 baseline. On August 3, 1993, Executive Order 12856 was issued, expanding the 33/50 program such that DOE must reduce its total releases of all toxic chemicals by 50 percent by December 31, 1999. The DOE is also requiring each DOE site to establish site-specific goals to reduce generation of all waste types.

Federal Facility Compliance Act. The Federal Facility Compliance Act, enacted on October 6, 1992, waives sovereign immunity for fines and penalties for Resource Conservation and Recovery Act violations at Federal facilities. However, a provision postpones fines and penalties after 3 years for mixed waste storage prohibition violations at DOE sites and requires DOE to prepare plans for developing the required treatment capacity for mixed waste stored or generated at each facility. Each plan must be approved by the host state or the U.S. Environmental Protection Agency, after consultation with other affected states, and a consent order must be issued by the regulator requiring compliance with the plan. The Federal Facility Compliance Act further provides that the DOE will not be subject to fines and penalties for land disposal restriction storage prohibition violations for mixed waste as long as it is in compliance with such an approved plan and consent order and meets all other applicable regulations.

National Historic Preservation Act, as amended (16 USC -470 et seq.). The National Historic Preservation Act, as amended, provides that sites with significant national historic value be placed on the National Register of Historic Places. There are no permits or certifications required under the Act. However, if a particular Federal activity may impact a historic property resource, consultation with the Advisory Council on Historic Preservation will generally generate a Memorandum of Agreement, including stipulations that must be followed to minimize adverse impacts. Coordinations with the State Historic Preservation officer are also undertaken to ensure that potentially significant sites are properly identified and appropriate mitigative actions are implemented.

Archaeological Resource Protection Act, as amended (16 USC -470aa et seq.). This Act requires a permit for any excavation or removal of archaeological resources from public or Indian lands. Excavations must be undertaken for the purpose of furthering archaeological knowledge in the public interest, and resources removed are to remain the property of the United States. Consent must be obtained from the Indian tribe owning lands on which a resource is located before issuance of a permit, and the permit must contain terms or conditions requested by the tribe.

Native American Grave Protection and Repatriation Act of 1990 (25 USC -3001). This law directs the Secretary of Interior to guide responsibilities in repatriation of Federal archaeological collections and collections held by museums receiving Federal funding that are culturally affiliated to Native American tribes. Major actions to be taken under this law include (a) establishing a review committee with monitoring and policy-making responsibilities, (b) developing regulations for repatriation, including procedures for identifying lineal descent or cultural affiliation needed for claims, (c) oversight of museum programs designed to meet the inventory requirements and deadlines of this law, and (d) developing procedures to handle unexpected discoveries of graves or grave goods during activities on Federal or tribal land.

American Indian Religious Freedom Act of 1978 (42 USC -1996). This act reaffirms Native American religious freedom under the First Amendment and sets United States policy to protect and preserve the inherent and constitutional right of American Indians to believe, express, and exercise their traditional religions. The act requires that Federal actions avoid interfering with access to sacred locations and traditional resources that are integral to the practice of religions.

Religious Freedom Restoration Act of 1993 (42 USC -2000bb et seq.). This Act prohibits the Government, including Federal departments, from substantially burdening the exercise of religion unless the Government demonstrates a compelling governmental interest and the action furthers a compelling Government interest and is the least restrictive means of furthering that interest.

Endangered Species Act, as amended (16 USC -1531 et seq.). The Endangered Species Act, as amended, is intended to prevent the further decline of endangered and threatened species and to restore these species and their habitats. The Act is jointly administered by the U.S. Departments of Commerce and the Interior. Section 7 of the Act requires consultation with the U.S. Fish and Wildlife Service to determine whether endangered and threatened species or their critical habitats are known to be in the vicinity of the proposed action.

Migratory Bird Treaty Act, as amended (16 USC -703 et seq.). The Migratory Bird Treaty Act, as amended, is intended to protect birds that have common migration patterns between the United States and Canada, Mexico, Japan, and Russia. It regulates the harvest of migratory birds by specifying things such as the mode of harvest, hunting seasons, and bag limits. The Act stipulates that it is unlawful at any time, by any means, or in any manner to "kill . . . any migratory bird." Although no permit for this project is required under the Act, DOE is required to consult with the U.S. Fish and Wildlife Service regarding impacts to migratory birds and to evaluate ways to avoid or minimize these effects in accordance with the U.S. Fish and Wildlife Service Mitigation Policy.

Bald and Golden Eagle Protection Act, as amended (16 USC -668-668d). The Bald and Golden Eagle Protection Act makes it unlawful to take, pursue, molest, or disturb bald (American) and golden eagles, their nests, or their eggs anywhere in the United States (Section 668, 668c). A permit must be obtained from the U.S. Department of the Interior to relocate a nest that interferes with resource development or recovery operations.

Wild and Scenic Rivers Act, as amended (16 USC 1271 et seq. 71:8301 et seq.). The Wild and Scenic Rivers Act, as amended, protects certain selected rivers of the Nation, which possess outstanding scenic, recreational, geological, fish and wildlife, historical, cultural, or other similar values. These rivers are to be preserved in a free-flowing condition to protect water quality and other vital national conservation purposes. The purpose of the Act is to institute a national wild and scenic rivers system, to designate the initial rivers that are a part of that system, and to develop standards for the addition of new rivers in the future.

Occupational Safety and Health Act of 1970, as amended (29 USC -651 et seq.). The Occupational Safety and Health Act establishes standards to enhance safe and healthful working conditions in places of employment throughout the United States. The Act is administered and enforced by the Occupational Safety and Health Administration, a U.S. Department of Labor agency. While the Occupational Safety and Health Administration and the U.S. Environmental Protection Agency both have a mandate to reduce exposures to toxic substances, the Occupational Safety and Health Administration's jurisdiction is limited to safety and health conditions that exist in the workplace environment.

In general, under the Act, it is the duty of each employer to furnish all employees a place of employment free of recognized hazards likely to cause death or serious physical harm. Employees have a duty to comply with the occupational safety and health standards and all rules, regulations, and orders issued under the Act. Occupational Safety and Health Administration regulations (published in Title 29 of the Code of Federal Regulations) establish specific standards telling employers what must be done to achieve a safe and healthful working environment. DOE places emphasis on compliance with these regulations at DOE facilities and prescribes through DOE orders the Occupational Safety and Health Act standards that contracts shall meet, as applicable to their work at Government-owned, contractor-operated facilities (DOE Order 5480.1B, 5483.1A). DOE keeps and makes available the various records of minor illnesses, injuries, and work-related deaths as required by Occupational Safety and Health Administration regulations.

Noise Control Act of 1972, as amended (42 USC -4901 et seq.). Section 4 of the Noise Control Act of 1972, as amended, directs all Federal agencies to carry out "to the fullest extent within their authority" programs within their jurisdictions in a manner that furthers a national policy of promoting an environment free from noise that jeopardizes health and welfare.

7.1.2 Executive Orders

Executive Order 12088 (Federal Compliance with Pollution Control Standards) (October 13, 1978), as amended by Executive Order 12580 (January 23, 1987) Federal Compliance with Pollution Control Standards, directs Federal agencies, including DOE, to comply with applicable administrative and procedural pollution control standards established by, but not limited to, the Clean Air Act, the Noise Control Act, the Clean Water Act, the Safe Drinking Water Act, the Toxic Substances Control Act (15 USC -2061 et seq.), and the Resource Conservation and Recovery Act.

Executive Order 11593 (National Historic Preservation) (May 13, 1971) directs Federal agencies, including DOE, to locate, inventory, and nominate properties under their jurisdiction or control to the National Register of Historic Places if those properties qualify. This process requires DOE to provide the Advisory Council on Historic Preservation the opportunity to comment on the possible impacts of the proposed activity on any potential eligible or listed resources.

Executive Order 11514 (National Environmental Policy Act) directs Federal agencies to continually monitor and control their activities to protect and enhance the quality of the environment and to develop procedures to ensure that fullest practicable provision of timely public information and understanding of the Federal plans and programs with environmental impact to obtain the views of interested parties. The DOE has issued regulations (10 CFR Part 1021) and DOE Order 5440.1E for compliance with this executive order.

Executive Order 11988 (Floodplain Management) directs Federal agencies to establish procedures to ensure that the potential effects of flood hazards and floodplain management are considered for any action undertaken in a floodplain and that floodplain impacts be avoided to the extent practicable.

Executive Order 11990 (Protection of Wetlands) directs governmental agencies to avoid, to the extent practicable, any short- and long-term adverse impacts on wetlands wherever there is a practicable alternative.

Executive Order 12344 (Naval Nuclear Propulsion Program) [enacted as permanent law by Public Law 98-525 (42 USC -7158)] prescribes the authority and responsibility of the Naval Nuclear Propulsion Program, a joint Navy/DOE organization, for matters pertaining to Naval nuclear propulsion. These responsibilities include all environmental and occupational safety and health aspects of the program.

Executive Order 12580 (Superfund Implementation) delegates to the heads of executive departments and agencies the responsibility for undertaking remedial actions for releases, or threatened releases that are not on the National Priority List and removal actions other than emergencies where the release is from any facility under the jurisdiction or control of executive departments and agencies.

Executive Order 12856 (Right to Know Laws and Pollution Prevention Requirements) This order directs all Federal agencies to reduce and report toxic chemicals entering any wastestream; improve emergency planning, response, and accident notification; and encourage clean technologies and testing of innovative prevention technologies. The executive order also provides that Federal agencies are persons for purposes of the Emergency Planning and Community Right-to-Know Act (SARA Title III), which obliges agencies to meet the requirements of the Act.

Executive Order 12898 (Environmental Justice) This order directs Federal agencies to achieve environmental justice by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations in the United States and its territories and possessions. The order creates an Interagency Working Group on Environmental Justice and directs each Federal agency to develop strategies within prescribed time limits to identify and address environmental justice concerns. The order further directs each Federal agency to collect, maintain, and analyze information on the race, national origin, income level, and other readily accessible and appropriate information for areas surrounding facilities or sites expected to have a substantial environmental, human health, or economic effect on the surrounding populations, when such facilities or sites become the subject of a substantial Federal environmental administrative or judicial action and to make such information publicly available.

Executive Order 12114 (Environmental Effects Abroad of Major Federal Actions) This order declares that Federal agencies are required to prepare environmental analyses for "major Federal actions significantly affecting the environment of the global commons outside the jurisdiction of any nation (e.g., the ocean or Antarctica)." According to the Executive Order, major Federal actions significantly affecting the environment of foreign countries may also require environmental analyses under certain circumstances. The procedural requirements imposed by the Executive Order are analogous to those under the National Environmental Policy Act.

7.1.3 Department of Energy Regulations and Orders

Through the authority of the Atomic Energy Act, DOE is responsible for establishing a comprehensive health, safety, and environmental program for its facilities. The regulatory mechanisms through which DOE manages its facilities are the promulgation of regulations and the issuance of DOE orders.

The DOE regulations are generally found in Title 10 of the Code of Federal Regulations. These regulations address such areas as energy conservation, administrative requirements and procedures, nuclear safety, and classified information. For purposes of this EIS, relevant regulations include 10 CFR Part 820, Procedures for DOE Nuclear Activities; 10 CFR Part 830.120, Quality Assurance; 10 CFR Part 834, Radiation Protection of the Public and the Environment (proposed); 10 CFR Part 835, Occupational Radiation Protection; 10 CFR Part 1021, Compliance with the National Environmental Policy Act; and 10 CFR Part 1022, Compliance with Floodplains/ Wetlands Environmental Review Requirements.

DOE orders generally set forth policy and the programs and internal procedures for implementing those policies. The major DOE orders pertaining to the eventual construction and operation of SNF facilities within the DOE Complex are listed in Table 7-1. The following sections provide a brief discussion of selected orders:

DOE Order 5440.1E, National Environmental Policy Act Compliance Program. This order establishes authorities and responsibilities of DOE officials and sets forth internal procedures for implementing the National Environmental Policy Act. This order was issued by DOE on November 10, 1992.

DOE Order 5480.1B, Environment Safety and Health Program for Department of

Energy Operations. This order establishes the Environment, Safety and Health Program for DOE operations.

7.1.4 Hazardous and Radioactive Materials Transportation Regulations

Transportation of hazardous and radioactive materials, substances, and wastes are governed by the U.S. Department of Transportation, U.S. Nuclear Regulatory Commission, and U.S. Environmental Protection Agency regulations. These regulations may be found in 49 CFR Parts 171 through 178, 49 CFR Parts 383 through 397, 10 CFR Part 71, and 40 CFR Part 262, respectively.

U.S. Department of Transportation regulations contain requirements for identifying a material as hazardous or radioactive. These regulations interface with those of the U.S. Nuclear Regulatory Commission or U.S. Environmental Protection Agency regulations for identifying material, but the U.S. Department of Transportation hazardous material regulations govern the hazard communication (such as marking, hazard labelling, vehicle placarding, and emergency response telephone number) and shipping requirements (such as required entries on shipping papers or U.S. Environmental Protection Agency waste manifests).

Table 7-1. DOE orders relevant to the DOE Spent Nuclear Fuel Management Program.

DOE Order	Subject
1300.2A	Department of Energy Technical Standards Program (5-19-92)
1360.2B	Unclassified Computer Security Program (5-18-92)
1540.2	Hazardous Material Packaging for Transport-Administrative Procedures (9-30-86; Chg. 1, 12-19-88)
3790.1B	Federal Employee Occupational Safety and Health Program (1-7-93)
4330.4B	Maintenance Management Program (2-10-94)
4700.1	Project Management System (3-6-87; Chg. 1, 6-2-92)
5000.3B	Occurrence Reporting and Processing of Operations Information (1-19-93; Chg. 1, 7-2-93)
5400.1	General Environmental Protection Program (11-9-88; Chg. 1, 6-29-90)
5400.2A	Environmental Compliance Issue Coordination (1-31-89; Chg.1, 1-7-93)
5400.4	Comprehensive Environmental Response, Compensation, and Liability Act Requirements (10-6-89)
5400.5	Radiation Protection of the Public and the Environment (2-8-90; Chg. 2, 1-7-93)
5440.1E	National Environmental Policy Act Compliance Program (11-10-92)
5480.1B	Environment, Safety and Health Program for DOE Operations (9-23-86; Chg. 5, 5-10-93)
5480.3	Safety Requirements for the Packaging and Transportation of Hazardous Materials, Hazardous Substances, and Hazardous Wastes (7-9-85)
5480.4	Environmental Protection, Safety, and Health Protection Standards (5-15-84; Chg. 4, 1-7-93)
5480.6	Safety of Department of Energy-Owned Nuclear Reactors (09-23-86)
5480.7A	Fire Protection (2-17-93)
5480.8A	Contractor Occupational Medical Program (6-26-92; Chg. 1, 10-19-92)
5480.9A	Construction Project Safety and Health Management (4-13-94)
5480.10	Contractor Industrial Hygiene Program (6-26-85)
5480.11	Radiation Protection for Occupational Workers (12-21-88; Chg. 3, 6-17-92)
5480.15	Department of Energy Laboratory Accreditation Program for Personnel Dosimetry (12-14-87)
5480.17	DOE Site Safety Representatives (10-05-88)
5480.18B	Nuclear Facility Training Accreditation Program (08-31-94)
5480.19	Conduct of Operations Requirements for DOE Facilities (7-9-90; Chg. 1, 5-18-92)
5480.20	Personnel Selection, Qualification, Training, and Staffing Requirements at DOE Reactor and Nonreactor Nuclear Facilities (2-20-91; Chg. 1, 6-19-91)
5480.21	Unreviewed Safety Questions (12-24-91)
5480.22	Technical Safety Requirements (2-25-92; Chg. 1, 9-15-92)
5480.23	Nuclear Safety Analysis Reports (4-30-92; Chg. 1, 3-10-94)
5480.24	Nuclear Criticality Safety (8-12-92)
5480.28	Natural Phenomena Hazards Mitigation (1-15-93)
5480.31	Startup and Restart of Nuclear Facilities (9-15-93)
5481.1B	Safety Analysis and Review System (9-23-86; Chg. 1, 5-19-87)
5482.1B	Environment, Safety, and Health Appraisal Program (9-23-86; Chg. 1, 11-18-91)
5483.1A	Occupational Safety and Health Program for DOE Contractor Employees at Government-Owned, Contractor-Operated Facilities (6-22-83)
5484.1	Environmental Protection, Safety, and Health Protection Information Reporting Requirements (2-21-81; Chg. 7, 10-17-90)
5500.1B	Emergency Management System (4-30-91; Chg. 1, 2-27-92)
5500.2B	Emergency Categories, Classes, and Notification and Reporting Requirements (4-30-91; Chg. 1, 2-27-92)

5500.3A	Planning and Preparedness for Operational Emergencies (4-30-91; Chg. 1, 2-27-92)
5500.4A	Public Affairs Policy and Planning Requirements for Emergencies (6-8-92)
5500.7B	Emergency Operating Records Protection Program (10-23-91)
5500.10	Emergency Readiness Assurance Program (4-30-91; Chg. 1, 2-27-92)
5630.11B	Safeguards and Security Program (8-2-94)
5630.12A	Safeguards and Security Inspection and Assessment Program (6-23-92)
5700.6C	Quality Assurance (8-21-91)
5820.2A	Radioactive Waste Management (9-26-88)
6430.1A	General Design Criteria (4-6-89)

U.S. Nuclear Regulatory Commission regulations applicable to radioactive materials transportation are found in 10 CFR Part 71, which includes detailed packaging design requirements and package certification testing requirements. Complete documentation of design and safety analysis and results of the required testing is submitted to the U.S. Nuclear Regulatory Commission to certify the package for use. This certification testing involves the following components: heat, physical drop onto an unyielding surface, water submersion, puncture by dropping package onto a rigid spike, and gas tightness. Some of the required tests simulate maximum reasonably foreseeable accident conditions.

U.S. Environmental Protection Agency regulations pertaining to hazardous waste transportation are found in 40 CFR Part 262. These regulations deal with the use of the U.S. Environmental Protection Agency waste manifest, which is the shipping paper for transporting Resource Conservation and Recovery Act hazardous waste.

7.1.5 Applicability of the Resource Conservation and Recovery Act to Spent Nuclear Fuel

Historically, DOE chemically reprocessed SNF to recover valuable products and fissionable materials, and as such, the SNF was not a solid waste under the Resource Conservation and Recovery Act.

World events have resulted in significant changes in DOE's direction and operations. In particular, in April 1992 DOE announced the phase-out of reprocessing for the recovery of special nuclear materials. With these changes, DOE's focus on most of its SNF has changed from reprocessing and recovery of materials to storage and ultimate disposition. This in turn has created uncertainty in regard to the regulatory status of some of DOE's SNF relative to the Resource Conservation and Recovery Act.

DOE has initiated discussion with the U.S. Environmental Protection Agency on the potential applicability of the Resource Conservation and Recovery Act to SNF. Further discussions with U.S. Environmental Protection Agency Headquarters and regional offices and state regulators are ongoing to develop a path forward toward meeting any Resource Conservation and Recovery Act requirements that might apply.

7.2 Consultation

The National Environmental Policy Act requires that Federal, state, and local agencies with jurisdiction or special expertise regarding any environmental impact be consulted and involved in the National Environmental Policy Act process. Agencies involved include those with authority to issue applicable permits, licenses, and other regulatory approvals, as well as those responsible for protecting significant resources (for example, endangered species, critical habitats, or historic resources). These agencies will be sent copies of the Final EIS.

Consultations with Federal and state agencies and native America tribes were initiated by DOE. Table 7-2 shows the dates and locations of the meetings held. Volume 2, Appendix B, contains meeting correspondence generated as a result of these meetings.

1. INTRODUCTION

The U.S. Department of Energy (DOE) is currently deciding the direction of its environmental restoration and waste management programs at the Idaho National Engineering Laboratory (INEL) for the next 10 years. Pertinent to this decision is establishing policies for the environmentally sensitive and safe transport, storage, and management of spent nuclear fuels (SNF). To develop these policies, it is necessary to revisit or examine the available options.

As a part of the DOE complex, the Hanford Site not only has a large portion of the nationwide DOE-owned inventory of SNF, but also is a participant in the DOE decision for management and ultimate disposition of SNF. Efforts in this process at Hanford include assessment of several options for stabilizing, transporting, and storing all or portions of DOE-owned SNF at the Hanford Site. Such storage and management of SNF will be in a safe and suitable manner until a final decision is made for ultimate disposition of SNF. The Hanford Site will be affected by the alternative chosen.

Five alternatives involving the Hanford Site are being considered for management of the SNF inventory: 1) the No Action Alternative, 2) the Decentralization Alternative, 3) the 1992/1993 Planning Basis Alternative, 4) the Regionalization Alternative, and 5) the Centralization Alternative. All alternatives will be carefully designed to avoid environmental degradation and to provide protection to human health and safety at the Hanford Site and surrounding region. For Hanford, these alternatives are briefly summarized below:

- No Action Alternative -- The No Action Alternative would preclude any additional transportation of SNF to or from Hanford but could include activities to maintain safe and secure materials and facilities. Hanford SNF would continue to be managed in the current mode and upgrade of existing facilities would occur only as required to ensure safety and security.
- Decentralization Alternative -- The Decentralization Alternative would require that DOE-owned fuel be managed at the location where it is removed from the reactor. Hanford SNF would be safely stored, with some limited onsite relocation of SNF. To accommodate this mission, existing facilities would be upgraded and new storage systems would be constructed.
- 1992/1993 Plannin~ Basis -- SNF would continue to be managed in the current mode, which includes upgrades, fuel stabilization, transport of some SNF to either INEL or Savannah River Site for storage, and construction of an SNF storage facility at Hanford.
- Regionalization Alternative -- The Regionalization Alternative contains options that range from storing all SNF west of the Mississippi River including Naval

SNF, to shipping all Hanford SNF offsite to either INEL or the Nevada Test Site. Existing facilities would be upgraded and new storage systems constructed, as in the Decentralization Alternative for SNF storage at Hanford, or packaging facilities would be constructed as in the Centralization (Minimum) Alternative for offsite shipment.

- Centralization Alternative -- The Centralization Alternative has two major options. Either all Hanford SNF would be shipped offsite to another location where all SNF would be centralized (minimum option), or the Hanford Site would become the centralized location (maximum option) for all DOE SNF to be stored until ultimate disposition.

The Spent Fuel Working Group Report (DOE 1993a) identified deficiencies related to existing SNF management at the various DOE sites. Most of these deficiencies result from degradation of the fuel and the facilities that store fuel because 6f the age of these facilities and the fuel storage conditions. Corrective actions to the identified deficiencies for each site, including the Hanford Site, are listed in DOE (1994a). Hanford Site corrective actions important to this EIS include the following:

1. alternative containerization of fuel stored in the 105-KE Basin to isolate a potential pathway of fuel constituents to the environment

2. preparation of a K Basins ElS and issuance of the record of decision to provide for management of SNF in the K Basins at the Hanford Site (SNF storage siting and configuration, path forward for ultirnate disposition, etc.)

3. removal of all fuel and sludge from the K Basins by December 2002 based on the K Basins ElS record of decision

4. technical evaluation and characterization of N Reactor fuel to support development of the K Basins EIS

5. removal of fuel from the Fast Flux Test Facility; the Plutonium and Uranium Recovery through EXtraction (PUREX) Plant; the 308 Building; the 324, 325, and 327 buildings; T Plant; and the 200-West Area Low-Level Burial Grounds to support prolonged safe, economic, environmentally sound management of those fuels.

On-going corrective actions with prior National Environmental Policy Act (NEPA) coverage, such as containerization of fuel in the 105-KE Basin, are included in the No Action Alternative. Other corrective actions are included within the scope of each of the remaining alternatives. The impacts of continued fuel and facility degradation in the No Action Alternative are not fully quantified, although it is generally recognized that prolonged storage in the existing facilities for an additional 40-year period might represent unacceptable risks, as reflected in DOE (1993a).

The Hanford Site portion of this ElS was prepared according to the National Environmental Policy Act (NEPA) of 1969, as amended; the Council on Environmental Quality (CEO) regulations (40 CFR Part 1500-1308) for the implementation of the NEPA; and DOE regulations (10 CFR 1021) that supplement the CEO regulations. This document discusses five alternatives for the management and storage of SNF, the affected environment, and potential impacts of the alternatives.

2. BACKGROUND

2.1 Hanford Site Overview

2.1.1 Site Description

The U.S. Department of Energy's Hanford Site lies within the semiarid Pasco Basin of the

Columbia Plateau in southeastern Washington State (Figure- 2.1). The Hanford Site occupies an area of about 1450 square kilometers (560 square miles) north of the confluence of the Yakima River with the Columbia River. The Hanford Site is about 50 kilometers (30 miles) north to south and 40 kilometers (24 - miles) east to west. This land, with restricted public access, provides a buffer for the smaller areas previously used for production of nuclear materials, and currently used for research, waste management and disposal, and environmental restoration; only about 6 percent of the land area has been disturbed and is actively used. The Columbia River flows through the northern part of the Hanford Site, and turning south, it forms part of the site's eastern boundary. The Yakima River runs near the southern boundary and joins the Columbia River south of the city of Richland, which bounds the Hanford Site on the southeast. Rattlesnake Mountain, the Yakima Ridge, and the Umptanum Ridge form the southwestern and western boundary. The Saddle Mountains form the northern boundary of the Hanford Site. Two small east-west ridges, Gable Butte and Gable Mountain, rise above the plateau of the central part of the Hanford Site. Underneath the Hanford Site are ancient basaltic flows with basaltic outcroppings on the surface and intermixed beds of sand and gravel from ancient periods of flooding and glacial epochs. Adjoining lands to the west, north, and east are principally range and agricultural land. The cities of Richland, Kennewick, and Pasco (Tri-Cities) constitute the nearest population center and are located southeast of the Hanford Site.

The Hanford Site is listed on the National Priorities List under the Comprehensive Environmental Response, Compensation, and Liability Act. The site encompasses more than 1500 waste management units and four groundwater contamination plumes that have been grouped into 78 operable units. Each unit has complementary characteristics of such parameters as geography, waste characteristics, type of facility, and relationship of contaminant plumes. This grouping into operable units allows for economies of scale to reduce the cost and the number of characterization investigations and remedial actions that will be required for the Hanford Site to complete cleanup efforts. More information on the locations of the units is included in Section 4.1. Current maps showing the locations of the operable units can be obtained from Westinghouse Hanford Company.

Figure 2-1. Hanford Site and vicinity.

2.1.2 History

The Hanford Site was acquired by the federal government in 1943. For more than 20 years, Hanford Site facilities were dedicated primarily to the production of plutonium for national defense and to the management of the resulting wastes. In later years, programs at the Hanford Site were diversified to include research and development for advanced reactors, renewable energy technologies, waste disposal technologies, and cleanup of contamination from past practices.

2.1.3 Mission

The new mission for Hanford emphasizes these components:

- Waste management of stored defense wastes and the handling, storage, and disposal of radioactive, hazardous, mixed, or sanitary wastes from current operations.

- Environmental restoration of approximately 1,500 inactive radioactive, hazardous, and mixed-waste sites and about 100 surplus facilities.

- Research and development in energy, health, safety, environmental sciences, molecular sciences, environmental restoration, and waste management.

- Technology development of new environmental restoration and waste management technologies, including site characterization and assessment methods; waste minimization, treatment, and remediation technology; and education outreach programs.

The DOE has set a goal of cleaning up Hanford's waste sites and bringing its facilities into compliance with local, state, and federal environmental laws by 2018.

2.1.4 Management

The Hanford Site is owned by the federal government and managed by the U.S. Department of Energy, Richland Operation's Office (DOE-RL). Westinghouse Hanford Company is the site operations and engineering contractor. Pacific Northwest Laboratory, which is operated for the DOE by Battelle Memorial Institute, manages the research and technology laboratories. In 1994, Bechtel Hanford Company and a team of contractors became DOE's environmental restoration contractor at the Hanford Site.

2.2 Regulatory Framework

The policy of DOE-RL is to carry out its operations in compliance with all applicable federal laws and regulations, state laws and regulations, presidential executive orders, and DOE orders. Environmental regulatory authority over the Hanford Site is vested both in federal agencies, primarily the U.S. Environmental Protection Agency (EPA), and in Washington State agencies, primarily the Department of Ecology. Significant environmental laws and regulations relevant to the management of SNF at Hanford are discussed in this section. First, major relevant federal and Washington State statutes are listed. Next, the specific topical concerns associated with spent nuclear fuel are discussed with appropriate citations to federal and state statutes and regulations. U.S. Department of Energy Orders will not be cited in this discussion because DOE Orders are not regulations. However, DOE Orders do delineate specific DOE procedures and provide detailed internal guidance for implementation of federal environmental, safety, and health regulations. DOE Orders establish specific standards, rules, and requirements that supplement the federal regulations for the design and construction of new facilities, and the operation of existing facilities to ensure safe and environmentally sound operations. Finally, it should be noted that environmental restoration and waste management activities at Hanford are governed by the Hanford Federal Facility Agreement and Consent Order (Tri-Party Agreement), which includes detailed provisions for state and federal jurisdiction, as well as specific goals for site management and cleanup. The Fourth Amendment to the Tri-Party Agreement (January 1994) contains specific milestones (M-34) related to the management of SNF at the Hanford Site.

2.2.1 Significant Federal and State Laws

Significant federal and state environmental and nuclear materials management laws applicable to the Hanford Site include the following (grouped by federal and state and listed alphabetically):

Federal Laws

- American Antiquities Act (16 U.S.C. 431-433)
- American Indian Religious Freedom Act (42 U.S.C. 1996)
- Archaeological and Historic Preservation Act (16 U.S.C. 469-469c)
- Archaeological Resources Protection Act (16 U.S.C. 470aa-470ll)
- Atomic Energy Act (AEA) (42 U.S.C. 2011 et seq.)
- Bald and Golden Eagle Protection Act (16 U.S.C 668-668d)
- Clean Air Act (CAA) as amended by the Clean Air Act Amendments of 1990 (42 U.S.C. 7401

et seq.)

- Clean Water Act (CWA) (33 U.S.C. 1251 et seq.)
- Comprehensive Conservation Study of the Hanford Reach of the Columbia River (PL 100-605)
- Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) as amended by the Superfund Amendments and Reauthorization Act (SARA) (42 U.S.C. 9601 et seq.)
- Emergency Planning and Community Right-to-Know Act of 1986 (42 U.S.C. 11001 et seq.)
- Endangered Species Act (16 U.S.C. 1531-1534)
- Energy Reorganization Act of 1974 (ERA) (42 USC 5801 et seq.)
- Federal Facilities Compliance Act (PL 102-386)
- Fish and Wildlife Coordination Act (16 U.S.C. 661-666c)
- Hazardous Materials Transportation Act (HMTA) (49 USC 1801 et seq.)
- Migratory Bird Treaty Act (16 U.S.C 703-711)

2.2.2 Environmental Standards for Spent Nuclear Fuel Storage Facilities

Design and performance standards for the construction and operation of SNF storage facilities arise from the Atomic Energy Act, Nuclear Waste Policy Act, Clean Water Act, and Clean Air Act, parallel state implementation statutes, and other major environmental/nuclear activities statutes. A general listing of regulations promulgated under these authorities will not be included in this discussion of the regulatory framework; relevant regulations will be cited as appropriate in the topical discussions that follow.

2.2.2.1 General Environmental Requirements for Construction and Operation.

Design and construction of new facilities, modification of existing facilities, and operation of all facilities would be conducted in accordance with applicable state and federal environmental regulations. Special consideration with respect to operations of SNF management facilities at Hanford are discussed in the following sections.

Columbia River water would be used to serve a wet SNF storage facility. The DOE has asserted that it has federally reserved water withdrawal rights with respect to its Hanford operations. Nevertheless, DOE submitted an application to the Washington State Department of Ecology on July 7, 1987, as a matter of comity for water withdrawal rights from the Columbia River for site characterization activities related to the now defunct Basalt Waste Isolation Project. It may be appropriate to maintain this protocol with Washington State in regard to future withdrawals from the river.

Operation of SNF facilities may involve the generation of waste materials or unintentional releases of waste materials to the environment. The Pollution Prevention Act requires prevention or reduction of waste at the source whenever feasible. Reporting and cleanup of spills from an SNF facility are governed by CERCLA regulations (40 CFR 300, "National Oil and Hazardous Substances Pollution Contingency Plan"), which apply to the release of hazardous substances into the environment, including radioactive substances.

Shipment of SNF is governed by Department of Transportation hazardous materials regulations in 49 CFR 171-179 (under the authority of the Hazardous Materials Transportation Act), which apply to the handling, packaging, labeling, and shipment of hazardous materials offsite, including radioactive materials and wastes. Safety standards for packaging and transporting radioactive materials are governed by U.S. Nuclear Regulatory Commission (NRC) standards established in 10 CFR Part 71, "Packaging of Radioactive Material for Transport and Transportation of Radioactive Material Under Certain Conditions."

2.2.2.2 Resource Conservation and Recovery Act. The status of SNF with respect to RCRA is discussed

in Volume 1. Most of the authority to administer the RCRA program, including treatment, storage and disposal standards, and permit requirements, has been delegated by EPA to the State of Washington, except for corrective action (cleanup). Washington State RCRA (WSHWMA) Dangerous Waste Regulations are found in WAC 173-303 (Washington Administrative Code). Generally, RCRA does not apply to source material, special nuclear material, by-product material, SNF, or radioactive-only wastes. Should SNF be processed into or commingled with a hazardous waste as defined by Subtitle C of RCRA, then the generation, treatment, storage, and disposal of the hazardous waste portion of such mixed waste would be subject to EPA regulations in 40 CFR 260-268 and 270-272.

2.2.2.3 Effluents. Regulations in 40 CFR 122 (and also in 40 CFR 125 and 129) apply to the dis-

charge of pollutants from any point source into waters of the United States. A National Pollutant Discharge Elimination System (NPDES) permit is required for such discharges, which would include any effluent discharge from an SNF storage facility into the Columbia River. The EPA has not yet delegated to the State of Washington the authority to issue NPDES permits at the Hanford Site. At 40 CFR 121 the regulations provide for state certification that any activity requiring a federal CWA water permit, i.e., an NPDES permit or a discharge of dredged or fill material permit, will not violate state water quality standards.

The EPA drinking water standards in 40 CFR 141, "National Primary Drinking Water Regulations," apply to Columbia River water at community water supply intakes downstream of the Hanford Site. Washington Administrative Code 173-200 sets water quality standards for groundwater, and WAC 173-201 establishes surface water quality standards for the State of Washington.

Department of Ecology regulations in WAC 173-216 establish a state permit program, com-

monly referred to as the 216 program, for the discharge of waste materials from industrial, commercial, and municipal operations into ground and surface waters of the state. Discharges covered by NPDES or WAC 173-218 (Underground Injection Control Program) permits are excluded from the 216 program.
The DOE has agreed to meet the requirements of the 216 program at the Hanford Site for discharges of liquids to the ground.

2.2.2.4 Air Quality. Hazardous emission standards in 40 CFR 61, "National Emission Standards for

Hazardous Air Pollutants," provide for the control of the emission of hazardous pollutants to the atmosphere, and standards in 40 CFR 61, Subpart H, "National Emission Standards for Emissions of Radionuclides Other Than Radon from Department of Energy Facilities," apply specifically to the emission of radionuclides from DOE facilities. Approval to construct a new facility or to modify an existing one may be required by these regulations. The EPA has not yet delegated this approval authority to the State of Washington for the Hanford Site.

The Clean Air Act Amendments of 1990 require the addition of 189 substances to the list of hazardous air pollutants to be regulated on a schedule that extends to 1999. The hazardous air pollutant list includes radionuclides. The amendments require the identification of source categories and the definition of required control technology (maximum available control technology) for each of these pollutants. Hanford may fall within the definition of a major source because total emissions from Hanford may exceed the triggering limit of 25 tons per year for any combination of listed hazardous air pollutants (emission standards using curies as the unit of measure for radionuclides will be promulgated in the future). This means that emission sources at Hanford may become subject to permitting and reporting requirements and to installation requirements (including retrofit) for control technology. A new SNF storage facility may be subject to the maximum available control technology requirements for new sources.

Washington State Department of Health regulations in WAC 246-247, "Monitoring and Enforcement of Air Quality and Emission Standards for Radionuclides," contain standards and permit requirements for the emission of radionuclides to the atmosphere from DOE facilities based on Department of Ecology standards in WAC 173-480, "Ambient Air Quality Standards and Emission Limits for Radionuclides."

The local air authority, Benton County Clean Air Authority, enforces General Regulation 80-7, which pertains to detrimental effects, fugitive dust, incineration products, odor, opacity, asbestos, and sulfur oxide emissions. Benton County Clean Air Authority has been delegated authority to enforce EPA asbestos regulations.

2.2.3 Protection of Public Health

Numerical standards for protection of the public from releases to the environment have been set by the EPA and appear in the Code of Federal Regulations. The most significant of the regulations are discussed in the following paragraphs.

Clean Air Act standards found in 40 CFR 61.92 apply to releases of radionuclides to the atmosphere from DOE facilities and state as follows:

> Emissions of radionuclides [other than radon-220 and radon-222] to the ambient air from Department of Energy facilities shall not exceed those amounts that would cause any member of the public to receive in any year an effective dose equivalent of 10 millirem/year.

Safe Drinking Water standards found in 40 CFR 141.16 apply indirectly to releases of radionuclides from DOE facilities to the extent that the releases impact community water systems:

> The average annual concentration of beta particle and photon radioactivity from man-made radionuclides in drinking water shall not produce an annual dose equivalent to the body or any internal organ greater than 4 millirem/year.

Also, maximum contaminant levels in community water systems of 5 pico- curies per liter of combined radium- 226 and radium-228, and maximum contaminant levels of 15 picocuries per liter of gross alpha particle activity, including radium-226 but excluding radon and uranium, are specified in 40 CFR 141. The tritium concentration that corresponds to a dose of 4 millirem per year is 20,000 picocuries per liter.

2.2.4 Species Protection

Regulations of the Endangered Species Act, the Bald and Golden Eagle Protection Act, and the Migratory Bird Treaty Act in 50 CFR 10-24, 222, 225-227, 402, and 450-453 apply to the Hanford Site. The Endangered Species Act requires a biological assessment to identify any threatened or endangered species likely to be affected by the proposed action.

2.2.5 Floodplains and Wetlands

Executive Order 11988, "Floodplain Management," Executive Order 11990, "Protection of Wetlands," and 10 CFR 1022, require an assessment of the effects of DOE actions on floodplains and wetlands. These requirements are directed at the protection of water quality and habitat.

2.2.6 Cultural and Historic Preservation

Requirements of the National Historic Preservation Act in 36 CFR 800, the American Antiquities Act in 25 CFR 261 and 43 CFR 3, and the Archaeological Resources Protection Act and the American Indian Religious Freedom Act in 43 CFR 7 apply to the protection of historic and cultural properties, including both existing properties and those discovered during excavation and construction. The American Indian Religious Freedom Act and the Native American Graves Protection and Repatriation Act also provide for certain rights of access by Native Americans to traditional areas of worship and religious significance.

2.3 Spent Nuclear Fuel Management Program

This section presents a summary of current plans, as of December 1994, for the management of existing SNF on the Hanford site. The following SNF and associated facilities are at Hanford (Bergsman 1994):

- N Reactor SNF- Zircaloy-clad metallic uranium fuel stored in water in the 105-KW and 105-KE basins and exposed to air in the Plutonium and Uranium Recovery through Extraction (PUREX) Plant dissolver cells A, B, and C.
- Single-pass reactor SNF - aluminum-clad metallic uranium fuel stored in water in the 105-KE and 105-KW basins and stored in water in the PUREX basin.
- Shippingport Core II SNF - Zircaloy-clad uranium dioxide fuel stored in water in T-Plant Canyon Pool Cell 4.
- Fast Flux Test Facility (FFTF) SNF - stainless steel-clad fuel stored in liquid sodium at the FFTF, consisting mostly of plutonium and uranium oxide fuel, but also uranium and/or plutonium metals, and carbide and nitride fuel.
- Miscellaneous commercial and experimental SNF - consisting mainly of Zircaloy-clad

uranium dioxide fuel stored in air in the 324, 325, and 327 buildings; TRIGA (training, research, and isotope reactors built by General Atomics) fuel stored in water in the 308 Building; miscellaneous fuel stored in air-filled shielded containers at the 200-West Area burial grounds; and aluminum-clad, uranium-aluminum alloy fuel stored in air in the Plutonium Finishing Plant.

Plans for management of Hanford SNF are included in the Hanford Spent Nuclear Fuel Project, Recommended Path Forward (Fulton 1994) and the Spent Nuclear Fuel Project Technical Baseline Document Fiscal Year 1995 (WHC 1995). It should be noted, however, that the SNF management program has continued to evolve since these documents were issued or drafted. Similarly, Hanford site-specific environmental documentation that will be required to support the Hanford SNF management program continues to evolve. Spent nuclear fuel EISs that are being prepared or that will be prepared include this programmatic EIS and a Hanford site- specific K Basins EIS. The programmatic EIS will lead to a record of decision that is scheduled to be published in June 1995. That record of decision will specify what SNF will be managed at which DOE sites, Naval Reactor Propulsion Program sites, or other sites. The K Basins EIS is expected to result in a record of decision that specifies where and how to relocate, stabilize, and safely store N Reactor and single-pass reactor SNF from the K Basins to address the urgent need to remedy safety and environmental vulnerabilities. The K Basins EIS record of decision will address management of this SNF over a 40-year period or until ultimate disposition.

During negotiations on the Fourth Amendment to the Tri-Party Agreement (TPA), the DOE, the State of Washington Department of Ecology, and the EPA agreed to an enforceable milestone that indirectly required issuing that record of decision by June 1996. The record of decision on the K Basins EIS would be dependent on the programmatic EIS record of decision. Other environmental documentation (EAs or EISs) will be prepared for any proposed actions related to SNF that are not specifically covered in the programmatic EIS or in the K Basins EIS.

Assuming the EISs are prepared as planned, the Hanford SNF management plan would identify and implement management approaches that will provide safe, cost-effective storage of SNF at existing facilities. Activities to identify, and then implement, the SNF management approach follow:

- Issuing the records of decision that are expected to result from the programmatic EIS and the K Basin EIS.
- Achieving accord with the TPA or renegotiating activities and milestones, as necessary.
- Providing facilities for SNF management as necessary to implement the EIS records of decision. SNF remaining onsite, as a result of the programmatic EIS record of decision could be placed in wet or dry storage in the 200-East Area until a decision on ultimate disposition has been made.
- Identifying and developing pathways for ultimate disposition of the SNF.
- Providing facilities and systems for preparing SNF for ultimate disposition.

  N Reactor and single-pass reactor SNF would be stabilized, as necessary, to implement the K Basins EIS record of decision. It is possible this stabilized form would be a metal or an oxide. Suitability of other SNF for ultimate disposition in its current form is yet to be demonstrated, but it is possible that FFTF and Shippingport SNF may not require further stabilization.

While the SNF management approach is being defined, the following key, near-term actions at the existing facilities are being implemented or are planned:

- Upgrading water treatment systems and retrieving sludges from the basins' floors.
- Performing necessary safety and security upgrades (e.g., water systems) to extend facility life until SNF removal can be accomplished.

- Transferring SNF from liquid-sodium storage at the FFTF to dry storage in interim storage casks. This activity would be integrated with FFTF deactivation.
- Transferring small quantities of SNF between existing facilities where deemed necessary to comply with other Hanford requirements.

Discussion of the SNF inventory and plans for managing that inventory are provided in the following sections. Planned SNF management activities are summarized in Table 2-1. Additional details on existing storage facilities are in Chapter 3.

2.3.1 N Reactor Spent Nuclear Fuel

N Reactor SNF is stored in three facilities (Bergsman 1994):

- 952 metric tons of uranium in 3815 closed canisters in the 105-KW Basin. The water in this basin has only low levels of radionuclide contamination.
- 1144 metric tons of uranium in 3666 open canisters in the 105-KE Basin. The water in this basin is contaminated with radionuclides, and there is a thick layer of sludge on the basin floor.
- 0.3 metric tons of uranium in the form of intact Mark IV fuel elements and fuel element pieces stored in air on the floor of PUREX dissolver cells A, B, and C.

Until recently, plans included 1) containerizing the fuel and sludge stored in the 105-KE Basin into Mark II (sealed) canisters; and 2) transferring the spent fuel in PUREX to the 105-KE Basin and containerizing it in the basin. Alternative approaches to each of these plans, including alternative containerization of fuel and sludge at the 105-KE Basin, expedited fuel removal from the K Basins and dry storage of fuel at PUREX, have been evaluated, and a path forward for these materials selected. PUREX SNF would be transferred to the K Basins and subsequently managed with the existing K Basins SNF inventory pending issuance of an environmental assessment. Expedited fuel removal from the K Basins has been selected in lieu of containerization because of benefits to worker safety and/or the environment. The 105-K Basins SNF would be relocated to a storage facility in the 200 Area, pending completion of the K Basins EIS. The impacts associated with implementation of this path forward are within the envelope of impacts analyzed in this EIS.

Table 2-1. Summary of planned spent nuclear fuel management activities.

In addition, work is ongoing to characterize the N Reactor and single-pass reactor fuel to provide data relevant to assuring continued safe storage and developing plans for future actions. Recent commitments to the Defense Nuclear Facilities Safety Board have set a date of December 1999 for completing removal of the SNF from the 105-K Basins.

Other N Reactor SNF, which may be recovered as a result of N Basin deactivation, would also be transferred to the 105-K Basins. A small quantity of this material (less than 0.5 MTHM) in the form of fuel fragments and chips is suspected to be in the sludge at the bottom of N Basin.

2.3.2 Single-Pass Reactor Spent Nuclear Fuel

The single-pass reactor SNF consists of residual fuel elements from the 105-KW and 105-KE reactors, plus residual elements from the clean-out of the 105-C and 105-D storage basins. Currently, 138 elements [0.4 metric tons of uranium (MTU)] are stored in the 105-KE Basin and 47 elements (0.1) are stored in the 105-KW Basin. In addition, four buckets filled with 779 single-pass reactor fuel elements are stored in the PUREX storage basin.

It was planned that the single-pass reactor fuel stored in PUREX would be transferred to the 105-KE

Basin, containerized, and possibly transferred to the 105-KW Basin before the previously planned Hanford SNF EIS record of decision would be issued. Activities to implement this action were initiated (Bergsman 1995). In parallel, alternative dry storage of this fuel was considered, consistent with the dry storage evaluation for N Reactor fuel at PUREX. To enable expeditious deactivation of the PUREX plant in support of the Hanford Site cleanup mission and because of the minimal impacts associated with relocation of this SNF to the 105-K Basins, shipment to the 105-K Basins was selected as the preferred approach for managing this SNF until issuance and implementation of the K Basins EIS record of decision. The SNF may be shipped directly to the 105-KW Basin instead of the 105-KE Basin and would be stored in a manner consistent with the requirements of the selected storage basin. The impacts associated with implementation of this path forward are within the envelope of impacts analyzed in this EIS.

2.3.3 Fast Flux Test Facility Spent Nuclear Fuel

The SNF from FFTF is stored in the following four FFTF locations, all of which use liquid sodium for cooling:

- the reactor core with a capacity of approximately(a) 82 fuel assemblies
- in-vessel storage with a capacity of 54 fuel assemblies
- interim decay storage with a capacity of 112 fuel assemblies and a limitation of 10 kilowatts per assembly
- the Fuel Storage Facility with a capacity of 380 fuel assemblies(b) and a limitation of 1.4 kilowatts per assembly.

The 1993 inventory of irradiated SNF at FFTF consists of fuel from 329 assemblies; an additional 55 non-irradiated driver fuel assemblies exist. Some irradiated fuel assemblies have been disassembled, with the fuel now placed in 40 Ident 69 containers or in the Interim Examination and Maintenance Cell. Some irradiated fuel has been shipped offsite, but is expected to be returned to Hanford.

The DOE plans to transfer FFTF spent nuclear fuel from the liquid sodium-cooled storage facilities into dry storage casks. These interim storage casks would hold six or seven assemblies per cask. Delivery of an initial ten casks has been scheduled for August 1995 and an environmental assessment for this activity has been submitted (Bergsman 1995). The majority of the casks would be sited in the 400 Area; however, a few may be sited at the Plutonium Finishing Plant because of requirements for additional physical security. A small fraction of the FFTF SNF is sodium bonded, and may be shipped directly offsite without emplacement in dry storage casks if the decision in this EIS is to relocate these materials to another DOE site.

---

a. Capacity for each core-loading varies.
b. The Fuel Storage Facility actually has a capacity of 466 fuel assemblies, but is limited to only 380 because of criticality requirements.

2.3.4 Shippingport Core II Spent Nuclear Fuel

The Shippingport Core II spent nuclear fuel is stored in water in the 221-T Building (T-Plant) Canyon Pool Cell 4. The 72 standard blanket assemblies will remain in basin storage in T-Plant until site-specific NEPA review is completed to enable implementation of dry storage or transfer offsite. Site-specific NEPA review will not be initiated until issuance of the record of decision for this EIS. (One un-irradiated blanket assembly is also stored in air in the T-Plant.)

2.3.5 Miscellaneous Spent Nuclear Fuel

A variety of miscellaneous spent nuclear fuel is stored in the 300 Area, Plutonium Finishing Plant, and low-level burial grounds (Bergsman 1994). Specific actions that have been identified (Bergsman 1995) follow:

- The spent nuclear fuel stored in air in the 324, 325, and 327 buildings (mostly commercial, light-water reactor fuel, i.e., Zircaloy-clad uranium dioxide) is planned for relocation onsite; an environmental assessment for this activity will be prepared. The planned storage facility is a dry storage cask.
- TRIGA fuel stored in water in the 308 Building is planned for relocation onsite to the 400 Area so that the 308 Building can be deactivated; an environmental assessment has been submitted for this activity. Alternative disposition of the TRIGA fuel may be implemented; transfer of this fuel to the Idaho National Engineering Laboratory (INEL) is assumed in the INEL 1992/1993 Planning Basis Alternative.
- Miscellaneous fuel residues in the 200 Area are currently being managed as remote-handled transuranic waste. The TRIGA SNF at the burial grounds will be relocated onsite during burial grounds retrieval operations.

3. SPENT NUCLEAR FUEL MANAGEMENT ALTERNATIVES

3.1 Description of Alternatives

Five major alternatives are being evaluated for safely storing SNF until ultimate disposition is determined. These five alternatives are 1) No Action, 2) Decentralization (with a subset of local stabilization and storage options), 3) 1992/1993 Planning Basis, 4) Regionalization (with options A, B1, B2, and C), and 5) Centralization (minimum and maximum options). The five alternatives and their impacts are being evaluated concurrently by the sites or agencies potentially affected by these alternatives, including Hanford, Savannah River Site (SRS), Idaho National Engineering Laboratory (INEL), Oak Ridge National Laboratory (ORNL), the Nevada Test Site (NTS), and the Naval Nuclear Propulsion Program.

This chapter describes the spent fuel inventories, activities, and facilities anticipated at Hanford under the various storage alternatives. The inventory of SNF expected to be stored at Hanford under each alternative is summarized in Table 3-1. There are eight types of fuel listed in Table 3-1 to represent the wide variety of SNF currently held at various sites across the United States. In addition, the United States has obligations for some SNF held in foreign countries. The specific kinds of SNF held at Hanford that contribute toward the total SNF inventory are shown in parentheses in column one of Table 3-1. In terms of metric tons of heavy metal, Hanford has about 80 percent of DOE's current SNF inventory, primarily because of the large inventory of spent fuel remaining from the shut-down N Reactor. The Centralization Alternative minimum option is not shown in Table 3-1 because the inventory would eventually be zero at Hanford under this option, as it is in the Regionalization Alternative Option C. An overview of the SNF inventory as of the year 2035, planned activities, and existing and new facilities that may result under each of the five storage alternatives is provided below.

The No Action Alternative described in Subsection 3.1.1 forms the basis for comparison with the remaining four storage alternatives and includes descriptions of the expected activities, and existing storage facilities. Decentralization (Subsection 3.1.2), the 1992/93 Planning Basis (Subsection 3.1.3), Regionalization (Subsection 3.1.4), and Centralization (Subsection 3.1.5) are discussed in the remaining sections.

Table 3-1. Spent nuclear fuel inventory at Hanford under the various storage options as of 2035 in MTHM. ,b

Fuel type (name of Hanford SNF that is part of this type)	No Action and Decentralization	1992/1993 Planning Basis	Regionalization A[c]	Regionalization B1[d]	Regionalization B2[e]	Regionalization C[f] and Centralization minimum option	Centralization maximum option
Naval SNF	0.00	0.00	0.00	10.23	65.23	0.00	65.23
Savannah River and aluminum-clad	0.00	0.00	0.00	8.76	8.76	0.00	213.09
Hanford (N Reactor and single-pass reactors)	2103.17[g]	2103.17	2103.17	2103.17	2103.17	0.00	2103.17
Graphite	0.00	0.00	0.00	27.60	27.60	0.00	27.61
Commercial miscellaneous fuels	2.30	2.30	0.00	125.18	125.18	0.00	156.51
Experimental, stainless steel clad (FFTF)	11.27	11.23	0.00	90.12	90.12	0.00	96.51
Experimental, Zircaloy clad (Shippingport)	15.70	15.70	0.00	64.84	64.84	0.00	77.99
Experimental, other such as ceramic, liquid/salt, etc.	0.00	0.00	0.00	0.29	0.29	0.00	1.70
TOTALS:	2132.44	2132.40	2103.17	2430.19	2485.19	0.00	2741.80

a. MTHM - Metric tons of heavy metal (thorium, uranium, and plutonium as applicable).

b. Source: Wichmann (1995). Quantities of SNF within a given category may be the result of adding together several quantities, some large and some small, stored at different locations. Individual values are known to within about 1%. Additional digits are shown in the table as a check on calculations, but inventory totals are known to only two significant figures.

c. All Hanford production SNF remains at Hanford. All other SNF goes to INEL (including Hanford commercial, experimental stainless-steel-clad, and TRIGA).

d. All SNF currently located or to be generated in the U.S. west of the Mississippi River is sent to and stored at the Hanford Site, with the exception of Naval SNF.

e. All SNF currently located or to be generated in the U.S. west of the Mississippi River and all Naval SNF are sent to and stored at the Hanford Site.

f. All Hanford Site SNF and all other SNF currently located or to be generated in the U.S. west of the Mississippi River is sent to and stored at either INEL or NTS. For Hanford, this alternative is identical to the Centralization Alternative minimum option (SNF is shipped offsite).

g. This represents the post-irradiation (end-of-life) quantity. The pre-irradiation quantity, (2116.67 MTHM) is sometimes quoted.

3.1.1 No Action Alternative

Under the No Action Alternative, only those actions that are deemed necessary for continued safe and secure management of the SNF would be conducted. Thus, the existing SNF would be maintained close to its current storage locations, and there would be minimal facility upgrades. Activities required to store SNF safely would continue at each specific site (DOE 1993b).

A description of the anticipated activities that would be necessary under the No Action Alternative is provided in Subsection 3.1.1.1, followed by descriptions of existing facilities (Subsection 3.1.1.2), and any new facilities (Subsection 3.1.1.3). A comprehensive inventory and description of the fuel at Hanford as of January 1993 is given by Bergsman (1994). That report provides detailed information on many of the spent fuel designs and radionuclide inventories.

3.1.1.1 Anticipated Activities. In order to carry out the No Action

Alternative, the following activities would occur at the Hanford Site:

- Characterization of the defense production reactor fuel would proceed to establish the basis for safe storage.

- Fuel and sludge would be containerized at the 105-KE Basin or other onsite location.

- The first 10 dry storage casks would be procured for Fast Flux Test Facility (FFTF) fuel.

Consolidation of SNF from defense production reactors into the 105-KW Basin could occur. Other fuel may be transferred to dry cask storage where required for safety.

3.1.1.2 Description of Existing Facilities. SNF is presently located

in 11 facilities on the Hanford Site: 105-KE and 105-KW Basins at the north end of Hanford in the 100-K Area; T Plant, low-level waste burial grounds, and Plutonium Finishing Plant in the 200 West Area; Plutonium and Uranium Recovery through EXtraction (PUREX) plant in the 200 East Area; FFTF in the 400 Area; and 308, 324, 325, and 327 buildings in the 300 Area in the southeast corner of the site. Continued storage in these facilities is being evaluated because the No Action Alternative includes activities required to ensure safe and secure storage. The Plutonium Finishing Plant and PUREX facilities are excluded from this evaluation because SNF will not remain in those two facilities under any of the alternatives. For the purposes of this analysis, SNF at PUREX is assumed to be relocated to the K Basins.

Most of the facilities at the Hanford Site are decades old, some over 40 years, except for the FFTF and its associated storage buildings. A general description, the capacity for additional storage of SNF, and the means by which SNF can be received or removed from each facility are provided in Table 3-2. The dimensional information is for the actual storage area and not for the entire facility in order to provide a basic idea of the storage area required for that specific inventory of SNF. In many cases, such as the facilities in the 300 Area, only small portions of the actual facilities are used to store the spent fuel.

The K Basins contain the vast majority of the SNF at Hanford. The T-Plant, 308, 325, and 327 buildings, and the Plutonium Finishing Plant contain small amounts of stored SNF of various kinds. Four FFTF locations contain all the FFTF spent fuel, presently stored in sodium: the Reactor Core, In Vessel Storage, Interim Decay Storage, and Fuel Storage Facility (a building separate from the reactor containment building). The first of 60 new dry storage casks are expected to be available for FFTF fuel by late 1995. The existing facilities have very little additional capacity (see Table 3-2). While there is presently excess capacity in the K Basins, this is expected to be consumed by the planned operations, regardless of the storage alternative chosen.

The accessibility and limits on loading SNF are provided as key factors in movement of any fuel from these facilities to other locations on or offsite. Rail access is available at the facilities storing most of the fuel (K Basins, PUREX, and T Plant); truck shipments would be used for the rest. Acceptable casks and procedures for moving these casks may require evaluation in many cases. Additional details on these facilities are provided by Bergsman (1994), Bergsman (1995), and Monthey (1993).

The changes to the existing facilities that were analyzed under the No Action Alternative of SNF storage are shown in Table 3-3.

Table 3-2. Description of existing facilities (Bergsman 1994; Bergsman 1995).

Facility	Description	Capacity	Access
105-KE Basin	Water storage pool; 38 m x 20 m x 6 m deep; concrete walls and floor; no sealant or liner	75% full, 100% full after containerization	By rail 27 MT crane, fairly restrictive
105-KW Basin	Water storage pool; 38 m x 20 m x 6 m deep; concrete walls and floor; epoxy sealant; no liner	75% full[a]	By rail 27 MT crane, fairly restrictive
T Plant: Cell 4	Water storage pool; 4 m x 8.4 m x 5.8 m deep (water)	50% full	By rail or truck All fuel handling remote
PUREX Plant: East end of 202A Bldg. plus Dissolver Cells A, B, and C	Water storage pool; 9.5 m x 6.1 m x 5.2 m deep; Dissolver Cell sizes vary	No additional capacity	Shipment by rail 36 MT crane
Plutonium Finishing Plant: 2736-ZB Bldg.	Dry storage in 55 gal drum	No additional capacity	Shipment by truck
Fast Flux Test Facility: Reactor in-vessel storage, interim decay storage, and fuel storage facility storage locations	Liquid sodium pool storage (fuel storage facility is separate from reactor containment building, with limit of <1.4kW/assembly)	More than 75% full	By truck 91 MT Crane
200 Area LL Burial Grounds: 218-W-4C Trench 1 and 7; and 218-W-3A Trench 8 and S6	Dry, retrievable storage; 13 lead-lined, concrete-filled 208 liter drums, soil covered; 22 concrete casks (1.66 m x 1.66 m x 1.22 m or 1.92 m high), soil covered; 39 EBR II casks (1.5 m high x 0.4 m diameter), soil covered; 1 Zircaloy Hull Container (152 cm long x 76 cm diameter)	Large additional capacity	By truck
308 Building Annex: Neutron Radiography Facility	Built in late 1970's water storage pool; 2.8 m diameter x 6 m deep	Small additional capacity	Truck shipments 4.5 MT crane
324 Building: B and D Cells	Dry storage in air; B Cell: 6.7 m x 7.6 m x 9.3 m high (SNF uses <10% of floor space). D Cell: 4 x 6.4 m x 5.2 m high (small part for fuel), thick concrete walls and floors with steel liners	Small additional capacity	Truck shipments only B Cell - 2.7 and 5.4 MT cranes; Airlock - 27 MT crane
325 Building: A and B Cells in 325 Radiochemical Facility; 325 Shielded Analytical Laboratory	Dry storage in air 325A - 1.8 m x 2.1 m x 4.6 m high (typical cell) 325B - 1.7 m x 1.7 m floor area (typical cell)	Small additional capacity	Truck shipments only 325A - 27 MT crane 325B - 2.7 MT crane
327 Building: A - F and I Cells; Upper and Lower SERF; Dry Storage vault; EBR II cask; Large Basin	Dry storage in air, except for water in large basin; variety of cell sizes, but storage only for fuel research	Small additional capacity	No direct rail Truck shipments 13.5 and 18 MT cranes

a. If 105-KE Basin fuel is consolidated with 105-KW Basin fuel, 105-KE Basin would be shut down. The storage capacity of 105-KW Basin would be increased by replacing all the storage racks to allow multitiered stacking of fuel storage canisters and by making minor facility modifications.

Table 3-3. Assumed changes to existing Hanford facilities in the No Action

Alternative.

Facility	Facility changes
105-KE Basin	Fuel and sludge to be containerized; plans to upgrade safety and security systems
105-KW Basin	Fuel is already containerized; plans to upgrade safety and security systems
T Plant	None
PUREX Plant	Fuel to be moved to alternative location (assumed to be 105-K Basins for this alternative)
Plutonium Finishing Plant	None
Fast Flux Test Facility	None: Procure 10 dry storage casks by 8/95 (Bergsman 1995). Casks to weigh 50 T with storage cavity 3.8 m high x 0.56 m diameter (Bergsman 1994)
200 Area LL Waste Burial Grounds	None
308 Building Annex	None
324 Building	None
325 Building	None
327 Building	None

3.1.1.3 Description of New Facilities. No new buildings were analyzed

for the Hanford Site under the No Action Alternative. The only activities that were analyzed are those described for containerizing the N Reactor fuel and procuring casks for storage of FFTF fuel. The casks would be stored above ground on an existing concrete pad at the FFTF (Bergsman 1995). Major changes in rail, electrical, water, or other utilities are not expected under this alternative.

3.1.2 Decentralization Alternative

In the Decentralization Storage Alternative, as in the No Action Alternative, the current spent fuel inventory would continue to remain close to the point of generation or defueling. There are some existing storage sites that may receive or ship spent fuels, such as naval spent fuel, under one of several options under the Decentralization Alternative, but these options do not impact Hanford (DOE 1993a). No SNF would be shipped offsite or received from other storage locations outside of Hanford, but local transport might take place to support safety requirements and research and development. The Decentralization Alternative differs from the No Action Alternative in that significant facility development and upgrades are assumed, and spent fuel characterization, research and development, and possibly stabilization would occur. Summaries of the anticipated activities (Subsection 3.1.2.1) and facility requirements (Subsections 3.1.2.2 and 3.1.2.3) are provided below.

3.1.2.1 Anticipated Activities. The Decentralization Alternative would

include the three activities (fuel characterization, fuel and sludge containerization, and cask procurement for FFTF fuel) mentioned above in Subsection 3.1.1 for the No Action Alternative as well as the following general activities:

- Characterization of defense production fuels (N Reactor and single-pass reactor) to determine the feasibility of dry storage
- Evaluation of dry storage for other fuels (Shippingport Core II, FFTF, miscellaneous)
- Research and development on N Reactor fuel stabilization
- Construction and utilization of wet and/or dry storage facilities as well as a stabilization facility to support storage.

Only the defense fuels are being considered for wet storage, but dry storage in casks or vaults could be used for all or part of Hanford's spent fuel inventory under various options (Bergsman 1995). There are four basic options considered for storage of the spent fuels at Hanford under the Decentralization Alternative. Options W and X include both wet and dry storage: wet storage for defense fuels and dry storage for all other spent fuels in either a vault or casks. Options Y and Z involve only dry storage, again either in a vault or casks, but these options include one of three stabilization options for the metallic defense fuels.

The three potential processes considered for stabilizing the defense fuels in conjunction with Options Y and Z are shear/leach/calcine (P), shear/leach/solvent extraction (Q), and drying and passivation (D). Process P consists of shearing the fuel into a continuous dissolver and dissolving it in a nitric acid solution. Eventually, the processed material (without any radionuclide removal) is calcined, pressed into a ceramic waste form, and sealed in metal canisters.

Process Q uses solvent extraction by which metallic defense fuels are dissolved, separating uranium and plutonium and a liquid high-level waste stream that would most likely be vitrified for disposal in a geologic repository. In Process Q it is assumed that the process would be carried out on the Hanford Site. In commenting on the draft EIS, British Nuclear Fuels Limited (BNFL) proposed such processing be carried out in their facilities overseas. A discussion of the proposed sub-option is provided in Attachment B. Except for the additional impacts associated with transporting SNF from the Hanford Site to a West Coast shipping port, transoceanic shipment, transport of the SNF overland to BNFL facilities, and return shipment of resource materials (uranium-trioxide and plutonium-dioxide) and vitrified high-level waste, environmental impacts would be similar to those determined for Process Q.

Process D consists of drying and passivating the spent fuel and then canning it for storage. The relationships between the storage and stabilizing options are shown in Table 3-4.

Option W involves moving the N Reactor fuel from the existing basin storage into a new basin to be built by the year 2001. Simultaneously, a modular dry vault would be built for storage of the rest of the spent fuel at Hanford. Option X considers the use of casks for dry storage instead of the vault, but still requires moving the N Reactor fuel to a new basin. The casks would be placed on concrete pads outside of any buildings and would include two types of cask designs: concrete modules holding a storage cask, and upright concrete casks designed specifically for the FFTF fuel. Option Y would result in all of the non-defense spent fuel at Hanford being placed in a large vault facility. The defense fuel would require processing in a new facility by one of three options (P, Q, or D) prior to canning and placement in storage. The defense fuels processed using Option P or Option D would be stored in the vault; however, Option Q would result in several products that would be stored or processed further as high-level waste (Bergsman 1995). The final option, Option Z, is similar to Option Y except that casks would be used instead of a dry storage vault for all of the nondefense spent fuels. The defense fuels are handled as in Option Y. Additional details are provided by Bergsman (1995).

Table 3-4. Options under the Decentralization Alternative for Hanford.

Storage option	Stabilization option	Description	Facility requirements
W	None	Wet storage of defense fuels Dry storage of other fuels	New basin New vault
X	None	Wet storage of defense fuels Dry storage of other fuels	New basin New casks
Y	P, Q, or D	Dry storage of all fuel; stabilize defense fuels prior to storage	New vault; new processing facility [calcining (P), solvent extraction (Q), or drying and passivation (D)]
Z	P, Q, or D	Dry storage of all fuel; stabilize defense fuels prior to storage	New dry storage casks; new processing facility [calcining (P), solvent extraction (Q), or drying and passivation (D)]

3.1.2.2 Description of Existing Facilities and Impacts from the

Decentralization Alternative. The description of the existing facilities used to store SNF at Hanford was provided in Subsection 3.1.1.2. The Decentralization Alternative would impact the facilities beyond that already mentioned for the No Action Alternative to the extent that fuel would be removed from several of them: the Shippingport fuel would be removed from T

Plant to a designated interim storage location on site; FFTF fuel would continue to be removed from the sodium-cooled storage facilities and placed in dry storage casks; and fuel in the 200-W burial grounds might be relocated onsite.

As shown in Table 3-2, there is very little excess capacity in any of the facilities in which fuel is currently stored. The storage basins, in addition to being old, were built for temporary holding, for a matter of months only; hence, bringing them up to standards for prolonged storage would be fraught with problems and would not be cost-effective. Except for the burial grounds, the locations in which SNF is currently held in air were not intended for prolonged storage either, having been built for temporary holding for research and development or pre-processing. The FFTF storage facilities are all dependent on maintaining sodium in the liquid state as coolant and storage medium, which is not cost-effective for 40 years of storage for nonbeneficial use. Hence, the existing facilities are not considered for use in the 40 year storage scenario.

3.1.2.3 Description of New Facilities. A minimum of two new facilities

are required, regardless of which option is chosen for storing spent fuel under the Decentralization Alternative. Both Options W and X require a new basin and either a new vault or a new cask storage facility. Descriptions of these potential new facilities are provided in Table 3-5. A proposed site consisting of about 260 hectares (one-quarter section) for construction of all new facilities is located as shown in Figure 4-1. The cask facility would cover about twice as much land area as a vault facility and would involve modular systems placed outside on concrete pads. While the basin requirement is dropped for Options Y and Z, a process facility is needed for the metallic defense fuels in addition to the new dry storage facility. The specifics of this facility vary depending on whether they involve shear/leach/calcining (process P), shear/leach/solvent extraction (process Q), or drying and passivation (process D). For process Q, it is assumed that a vitrification plant and storage facilities will be available for the processed spent fuel that would then consist of three products. The vitrification plant and storage for high-level wastes are part of the overall plan for Hanford.

The potential processing facilities that will result from this alternative will require increased utilities, compared with the new dry storage facilities that are not expected to have major utility requirements. A rail system for receiving spent fuel at the various facilities may be required and could be tied into the existing system. Water requirements are expected to be insignificant. Estimates of the power requirements for processes P, Q, and D are 10 megawatts, 18 megawatts, and 3 megawatts, respectively. While the existing excess electrical capacity of 21 megawatts would be sufficient for one of these facilities, other potential uses of the existing electrical power capacity may require upgrading the existing power system (Bergsman 1995).

3.1.3 1992/1993 Planning Basis Alternative

The 1992/1993 Planning Basis Alternative defines those activities that were already scheduled at the various sites for the transportation, receipt, processing, and storage of SNF.

3.1.3.1 Description of Spent Fuel Inventory As in the previous two

alternatives, no new spent fuel would be received at Hanford under the 1992/1993 Planning Basis Alternative. However, the 101 spent fuel elements currently in the 308 Building from TRIGA reactors and the small amount of TRIGA fuel from Oregon State University currently in the 200-W Area burial grounds would be shipped to INEL.

Table 3-5. Description of required facilities under the Decentralization Alternative.

New facility	Description	Capacity
Water Basin (W, X)	Building: 110 m long x 42.7 m wide x 19.8 m high	2103 MTU in 8000 canisters

	Land use: <8094 m2 (<2 acres) Water storage pool: rectangular, 520 m2, cast-in-place concrete Canisters: double barreled, each 0.23 m diameter x 0.74 m high Construction: 3 year duration, operation by 2001	
Dry Storage Vault Facility (W)	Building: 39.6 m long x 48.8 m wide x 19.8 m high Land use: <4047 m2 (<1 acre) Modular vault: metal tubes vertically arrayed in cast-in-place concrete structure; inert cover gas; natural convection cooling. Canisters: short, 0.508 m diameter x 3.96 m (FFTF fuels); long, 0.559 m diameter x 4.57 m (other non-defense fuels) Construction: 3 year duration, operation by 2001	30 MTHM in 60 short and 25 long canisters
Dry Storage Cask Facility (X)	Building: none, concrete pads Land use: <8094 m2 (<2 acres) Cask Systems: 1) FFTF casks, 2.29 m diameter x 4.57 m high, 45.4 MT each, 2) Concrete module with fuel cask; reference storage module is 2.96 m wide x 5.52 m deep x 4.57 m high Canisters: 0.508 m diameter x 3.96 m (FFTF cask); 1.68 m diameter x 4.88 m long, weighs 90.8 MT (storage module) Construction: 3 year duration, operation by 2001	30 MTHM, 60 cask/ canisters (FFTF design) and 6 storage modules/ casks
Shear/Leach / Calcine Process or Z Facility (Y)	Building: multilevel, steel-reinforced, cast in place concrete; 110.3 m long x 55.2 m wide x 25.9 m high (15.8 m above grade); shielded main canyon is 6.1 m wide x 70.1 m long x 25.9 m high; Land Use: 6070 m2 (1.5 acres) Operation: 24 hours/day, 7 days/week for 4 years to stabilize defense fuels; 75% efficiency; 280 day/year Construction: 3 year duration, operation by 2001	2103 MTU in 4 years 2.5 MTU/day
Dry Storage Vault Facility (Y)	Building: 100.6 m long x 88.4 m wide x 18.3 m high Land use: <8094 m2 (<2 acre) Modular vault: metal tubes vertically arrayed in cast-in-place concrete structure; inert storage atmosphere; natural convection cooling. Canisters: 0.559 m diameter x 4.11 m (defense fuels); short, 0.508 m diameter x 3.96 m (FFTF fuels); long, 0.559 m diameter x 4.57 m (other non-defense fuels) Construction: 3 year duration, operation by 2001	2133 MTHM in ~1200 defense canisters, 60 short and 25 long non-defense canisters
Dry Storage Cask Facility (Z)	Same as Dry Cask Storage Facility described for Option X Land use: 20,234 m2 (5 acres) Canisters: add storage modules/casks for stabilized defense fuels; same storage container dimensions as for Option X	2133 MTHM in 60 cask/ canisters (FFTF), 230 modules/ casks (defense), and 6 modules/ casks (other non-defense)
Solvent Extraction Fuel Process Facility (Y or Z)	Building: multilevel, steel-reinforced, cast in place concrete; 26.5 m long x 77.7 m wide x 25.9 m high (15.8 m above grade); shielded main canyon is 6.1 m wide x 76.2 m long x 25.9 m high; Land Use: 6070 m2 (1.5 acres) Canisters: generates 2 kg/MTU of fuel processed, resulting in about 30 cans of glass for 2103 MTU of fuel Operation: 24 hours/day, 7 days/week for 4 years to stabilize defense fuels; 75% efficiency; 280 day/year Construction: 3 year duration, operation by 2001	2103 MTU in 4 years 2.5 MTU/day
Fuel Drying	Building: multilevel, steel-reinforced, cast	2103 MTU in 4

and Passivation Facility (Y or Z)	in place concrete; 115.8 m long x 64.0 m wide x 25.9 m high (15.8 m above grade); shielded main canyon is 6.1 m wide x 54.9 m long x 25.9 m high; Land Use: 6070 m2 (1.5 acres) Operation: 24 hours/day, 7 days/week for 4 years to stabilize defense fuels; 75% efficiency; 280 day/year Construction: 3 year duration, operation by 2000	years, 2.5 MTU/day

a. Source: Bergsman (1995).

3.1.3.2 Anticipated Activities Most of the activities previously

discussed for the decentralization storage alternative were already planned prior to this review. It was expected that all newly generated SNF that was owned by the U.S. Government would be sent to either INEL or to SRS. No new spent fuel was expected to be shipped to Hanford other than possibly limited quantities of material for research or other scientific endeavors supporting the nuclear industry. Upgrades and replacements of existing storage capacity were already planned and would involve those facilities described in Subsection 3.1.2 for the Decentralization Alternative. Thus, the activities that would be conducted under the 1992/1993 Planning Basis are the same as for the Decentralization Alternative under the four options listed in Table 3-4, except for the additional activity of shipping TRIGA spent fuel to INEL.

3.1.3.3 Description of Existing Facilities and Changes Required by

Alternative The description provided in Subsection 3.1.1.2 on the existing facilities for storing SNF at Hanford also applies to this alternative. No additional changes to facilities are anticipated from the 1992/1993 Planning Basis except that the 308 Building and the 200W Area burial grounds would no longer contain TRIGA spent fuel.

3.1.3.4 Description of New Facilities. The facilities that would be

required under the 1992/1993 Planning Basis are the same as those shown previously in Table 3-5 for the Decentralization Alternative. The impact on existing utilities would be the same as for the Decentralization Alternative, namely from 3 to 18 megawatts of power for stabilization facilities and minimal other impacts.

3.1.4 Regionalization Alternative

This alternative provides for the redistribution of SNF to candidate sites based on similarity of fuel types (Option A) or on geographic location (Options B1, B2, and C), in order to optimize the storage of SNF owned by the U.S. Government.

The Regionalization Alternative as it applies to the Hanford Site consists of the following options:

- Option A (regionalized by fuel type) - Defense production SNF would remain at Hanford; other types of SNF would be sent to INEL.
- Option B1 (geographic regionalization) - All SNF west of the Mississippi River except Naval SNF would be sent to Hanford.
- Option B2 (geographic regionalization) - All SNF west of the Mississippi River and Naval SNF would be sent to Hanford.
- Option C (geographic regionalization) - All Hanford SNF would be sent to INEL or NTS.

Facilities and features of Regionalization Option A would be the same as those described for Hanford defense production fuel in the Decentralization

Alternative. The facilities and features for all other Hanford SNF would be very similar to those described for that SNF in the Centralization Alternative minimum option.

Facilities and features of Regionalization Options B1 and B2 would be incremental to those described for the Decentralization Alternative and would include facilities and features similar to those described in the Centralization Alternative maximum option.

Facilities and features of Regionalization Option C would be equivalent to those described for the Centralization Alternative minimum option.

3.1.4.1 Description of Spent Fuel Inventory. The spent fuel inventory

that would be stabilized and/or stored for each of the Regionalization options is shown in Table 3-1.

3.1.4.2 Activities Required by Each Option.

Option A, Suboption X

- wet storage of N Reactor and single-pass reactor fuel
- shipment of other Hanford Site fuel to INEL
- use of existing facilities (FFTF and T Plant) and new wet pool facilities to load shipping casks.

For N Reactor and single-pass reactor fuel, this option is the same as the Decentralization Alternative; for all other Hanford Site fuel, this option is nearly the same as for the Centralization Alternative minimum option.

Option A, Suboption Y

- dry storage of all defense production fuel in a large vault facility
- transport of other Hanford Site fuel to INEL
- defense production fuel stabilized prior to storage
- use of existing facilities (FFTF and T Plant) and a stabilization facility to load shipping casks
- leakers, if any, unloaded in a special module at a stabilization facility.

For N Reactor and single-pass reactor fuel, this option is identical to the Decentralization Alternative; for other Hanford Site fuel, this option is nearly identical to the Centralization Alternative minimum option.

Option A, Suboption Z

- dry storage of all fuel in casks in a large facility
- defense production fuel stabilized prior to storage
- dry storage casks loaded at existing facilities (FFTF and T Plant)
- use of existing facilities (FFTF and T Plant) and a stabilization facility to load shipping casks
- leakers unloaded in a special module at a stabilization facility.

For N Reactor and single-pass reactor fuel, this option is identical to the Decentralization Alternative; for other Hanford Site fuel, this option is nearly identical to the Centralization Alternative minimum option.

Option B1

All fuel from offsite would be stored dry in casks in a large facility, although a very small amount might require wet storage for an interim period prior to dry storage. SNF received from other DOE locations would arrive stabilized and canned as necessary for storage. SNF received from universities and SNF of U.S. origin from foreign research locations would require canning prior to storage. The required receiving and canning would be done in a new facility because of the extended period over which the fuel would be received. A small amount of fuel would arrive after only limited time since reactor discharge, which would require temporary water storage until it aged sufficiently to be dry stored. That water storage would be included in the receiving and canning facility. Technology development would be conducted in a separate, nearby facility.

Option B2

The activities for this option would be the same as those for Option B1, except that additional storage would be required for Naval fuel.

Option C

Hanford fuel would be stabilized as necessary, loaded, and shipped offsite.

3.1.4.3 Existing Facilities. Upgrades, replacements, and additions to

the existing facilities would occur as required under the Decentralization Alternative.

3.1.4.4 New Facilities. Research and development and pilot programs

for characterization, stabilization, and other needs to support future decisions on the ultimate disposition of SNF would also occur. Refer to Table 3-6 for the potential facility requirements under the three storage and three stabilization options. A description of these options is given in Section 3.1.2.1, Anticipated Activities under the Decentralization Alternative. Options X, Y, and Z with their respective stabilization suboptions are the same as those for the Regionalization and Decentralization Alternatives (see **Table 3-4).** What is different is the specific assortment of fuel to be managed in each of the alternatives. The stabilization facilities required under the Regionalization Alternative are the same as those listed in Table 3-5.

Table 3-6. Description of required facilities under Regionalization Alternatives.

Alternatives	New Facility	Description	Capacity
Regionalization A/ Suboption X RAX	Water basin	Building: 109.7 m long x 42.7 m wide x 12.2 m high pre-cast concrete Land use: <8094 m2 (<2 acres) Water storage pool: rectangular, 520 m2, cast-in-place concrete Canisters: double barreled, each 0.23 m diameter x 0.74 m high Construction: 3-year deviation, operation starting in 2001	~2103 MTU in 8000 canisters
Regionalization A/ Suboption Y RAY	Shear/leach/calcine stabilization process	See Table 3-5	
Regionalization A/ Suboption RAY	Large modular dry storage vault	Building: 94.5 m long x 88.4 m wide x 18.3 m high cast-in-place concrete, pre-cast concrete superstructure Land Use: ~8094 m2 (~2 acres) Canisters: 0.58 m diameter x 4.11 m high Construction: 3-year duration, operation to start in 2001	~2103 MTU in 1200 canisters
Regionalization A\ Suboption RAZ	Shear/leach/calcine stabilization process	See Table 3-5	
Regionalization A/	Concrete storage module	Building: 3.0 m wide x 5.5 m long x 4.6 m high Land Use: 16,187 m2 (4 acres)	2013 MTU in

Suboption RAZ prefabricated dry storage module casks	holding NUHOMSa casks	Casks: 1.7 m diameter x 4.9 m long Construction: 3 year duration, operation to begin in 2001	230

Table 3-6. (contd)

Alternatives	New Facility	Description	Capacity
Note: Facilities required for Alternatives RB1 and RB2 are in addition to those required for Decentralization			
Regionalization B1, RB1	Incremental cask storage	Building: 121.9 m x 365.8 m Similar to but larger than that for Decentralization Option X	330 MTHM 188 shipping casks, 50 storage casks
	Receiving and canning facility	Building: 53.3 long x 53.3 m wide x 16.8 m high 3 foot thick cast-in-place concrete	
	Technology development facility	Building: 53.3 m long x 30.5 m wide x 16.8 m high pre-cast concrete Land use for all three RB1 facilities: 40,469 m2 (10 acres) Construction: Receiving/canning and tech. dev. 1998-2001; for 90% of storage facility 2000-2010; for remaining 10% storage 2010-2035; operating period: 2000 through 2035	
Regionalization B2, RB2	Prefabricated by storage cask facility	Building: 914.4 m x 121.9 m; similar to but larger than Option X for Decentralization	400 MTHM (for total, with Decentralization, of 2500 MTHM) 188 shipping casks 50 storage casks
	Receiving and canning facility	Sames as for RB1	
	Technology development facility Land use for all three RB2 facilities: 101,172 m2 (25 acres)	Same as for RB1	

a. NUHOMs casks [Nutech Horizontal Modular Storage (from Pacific Nuclear)]

3.1.5 Centralization Alternative

Under the Centralization Alternative for SNF storage, all current and future SNF from DOE and the Naval Nuclear Propulsion Program would be sent to one DOE site or other location. The activities at each site would depend on whether the SNF was being received or shipped offsite. Sites not selected would close down their storage facilities once the fuel had been removed. The following information summarizes the expected impact at Hanford and provides insight into the characteristics of the SNF and facilities that would be involved in shipping these fuels to

Hanford.

3.1.5.1 Description of Spent Nuclear Fuel Inventory The SNF inventory

that would exist at Hanford under this alternative would include that which is presently at Hanford (see Table 3-1), as well as any new fuel shipped to Hanford. If the minimum option occurs under the Centralization Alternative, then all of this spent fuel would be shipped offsite and there would no longer be a spent fuel inventory at Hanford, barring any required for research. If the maximum option occurs, the spent fuel at all of the other sites across the United States would eventually be transported to Hanford.

The locations from which spent fuel would be sent, in addition to SRS and INEL, include Argonne National Laboratories East and West, Babcock and Wilcox, Brookhaven National Laboratory, General Atomics, Los Alamos National Laboratory, Oak Ridge National Laboratory, Sandia National Laboratories, West Valley, and Fort St. Vrain. Naval spent nuclear fuel from shipyards and prototypes would be sent first to the equivalent of the Expended Core Facility, which would be relocated to Hanford. There the fuel would be examined by the Naval Nuclear Propulsion Program prior to being turned over to DOE for storage at Hanford. Foreign fuel that may be returned to the United States following irradiation or testing offsite would also be included in this inventory under the Centralization Alternative. Summaries of the spent fuel at each site are shown in Volume I, Attachments B, C, and D and Volume III of DOE (1993a). Additional information is in DOE (1992a) (Fort St. Vrain and Peach Bottom high-temperature gas-cooled reactor spent graphite fuel).

3.1.5.2 Anticipated Activities. If Hanford is chosen as the site for

storing the entire spent fuel inventory, the upgrades, increases, and replacements of storage capacity would occur as required for the existing spent fuel as well as to accommodate the increased spent fuel inventory. If the Centralization Alternative is chosen and Hanford is not selected, the activities would include stabilization to ensure safe storage and transportation offsite.

All fuel received from offsite would be stored dry in casks in a large facility, although some may require wet storage for an interim period prior to dry storage. SNF received from other DOE sites will arrive stabilized and canned as necessary for storage. SNF received from universities and from foreign locations would require containerization prior to storage. Naval SNF would arrive uncontainerized, but would not require containerization. The required receiving and containerizing would be done in a new facility because of the large throughput involved and the extended period (40 years instead of 4) during which the fuel would be received. Some university and foreign fuel would require temporary wet storage. That water storage is included in the receiving and canning facility. Technology development would be conducted in a separate, nearby facility.

3.1.5.3 Description of New Facilities. The new facilities required for

the alternative in which all U.S. DOE SNF would be stored at the Hanford Site are of the same type as, but larger than, those required for Regionalization Alternative Option B2:

- The Prefabricated Dry Storage Cask Facility for offsite SNF would be approximately 120 meters x 1200 meters.
- The Receiving and Canning Facility would be approximately 110 meters x 50 meters x 20 meters high.
- The Technology Development Facility would be approximately 50 meters x 40 meters x 20 meters high.
- The land required for these three facilities together would be approximately 14 hectares (35 acres).

3.2 Comparison of Alternatives

A summary of environmental impacts among the various alternatives is provided in **Table 3-7.** The alternatives are briefly described below to aid in interpreting the material presented.

The No Action Alternative identifies the minimum actions deemed necessary for continued safe and secure storage of SNF at the Hanford Site. Upgrade of the existing facilities would not occur other than as required to ensure safety and security.

The Decentralization Alternative includes additional facility upgrades over those considered in the No Action Alternative, specifically, new wet storage (for defense production fuel only) or dry storage facilities, fuel processing via shear/leach/calcination or shear/leach/solvent extraction, with research and development activities to support such processing.

The 1992/93 Planning Basis Alternative differs from the Decentralization Alternative only in that TRIGA fuel currently stored at the Hanford Site would be shipped offsite. The storage and stabilization options identified for the Decentralization Alternative are also assumed for the 1992/1993 Planning Basis Alternative.

The Regionalization Alternative as it applies to the Hanford Site consists of the following options:

- Option A (fuel type) - Defense production SNF would remain at Hanford; other types of fuel would be sent to INEL.
- Option B1 (geographic) - All SNF west of the Mississippi River, except Naval SNF would be sent to Hanford.
- Option B2 (geographic) - All SNF west of the Mississippi River and Naval SNF would be sent to Hanford.
- Option C (geographic) - All Hanford SNF would be sent to INEL or NTS.

Table 3-7. Summarized comparisons of the alternatives[a].

a. Hyphenated numbers indicate range of values depending on processing options selected.

b. Minimum value represents requirements during the period after all fuel has been placed into dry storage or has been shipped offsite. Maximum value represents requirements during the interim period (less than 4 years) while SNF is being processed and prepared for storage or shipment offsite, assuming concurrent operation of the process facility and the existing facilities where SNF is currently stored (as in the No Action Alternative).

c. Spent filters and ion exchange resins are the only sources of TRU waste. Filters and resins are charged before they become TRU waste.

Two options exist at the Hanford Site for the Centralization Alternative: 1) the minimum option, in which all SNF on the Hanford Site would be shipped offsite, and 2) the maximum option, in which all SNF within the DOE complex would be shipped to the Hanford Site for management and storage. In the latter case, dry storage of all fuel sent to the Hanford Site from offsite would be assumed. A facility equivalent to the Decentralization suboptions would be assumed for stabilization of defense production fuel prior to storage; fuel received from offsite would have been stabilized for dry storage prior to receipt.

4. AFFECTED ENVIRONMENT

4.1 Overview

The Hanford Site is characterized by a shrub-steppe climate with large sagebrush dominating the vegetative plant community. Jack rabbits, mice, badgers, deer, elk, hawks, owls, and many other animals inhabit the Hanford Site. The nearby Columbia River supports one of the last remaining spawning areas for Chinook salmon and hosts a variety of other aquatic life. The climate is dry with hot summers and usually mild winters. Severe weather is rare. With construction of dams along the Columbia River, flooding is nearly nonexistent.

The Hanford Site was a major contributor to national defense during World War II and the Cold War era. The site was selected because it was sparsely settled and the Columbia River provided an abundant supply of cold, clean water to cool the reactors. As a result of wastes generated by these national defense activities, there are presently more than 1500 waste management units and four major groundwater contamination plumes. These have been grouped into 78 operable units: 22 in the 100 Area (reactor area), 43 in the 200 Area (chemical processing and refining areas), 5 in the 300 Area (research and development area), and 4 in the 1100 Area (storage area). An additional four units are found in the 600 Area (the rest of the Hanford Site). Each of these operable units is following a schedule for clean-up established by the Hanford Federal Facility Agreement and Consent Order (Tri-Party Agreement), which involves the U.S. Department of Energy (DOE), the Washington Department of Ecology, and the EPA.

4.2 Land Use

A brief description of the existing land use on the Hanford Site and adjacent lands and a brief discussion devoted to the existing land use on the proposed project site area follow.

4.2.1 Land Use at the Hanford Site

The Hanford Site is used primarily by DOE. Public access is limited to travel on the two access roads as far as the Wye Barricade, on Highway 240, and on the Columbia River (see Figure 4-1). The site encompasses 1450 square kilometers (560 square miles), of which most is

Figure 4-1. Hanford Site showing proposed spent nuclear fuel facility location.

open vacant land with widely scattered facilities, old reactors, and processing plants (Figure 4-1). In the past, DOE has stated that it intends to maintain active institutional control of the Hanford Site in perpetuity (DOE 1989). In the future, DOE could release or declare excess portions of the Hanford Site not required for DOE activities. Alternatively, Congress could act to change the management or ownership of the Hanford Site. The DOE operational areas are described below:

- The 100 Area [11 square kilometers (4.2 square miles)], which borders the right bank (south shore) of the Columbia River, is the site of eight retired plutonium production reactors and N Reactor, which is in shutdown deactivation status.

- The 200-West and 200-East Areas [16 square kilometers (6.2 square miles)] are located on a plateau about 8 and 11 kilometers (5 and 7 miles), respectively, from the Columbia River. These areas have been dedicated for some time to fuel reprocessing and waste processing management and disposal activities. The proposed project would be located between these areas.

- The 300 Area [1.5 square kilometers (0.6 square miles)], located just north of the city of Richland, is the site of nuclear research and development.
- The 400 Area [0.6 square kilometers (0.25 square miles)] is about 8 kilometers (5 miles) north of the 300 Area and is the site of the Fast Flux Test Facility (FFTF) used in the testing of breeder reactor systems. Also included in this area is the Fuels and Material Examination Facility.
- The 600 Area comprises the remainder of the Hanford Site and includes the Arid Land Ecology Reserve (ALE) [310 square kilometers (120 square miles)], which has been set aside for ecological studies, and the following facilities and sites:
  - a commercial low-level radioactive waste disposal site [4 square kilometers (1.7 square miles)], part of which is leased by the State of Washington.
  - Washington Public Power Supply System nuclear power plants [4.4 square kilometers (1.7 square miles)].
  - a 2.6-square kilometer (1 square mile) parcel of land transferred to Washington State as a potential site for the disposal of nonradioactive hazardous wastes.
  - a wildlife refuge of about 130 square kilometers (50 square miles) under revocable use permit to the U.S. Fish and Wildlife Service.
  - an area of about 6 square kilometers (2.3 square miles) has been provided to site a National Science Foundation Laser Gravitational-Wave Interferometer Observatory west of the 400 Area. When completed, this facility will occupy about 0.6 square kilometers (0.2 square miles).
  - a recreational game management area of about 225 square kilometers (87 square miles) under revocable use permit to the Washington State Department of Game.
  - support facilities for the controlled access areas.

In addition, an area comprising 310 square kilometers (120 square miles) has been designated for use as the ALE by the U.S. Fish and Wildlife Service for a wildlife refuge and by the Washington State Department of Wildlife for a game management area (DOE 1986a). The entire Hanford Site has been designated a National Environmental Research Park.

The Columbia River adjacent to the Hanford Site is a major site for public use by boaters, water skiers, fishermen, and hunters of upland game birds and migratory waterfowl. Some land access along the shore and on certain islands is available for public use.

4.2.2 Land Use in the Vicinity of the Hanford Site

Land use adjacent to the Hanford Site to the southeast and generally along the Columbia River includes residential, commercial, and industrial development. The cities of Richland, Kennewick, and Pasco are located along the Columbia River and are the closest major urban land uses adjacent to the Hanford Site. These cities (known as the Tri-Cities) together support a population of approximately 96,000.

Irrigated orchards and produce crops, dry-land farming, and grazing are also important land uses adjacent to the Hanford Site. In 1985 wheat represented the largest single crop in terms of area planted in Benton and Franklin counties with 190 square kilometers (73 square miles). Corn, alfalfa, hay, barley, and grapes are other major crops in Benton and Franklin counties. In 1986 the Columbia Basin Project, a major irrigation project to the north of the Tri-Cities, produced gross crop returns of $343 million, representing 19 percent of all crops grown in Washington State. In 1986 the average gross crop value per irrigated acre was $664.00. The largest percent age of irrigated acres produced alfalfa hay, 29.4 percent of irrigated acres; wheat, 15.0 percent; and corn (feed grain), 9.4 percent. Other significant crops are potatoes, apples, dried beans, asparagus, and pea seed.

4.2.3 Potential Project Land Use

The potential project site (Centralization Alternative) is located between the 200-West and 200-East Areas. The land is currently vacant. The proposed project would consist of constructing an SNF facility on the site. This potential project would involve typical land uses that occur during construction phases and a more industrial/commercial land use after reaching the operational stage.

4.2.4 Native American Treaty Rights

In prehistoric and early historic times, the Hanford Reach of the Columbia River was populated by Native Americans of various tribal affiliations. The Wanapum and the Chamnapum bands of the Yakama[a] tribe lived along the Columbia River from south of Richland upstream to Vantage (Relander 1986; Spier 1936). Some of their descendants still live nearby at Priest Rapids Dam (the Wanapum Tribe); others have been incorporated into the Yakama and Umatilla reservations. Palus people, who lived on the lower Snake River, joined the Wanapum and Chamnapum to fish the Hanford Reach of the Columbia River, and some inhabited the river's east bank (Relander 1986; Trafzer and Scheuerman 1986). Walla Walla and Umatilla people also made periodic visits to fish in the area. These people retain traditional secular and religious ties to the region, and many, young and old alike, have knowledge of the ceremonies and lifeways of their aboriginal culture. The Washane, or Seven Drums religion, which has ancient roots and had its start on what is now the Hanford Site, is still practiced by many people on the Yakama, Umatilla, Warm Springs, and Nez Perce reservations. Native plant and animal foods, some of which can be found on the Hanford Site, are used in the ceremonies performed by sect members.

Native American Lands designated on the Hanford Site fall under the protective rights of the Treaty of 1855 and the National Historic Preservation Act; these will be addressed further in the Cultural Resources Section. Under the Treaties of 1855, lands now occupied by the Hanford Site and other southeastern Washington lands were ceded to the United States by the confederated tribes and bands of the Yakama Indian Nation, the Confederated Tribes of the Umatilla Indian Reservation, and the Nez Perce Tribe. Under these treaties, the Native American tribes obtained the right to perform certain activities on those lands, including the rights to hunt, to fish at all usual and accustomed places and to erect temporary buildings for curing fish, to gather roots and berries, and to pasture horses and cattle on open unclaimed lands. The Wanapum Tribe, although members never signed a treaty, claims similar rights on ceded lands along the Columbia River.

Tribal members have expressed an interest in renewing their use of these resources in accordance with the Treaty of 1855, and the DOE is assisting them in this effort. Certain landmarks, especially Rattlesnake Mountain, Gable Mountain, Gable Butte, Goose Egg Hill, and various sites along the Columbia River, are sacred to them. The many cemeteries found along the river are also considered to be sacred.

---

[a] The spelling Yakama rather than Yakima has been adopted by the Yakama Nation.

4.3 Socioeconomics

Activity on the Hanford Site plays a dominant role in the socioeconomics of the Tri-Cities (Richland, Pasco, and Kennewick) and other parts of Benton and Franklin counties. The Tri-Cities serves as a market center for a much broader area of eastern Washington, including Adams, Columbia, Grant, Walla Walla, and Yakima counties. The Tri-Cities also serves parts of northeastern Oregon, including Morrow, Umatilla, and Wallowa counties. Socioeconomic impacts of changes at Hanford are mostly confined to the immediate Tri-Cities community and Benton and Franklin counties (Yakima County to a lesser extent). However, because of the significance of the wider agricultural region and surrounding communities in the Tri-Cities' economic base, this section briefly discusses the wider region as well. Detailed analyses of the socioeconomics are found in Scott et al. (1987) and Watson et al. (1984). Additionally, the impact of the proposed SNF facility might be altered by changes in socioeconomic resources in the surrounding counties of Adams, Columbia, Grant, Walla Walla, and Yakima in Washington state; and Morrow, Umatilla, and Wallowa counties in Oregon (these and Benton and Franklin counties comprise the designated region of influence; see Figure 4-2). This section describes the population, economic activity, housing, and public services and public finance of each county within the region of influence and the Tri-Cities. Because Benton and Franklin counties are expected to be most impacted from changes in Hanford Site activities, the information presented in this section concentrates on those counties, with less attention paid to the other areas within the defined region of influence.

Figure 4-2. Areas of Washington and Oregon where socioeconomic resources may be affected by the proposed spent nuclear fuel facility (designated region of influence).

Table 4.3-1 summarizes the regional (Benton and Franklin counties) projections for employment, labor force, population, and Hanford Site employment by year for the years 1995-2004. Population projections were provided by the Washington State Office of Financial Management (1992a); employment projections were based on projections from the U.S. Department of Commerce (1992); labor force projections were based on an historical average unemployment rate of 8.8%; and Hanford Site employment projections were provided by DOE. It is anticipated at the time of this writing that a down-turn in Hanford Site employment will occur. The extent of the down-turn is unknown.

4.3.1 Demographics

This subsection briefly summarizes pertinent demographic information for each of the counties within the region of influence. Data for Washington were provided by the U.S. Department of Commerce (1992) and the Washington State Office of Financial Management (1992a,b). Data for Oregon were provided by the U.S. Department of Commerce (1992) and the Center for Population Research and Census (1993). Table 4.3-2 summarizes the population figures from 1960 to 1992 for each of the affected counties.

During the period from 1980 to 1990, growth in the affected Washington counties has been less than that of the state, with growth in the counties ranging from -0.07 percent (Columbia County) to 1.22 percent (Grant County) per year. During this same period, annual growth for the state of Washington averaged 1.66 percent. Washington counties within the region of influence also tended to have a younger population, with median ages ranging from 28.7 years to 39.0 years, as compared to the state median age of 33.1 years. These counties also tended to have a larger average household size than the state average, ranging from 2.44 to 3.03 persons, while the state average household size was listed at 2.53 persons.

Table 4.3-3 summarizes population projections through 2005 for each of the counties within the region of influence. All of the Washington counties are expected to experience continued growth, although most have projected growth rates less than that of the state. Washington is projected to have an increase in population of 21.8 percent by 2005 (from 4,866,692 in 1990 to 5,925,888 in 2005) for an annual average increase of 1.45 percent. Growth in the Oregon

a. 1991 estimate.
b. Dash indicates the information was not available.

Table 4.3-3. Population projections by county in the designated region of influence.

County	1995 Forecast	1990 - 1995 % Change	2000 Forecast	1995 - 2000 % Change	2005 Forecast	2000 - 2005 % Change
Adams	13,867	1.94	14,163	2.14	14,424	1.84
Benton	121,328	7.79	128,752	6.12	136,892	6.32
Columbia	4,025	0.03	4,037	0.30	4,074	0.90
Franklin	41,336	10.31	44,630	7.97	48,213	8.03
Grant	58,026	5.97	60,518	4.30	62,983	4.07
Walla Walla	49,047	1.26	49,910	1.76	50,891	1.97
Yakima	199,578	5.70	207,870	4.15	216,245	4.03
Morrow	8,095	6.16	8,596	6.19	9,157	6.53
Umatilla	62,658	5.75	66,056	5.42	69,506	5.22
Wallowa	7,065	2.23	7,253	2.66	7,496	3.35

counties within the region of influence occurred rapidly during the 1970s; however, since 1980 population growth has tapered off. The Oregon counties within the region of influence are also expected to experience continued growth, although all have projected growth rates less than that of the state. Oregon is projected to have an increase in population of 25.5 percent (from 2,842,321 in 1990 to 3,566,189 in 2005) by 2005 for an annual average increase of 1.70 percent.

Within Benton and Franklin counties, the 1992 estimates distributed the Tri-Cities population as follows: Richland, 33,550; Kennewick, 44,490; and Pasco, 20,840. The combined populations of Benton City, Prosser, and West Richland totaled 10,460 in 1992. The unincorporated population of Benton County was 30,000. In Franklin County, incorporated areas other than Pasco had a total population of 2,540. The unincorporated population of Franklin County was 15,820.

4.3.2 Economics

This subsection summarizes pertinent economic activity within the region of interest and the Tri-Cities, including information on the general economy, employment, income, and impact of the Hanford Site. Historically, the primary industries within the region of influence have been related to agriculture; a multitude of crops encompassing many fruits, vegetables, and grains, are grown each year. Nearly all of the counties in the region of influence are home to food processing industries. Other primary industries within the region of influence include those relating to the wood industry: lumber, wood, and paper products. The data source for the Washington counties was the 1993 Washington State Yearbook (Office of the Secretary of State 1993), and the data source for the Oregon counties data was the 1991-92 Oregon Blue Book (Office of the Secretary of State 1991). Table 4.3-4 summarizes the primary industries, total employment for 1990, and total payroll for 1990 for the region of influence.

4.3.2.1 Employment in the Region of Interest. This subsection provides

information on the employment and payroll breakdown by sector for each county within the region of influence. The source for the Washington counties was Washington State Employment Security Office (1992). The source for the Oregon counties was Department of Human Resources (1990). Tables 4.3-5 and and 4.3-6 provide information on average employment and payroll for 1990, broken down by industry, for each of the counties within the region of influence. For the Washington counties, the average employment includes only persons covered by the Employment Security Act and federal employment covered by Title 5, USC 85. For the Oregon counties, average employment includes only employees of businesses covered by the Employment Division Law.

Table 4.3-4. County economic summary.

County	Primary Industries	1990 Total Employment	1990 Total Payroll ($ Million)
Adams	Food processing, agriculture	6,142	87.2
Benton	Food processing, chemicals, metal products, nuclear products	50,216	1,200.0
Columbia	Agriculture, food processing, wood products	1,559	22.3
Franklin	Food processing, publishing, agriculture, metal fabrication	17,958	284.6
Grant	Food processing, agriculture	20,851	346.0
Walla Walla	Food processing, agriculture, wood and paper products, manufacturing	20,546	366.5
Yakima	Agriculture, food processing, wood products, manufacturing	82,706	1,300.0
Morrow	Agriculture, food processing, utilities, lumber, livestock, recreation	2,791	53.5
Umatilla	Agriculture, food processing, wood products, tourism, manufacturing, recreation	21,448	366.0
Wallowa	Agriculture, livestock, lumber, recreation	2,216	37.9

4.3.2.2 Employment in the Tri-Cities. Three major sectors have been

the principal driving forces of the economy in the Tri-Cities since the early 1970s: (1) the DOE and its contractors, which operate the Hanford Site; (2) Washington Public Power Supply System in its construction and operation of nuclear power plants; and (3) agriculture, including a substantial food-processing industry. With the exception of a minor amount of agricultural commodities sold to local area consumers, the goods and services produced by these sectors are exported from the Tri-Cities. In addition to direct employment and payrolls, these major sectors also support a sizable number of jobs in the local economy through their procurement of equipment, supplies, and business services.

Table 4.3-5. Employment by industry in the region of influence, 1990 figures.

Industry	Adams	Benton	Columbia	Franklin	Grant	Morrow	Umatilla	Walla Walla	Wallowa	Yakima

Not Elsewhere Classified	1.6	0	0	0	29.7	8.6	0	0.2	1.0	0.3

1) The DOE and its Contractors (Hanford). Hanford continued to dominate the local employment picture with almost one-quarter of the total nonagricultural jobs in Benton and Franklin counties in 1992 (16,100 of 67,300). Hanford's payroll has a widespread impact on the Tri-Cities economy and state economy in addition to providing direct employment. These effects are further described in Subsection 4.3.

2) Washington Public Power Supply System. Although activity related to nuclear power construction ceased with the completion of the WNP-2 reactor in 1983, the Washington Public Power Supply System continues to be a major employer in the Tri-Cities area. Headquarters personnel based in Richland oversee the operation of one generating facility and perform a variety of functions related to two mothballed nuclear plants and one standby generating facility. In 1992, the Washington Public Power Supply System headquarters employment was more than 1700 workers. Washington Public Power Supply System activities generated a payroll of approximately $80.4 million in the Tri-Cities during the year.

3) Agriculture. In 1990 agricultural activities in Benton and Franklin counties were responsible for approximately 12,900 jobs, or 17 percent of the area's total employment. According to the U.S. Department of Commerce's Regional Economic Information System, about 2200 people were classified as farm proprietors in 1990. Farm proprietors' income from this same source was estimated at $121 million in the same year.

Crop and livestock production in the bicounty area generated about 7600 wage and salary jobs in 1990, as represented by the employees covered by unemployment insurance. The presence of seasonal farm workers would increase the total number of farm workers. Apart from the difficulty of obtaining reliable information on the number of seasonal workers, however, is the question of how much of these earnings are actually spent in the local area. For this analysis, the assumption is that the impact of seasonal workers on the local economy is sufficiently small to be safely ignored.

The area's farms and ranches generate a sizable number of jobs in supporting activities, such as agricultural services (for example, application of pesticides and fertilizers or irrigation system development) and sales of farm supplies and equipment. These activities, often called agribusiness, are estimated to employ 900 people. Although formally classified as a manufacturing activity, food processing is a natural extension of the farm sector. More than 20 food processors in Benton and Franklin counties produce such items as potato products, canned fruits and vegetables, wine, and animal feed.

In addition to those three major employment sectors, three other components are readily identified as contributors to the economic base of the Tri-Cities economy. The first component, categorized as other major employers, includes five employers: (1) Siemens Nuclear Power Corporation in north Richland, (2) Sandvik Special Metals in Kennewick, (3) Boise-Cascade in Wallula, (4) Burlington Northern Railroad in Pasco, and (5) Iowa Beef Processors in Wallula. The second component is tourism. The Tri-Cities area has increased its convention business substantially in recent years, in addition to business generated by travel for recreation. The final component in the economic base relates to the local purchasing power generated from retired former employees. Government transfer payments in the form of pension benefits constitute a significant proportion of total spendable income in the local economy.

Retirees. Although the Benton and Franklin counties have a relatively young population (approximately 56 percent under the age of 35), 15,093 people over the age of 65 resided in Benton and Franklin counties in 1990. The portion of the total population that is 65 years and older is currently increasing at about the same rate as that being experienced by Washington State (3.0 percent and 3.1 percent, respectively). This segment of the population supports the local economy on the basis of income received from government transfer payments and pensions, private pension benefits, and prior individual savings.

Although information on private pensions and savings is not available, data are available regarding the magnitude of government transfer payments. The U.S. Department of Commerce's Regional Economic Information System has estimated transfer payments by various programs at the county level. A summary of estimated major government pension benefits received by the residents of Benton and Franklin counties in 1990 is shown in Table 4.3-7. About two-thirds of the Social Security payments go to retired workers; the remainder are for disability and other payments. The historical importance of government activity in the Tri-Cities area is reflected in the relative magnitude of the government employee pension benefits as compared to total payments.

Table 4.3-7. Government retirement payments in Benton and Franklin counties in 1990 ($ million).

Source	Benton County	Franklin County	Total
Social Security (including survivors and disability)	101.5	31.1	132.6
Railroad retirement	2.7	3.6	6.3
Federal civilian retirement	10.5	2.8	13.3
Veterans pension and military retirement	14.7	3.1	17.8
State and local employee retirement	22.3	5.5	27.8
Total	151.7	46.1	197.8

4.3.2.3 Income Sources. Three measures of income are presented in

Table 4.3-8: total personal income, per capita income, and median household **income.** Total personal income is comprised of all forms of income received by the populace, including wages, dividends, and other revenues. Per capita income is roughly equivalent to total personal income divided by the number of people residing in the area. Median household income is the point at which half of the households have an income greater than the median and half have less. The source for total personal income and per capita income was the U.S. Department of Commerce's Regional Economic Information System; while median income figures for Washington State were provided in Washington State Office of Financial Management (1992b), and by personal communication with the Bureau of Census Housing Division for Oregon.

In 1990 the total personal income for the Washington was $92.2 billion; of this, the counties within the region of influence comprised 8.0 percent. Per capita income for Washington State was $18,777; all Washington counties within the region of influence had per capita incomes less than that of the state. All Washington counties within the region of influence, with the exception of Benton, had median household incomes less than the state median of $32,725.

In 1990 the total personal income for Oregon was $49.2 billion; of this, the counties within the region of influence comprised 2.4 percent. Per capita income for Oregon State was $17,182; two of the three affected Oregon counties had per capita incomes greater than that of the state in 1990; however, only one of the three counties had a median household income greater than the state median of $27,250.

Table 4.3-8. Income measures by county, 1990 figures.

County	Total Personal Income ($ Million)	Per Capita Income ($)	Median Income ($)
Adams	231	16,897	25,750

Benton	1,960	17,332	33,800
Columbia	72	17,927	21,000
Franklin	553	14,734	26,300
Grant	854	15,511	23,625
Walla Walla	799	16,438	25,400
Yakima	2,920	15,374	24,525
Morrow	144	18,868	29,969
Umatilla	896	15,069	22,791
Wallowa	121	17,461	21300

4.3.2.4 Hanford Employment. In 1991 Hanford employment accounted

directly for 24 percent of total nonagricultural employment in Benton and Franklin counties and slightly more than 0.6 percent of all statewide nonagricultural jobs. In 1991 Hanford Site operations directly accounted for an estimated 42 percent of the payroll dollars earned in the area.

Previous studies have revealed that each Hanford job supports about 1.2-additional jobs in the local service sector of Benton and Franklin counties (about 2.2 total jobs) and about 1.5 additional jobs in the state's service sector (about 2.5 total jobs) (Scott et al. 1987). Similarly, each dollar of Hanford income supports about 2.1 dollars of total local incomes and about 2.4 dollars of total statewide incomes. Based on these multipliers, Hanford directly or indirectly accounts for more than 40 percent of all jobs in Benton and Franklin counties.

Based on employee residence records as of December 1993, 93 percent of the direct employment of Hanford is comprised of residents of Benton and Franklin counties. Approximately 81 percent of the employment is comprised of residents who reside in one of the Tri-Cities. More than 42 percent of the employment is comprised of Richland residents, 30 percent of Kennewick residents, and 9 percent of Pasco residents. West Richland, Benton City, Prosser, and other areas in Benton and Franklin counties account for 12 percent of total employment. Table 4.3-9 contains the estimated percent of Hanford employees residing in each of the counties within the region of influence. The information available did not include the residences of DOE employees nor those of ICF Kaiser Hanford Company or the Bechtel Hanford Company. It was assumed that the distribution of these employees would be similar to the distribution of the other Hanford contractors.

Table 4.3-9. Hanford employee residences by county.

County	Percent of Employees in Residence
Adams	0.18%
Benton	84.16%
Columbia	0.01%
Franklin	9.07%
Grant	0.25%
Walla Walla	0.21%
Yakima	5.08%
Morrow	0.01%
Umatilla	0.01%

Hanford and contractors spent nearly $298 million, or 45.6 percent of total procurements of $653 million, initially through Washington firms in 1993. About 18 percent of Hanford orders were filled by Tri-Cities firms.

Hanford contractors paid a total of $10.9 million in state taxes on operations and purchases in fiscal year 1988 (the most recent year available). Estimates show that Hanford employees paid $27.0 million in state sales tax, use taxes, and other taxes and fees in fiscal year 1988. In addition, Hanford paid $0.9 million to local government in Benton, Franklin, and Yakima counties in local taxes and fees (Scott et al. 1989).

4.3.3 Emergency Services

This subsection contains information on the law enforcement, fire protection, and health services provided by each county within the region of influence. These figures are presented in Table 4.3-10, with more detailed information about the Tri-Cities area. Law enforcement figures were obtained from each county sheriff's office in December 1993. Data on fire protection and health care facilities were provided by the Office of the Secretary of State (1993).

Table 4.3-10. Emergency services within the region of influence.

County	Commissioned Officers - County Sheriff	Number of Fire Districts - Unincorporated	Number of Hospitals
Adams	16 + Sheriff	7	2
Benton	40	6	3
Columbia	10 + Sheriff	3	1
Franklin	18 + Sheriff	4	1
Grant	35 + Sheriff	12	1
Walla Walla	16 + Sheriff	8	2
Yakima	63	12	3
Morrow	70	NA	NA
Umatilla	12	NA	NA
Wallowa	5	NA	NA

Police protection in Benton and Franklin counties is provided by the Benton and Franklin County sheriff's departments, local municipal police departments, and the Washington State Patrol Division headquartered in Kennewick. Table 4.3-11 shows the number of commissioned officers and patrol cars in each department in June 1992.

Table 4.3-11. Police personnel in the Tri-Cities in 1992.

Area	Commissioned Officers	Patrol Cars
Kennewick Municipal	58	32
Pasco Municipal	39	11
Richland Municipal	44	35
West Richland Municipal	7	9
County Sheriff, Benton County	43	50
County Sheriff, Franklin County	23	23

Source: Personal communication with each department office, January 1993.

The Kennewick, Richland, and Pasco municipal departments maintain the largest staffs of commissioned officers with 53, 44, and 38, respectively.

The Hanford Fire Department, composed of 126 firefighters, is trained to dispose of hazardous waste and to fight chemical fires. During the 24-hour duty period, five firefighters cover the 1100 Area, seven protect the 300 Area, seven watch the 200-East and 200-West Areas, six are responsible for the 100 Areas, and six cover the 400 Area, which includes the WPPSS area. To perform their responsibilities, each station has access to a Hazardous Material Response Vehicle that is equipped with chemical fire extinguishing equipment, an attack truck that carries foam and Purple-K dry chemical, a mobile air truck that provides air for gasmasks, and a transport tanker that supplies water to six brush-fire trucks. The Hanford Fire Patrol owns five ambulances and maintains contact with local hospitals.

Table 4.3-12 indicates the number of fire-fighting personnel, both paid and unpaid, on the staffs of fire districts in the Tri-Cities area.

The Tri-Cities area is served by three hospitals: Kadlec Hospital, Kennewick General, and Our Lady of Lourdes. In addition, the Carondelet Psychiatric Care Center is located in Richland. Kadlec Hospital, located in Richland, has 136 beds and functions at 39.5 percent capacity. Their 5754 annual admissions represent more than 42 percent of the Tri-Cities market. Non-Medicare/Medicaid patients accounted for 86 percent, or 4982 of their annual admissions. An average stay of 3.8 days per admission was reported for 1991.

Table 4.3-12. Fire protection in the Tri-Cities in 1992[a].

Station	Fire-Fighting Personnel	Volunteers	Total	Service Area
Kennewick	54	0	54	City of Kennewick
Pasco	30	0	30	City of Pasco
Richland	50	0	50	City of Richland
BCRFD[b] 1	6	120	126	Kennewick Area
BCRFD 2	1	31	32	Benton City
BCRFD 4	4	30	34	West Richland

a. Source: Personal communication with each department office, January 1993.

b. BCRFD = Benton County Rural Fire Department.

Kennewick General Hospital maintains a 45.5 percent occupancy rate of its 71 beds with 3619 annual admissions. Non-Medicare/Medicaid patients in 1991 represented 58 percent of its total admissions. An average stay of 3.5 days per admission was reported.

Our Lady of Lourdes Health Center, located in Pasco, reported an occupancy rate of 36.5 percent; however, a significant amount of outpatient care is performed there. The out patient income serves as a primary source of income for the center. In 1990 Our Lady of Lourdes had 3328 admissions, of which 52 percent were non-Medicare/Medicaid patients. The institution reported an average admission stay of 5.33 days.

4.3.4 Infrastructure

4.3.4.1 Housing. This section provides information on the total number

of housing units, the number of occupied housing units, and a breakdown of total housing units by type for each of the counties within the region of influence. Additionally, specific information on the housing market in the Tri-Cities is included. The data source for Washington counties was the Washington State Office of Financial Management (1992b). The data source for the Oregon counties was by personal communication with the Population Research Center at Portland State University. The data source for the Tri-Cities was by personal communication with the Washington State Office of Financial Management. Table 4.3-13 summarizes housing information by county for 1990 for the region of influence.

In 1993 nearly 94 percent of all housing (of 40,344 total units) in the Tri-Cities was occupied. Single-unit housing, which represents nearly 58 percent of the total units, had a 97 percent occupancy rate throughout the Tri-Cities. Multiple-unit housing, defined as housing with two or more units, had an occupancy rate of nearly 94 percent. Pasco had the lowest occupancy rate, 92 percent, in all categories of housing; followed by Kennewick, 95 percent, and Richland, 96 percent. Mobile homes, which represent 9 percent of the housing unit types, had the lowest occupancy rate, 90 percent. In 1989 mobile homes had the highest occupancy rate, 93 percent. Table 4.3-14 shows a detailed listing of total units and occupancy rate by type in the Tri-Cities.

Table 4.3-13. Housing by county in 1990.

County	Total	Occupied	Vacancy Rate	Single Family	Multiple Family	Mobile Homes
Adams	5,263	4,586	12.9%	3,324	643	1,296
Benton	44,877	42,227	5.9%	28,193	10,592	6,092
Columbia	2,046	1,582	22.7%	1,597	146	303
Franklin	13,664	12,196	10.7%	7,782	3,289	2,593
Grant	22,809	19,745	13.4%	13,692	2,661	6,456
Walla Walla	19,029	17,623	7.4%	13,071	3,837	2,121
Yakima	70,852	65,985	6.9%	49,356	11,174	10,322
Morrow	3,412	2,803	17.8%	1,828	366	1,192
Umatilla	24,333	22,020	9.5%	15,178	4,503	4,418
Wallowa	3,755	2,796	25.5%	2,935	235	554

4.3.4.2 Human Services. The Tri-Cities offer a broad range of social

services. State human service offices in the Tri-Cities include the Job Services office of the Employment Security Department; Food Stamp offices; the Division of Developmental Disabilities; Financial and Medical Assistance; the Child Protective Service; emergency medical service; a senior companion program; and vocational rehabilitation.

Table 4.3-14. Total units and occupancy rates (1993 estimates)a.

City	All Units	Rate	Single Units	Rate	Multiple Units	Rate	Mobile Homes	Rate
Richland	14,388	96	9,921	98	3,827	95	640	88
Pasco	7,846	92	3,679	96	2,982	91	1,016	86
Kennewick	18,110	95	9,824	97	5,944	96	1,942	97
Tri-Cities	40,344	94	23,424	97	12,753	94	3,598	90

a. Source: Personal communication, Office of Financial Management, State of Washington, Forecast Division.

The Tri-Cities are also served by a large number of private agencies and voluntary human services organizations. The United Way, an umbrella fund-raising organization, incorporates 25 participating agencies offering more than 50 programs (United Way 1992).

4.3.4.3 Government. This subsection presents the county government

revenues by source (Table 4.3-15) and expenditures by function (Table 4.3-16) for each of the counties within the region of influence. The data were taken from U.S. Department of Commerce (1990, 1993). All county data, with the exception of Benton and Yakima counties, are from 1986-87. Benton and Yakima county data are from 1990-91. These years were the most recent ones available.

4.3.4.4 Public Education. This subsection provides information on the

educational sectors of each of the counties. The source for school district information, secondary education, and enrollment data for the Washington counties was the Office of the Secretary of State (1993); student/teacher ratios were provided by personal communication with the school districts. Information on the Oregon counties was provided by personal communication with the individual counties. Table 4.3-17 summarizes information on the number of school districts, enrollment, and post-secondary institutions within the region of influence.

In the Tri-Cities area, Benton County primary and secondary education is served by six school districts with an enrollment of 24,876 students in 1992. The student/teacher ratio in the Finley School District is 20.2; in Kennewick, 24.0; in Kiona Benton-City, 25.0; in Prosser, 22.0 for elementary and 25.0 for secondary; and in Richland, 23.0. The Paterson School District had an enrollment of 54 students in 1992, therefore a student/teacher ratio was not sought. Currently, the Kennewick, Richland, and Kiona-Benton City school districts are operating at or near capacity; Kennewick is working to alleviate some of the overcrowded conditions by constructing one new middle school and two new elementary schools. In addition, plans are under way for the construction of a new high school, scheduled to open in 1997. Kiona-Benton City is in the process of building additions at elementary and middle schools. The county also has a post-secondary institution located in Richland, a branch campus of Washington State University, WSU Tri-Cities. Enrollment for spring 1992 was 981 students.

Franklin County primary and secondary education is served by four school districts with an enrollment of 8,756 students in 1992 and a student/teacher ratio of 7.0 in Kahlotus; 17.6 in

North Franklin; and 18.1 in Pasco. The Star School District had an enrollment of 15 students in 1992; therefore, a student/teacher ratio was not sought. Currently, Pasco School District is operating at or near capacity; however, the district is in the process of remodeling an old high school. The county also has a post-secondary institution of learning in Pasco, Columbia Basin Community College. Enrollment for 1992 was 6424 students.

4.4 Cultural Resources

The Hanford Site is known to be rich in cultural resources. It contains numerous, well-preserved archaeological sites representing both the prehistoric and historical periods and is still thought of as a homeland by many Native American people. A total of 248 known sites are prehistoric, 202 are historic, and 14 sites contain both prehistoric and historic components. Management of Hanford's cultural resources follows the Hanford Cultural Resources Management Plan (Chatters 1989) and is conducted by the Hanford Cultural Resources Laboratory of Pacific Northwest Laboratory (PNL). The Plan contains contingency guidelines for handling the discovery of previously unknown cultural resources encountered during construction activities.

Cultural resources are defined as any prehistoric or historic district, site, building, structure, or object considered to be important to a culture, subculture, or community for scientific, traditional, religious or any other reason. These are usually divided into three major categories: prehistoric and historic archaeological resources, architectural resources, and traditional cultural resources. Significant cultural resources are those that are eligible or potentially eligible to the National Register of Historic Places (36 CFR 60.4).

Consultation is required to identify traditional cultural properties that are important to maintaining the cultural heritage of Native American Tribes. Under the Treaties of 1855, lands ultimately occupied by the Hanford Site were ceded to the United States by the confederated tribes and bands of the Yakama Indian Nation, and Confederated Tribes of the Umatilla Indian Reservation. Under the treaty, the Native American Tribes acquired the rights to perform certain activities on open unclaimed lands, including the rights to hunt, fish, gather foods and medicines, and pasture livestock on these lands. By the time the Hanford Site was established, little open unclaimed land remained. The Wanapum Band and the Joseph Band of the Nez Perce Tribes never signed a treaty but have cultural ties to these lands.

The methodology for identifying, evaluating, and mitigating impacts to cultural resources is defined by federal laws and regulations including the National Historic Preservation Act (NHPA), the Archaeological Resource Protection Act (ARPA), the Native American Graves Protection and Repatriation Act (NAGPRA) and the American Native American Religious Freedom Act (AIRFA). A project affects a significant resource when it alters the property's characteristics, including relevant features of its environment or use, that qualify it as significant according to the National Register criteria. These effects may include those listed in 36 CFR 800.9. Impacts to traditional Native American properties can be determined only through consultation with the affected Native American groups.

4.4.1 Prehistoric Archaeological Resources

People have inhabited the Middle Columbia River region since the end of the glacial period. More than 10,000 years of prehistoric human activity in this largely arid environment have left extensive archaeological deposits along the river shores (Leonhardy and Rice 1970; Greengo 1982; Chatters 1989). Well-watered areas inland from the river show evidence of concentrated human activity (Chatters 1982, 1989; Daugherty 1952; Greene 1975; Leonhardy and Rice 1970; Rice 1980), and recent surveys indicate extensive, although dispersed, use of arid lowlands for hunting. Graves are common in various settings, and spirit quest monuments are still to be found on high, rocky summits of the mountains and buttes (Rice 1968a). Throughout most of the region, hydroelectric development, agricultural activities, and domestic and industrial construction have destroyed or covered the majority of these deposits. Amateur artifact collectors have had an immeasurable impact on what remains. Within the Hanford Site, from which the public is restricted, archaeological deposits found in the Hanford Reach of the Columbia River and on adjacent plateaus and mountains have been spared some of the disturbances that have befallen other sites. The Hanford Site is thus a de facto reserve of archaeological information of the kind and quality that has been lost elsewhere in the region.

Currently 248 prehistoric archaeological sites are recorded in the files of the Hanford Cultural Resources Laboratory. Of 48 sites included on the National Register of Historic Places (National Register), two are single sites, Hanford Island Site (45BN121) and Paris Site (45GR317), and the remainder are located in seven archaeological districts (Table 4.4-1). In addition, a draft request for Determination of Eligibility has been prepared for one traditional cultural property district (Gable Mountain/Gable Butte). Three other sites, Vernita Bridge (45BN90) and Tsulim (45BN412), and 45BN163, are considered eligible for the National Register. Archaeological sites include remains of numerous pithouse villages, various types of open campsites, and cemeteries along the river banks (Rice 1968a, 1980), spirit quest monuments (rock cairns), hunting camps, game drive complexes, and quarries in mountains and rocky bluffs (Rice 1968b), hunting/kill sites in lowland stabilized dunes, and small temporary camps near perennial sources of water located away from the river (Rice 1968b).

Many recorded sites were found during four archaeological reconnaissance projects conducted between 1926 and 1968 (Krieger 1928; Drucker 1948; Rice 1968a, 1968b). Systematic archaeological surveys conducted from the middle 1980s through 1993 are responsible for the remainder (e.g., Chatters 1989; Chatters and Cadoret 1990; Chatters and Gard 1992; Chatters et al. 1990, 1991, 1992, 1993). Little excavation has been conducted at any of the sites, and the Mid-Columbia Archaeological Society has done most of that work. They have conducted minor test excavations at several sites on the river banks and islands (Rice 1980) and a larger scale test at site 45BN157 (Den Beste and Den Beste 1976). The University of Idaho also excavated a portion of site 45BN179 (Rice 1980) and collaborated with the Mid-Columbia Archaeological Society on its other work. Test excavations have been conducted by the Hanford Cultural Resources Laboratory at the Wahluke (45GR306), Vernita Bridge (45BN90), and Tsulim (45BN412) sites and at 45BN446, 45BN423, 45BN163, 45BN432, and 45BN433; results support assessments of significance for those sites. Most of the archaeological survey and reconnaissance activity has concentrated on islands and on a strip of land less than 400 meters wide on either side of the river (Rice 1980), but this is changing because of a Hanford Cultural Resources Laboratory effort to inventory a 10 percent sample of the site by 1994. During his reconnaissance of the Hanford Site in 1968, Rice inspected portions of Gable Mountain, Gable Butte, Snively Canyon, Rattlesnake Mountain, and Rattlesnake Springs but gave little attention to other areas (Rice 1968b). He also inspected additional portions of Gable Mountain and part of Gable Butte in the late 1980s (Rice 1987). Other reconnaissance of the Basalt Waste Isolation Project Reference Repository Location (RRL) (Rice 1984) included a proposed land exchange in T22N, R27E, Section 33 (Rice 1981), and three narrow transportation and utility corridors (Ertec Northwest, Inc. 1982; Morgan 1981; Smith et al. 1977). The 100 Areas were surveyed in 1991 through 1993, revealing a large number of new archaeological sites (Chatters et al. 1992; Wright 1993). To date only about

b. Not applicable.

6 percent of the Hanford Site has been surveyed. Cultural resource reviews are conducted when projects are proposed for areas that have not been previously reviewed; about 100 to 120 reviews were conducted annually through 1991; this figure rose to more than 400 reviews during 1993.

4.4.2 Native American Cultural Resources

In prehistoric and early historic times, the Hanford Reach of the Columbia River was heavily populated by Native Americans of various tribal affiliations. The Wanapum and the Chamnapum band of the Yakama tribe dwelt along the Columbia River from south of Richland upstream to Vantage (Relander 1956; Spier 1936). Some of their descendants still live nearby at Priest Rapids, and others have been incorporated into the Yakama and Umatilla reservations. Palus people, who lived on the lower Snake River, joined the Wanapum and Chamnapum to fish the Hanford Reach of the Columbia River and some inhabited the river's east bank (Relander 1956; Trafzer and Scheuerman 1986). Walla Walla and Umatilla people also made periodic visits to fish in the area. These people retain traditional secular and religious ties to the region, and many, young and old alike, have knowledge of the ceremonies and lifeways of their aboriginal culture. The Washane, or Seven Drums religion, which has ancient roots and had its start on what is now the Hanford Site, is still practiced by many people on the Yakama, Umatilla, Warm Springs, and Nez Perce reservations. Native plant and animal foods, some of which can be found on the Hanford Site, are used in the ceremonies performed by sect members.

4.4.3 Historic Archaeological Resources

The first Euro-Americans who came to this region were Lewis and Clark, who traveled along the Columbia and Snake rivers during their 1803-1806 exploration of the Louisiana Territory. They were followed by fur trappers, who also passed through on their way to more productive lands upriver and downstream and across the Columbia Basin. It was not until the 1860s that merchants set up stores, a freight depot, and the White Bluffs Ferry on the Hanford Reach. Chinese miners began to work the gravel bars for gold. Cattle ranches opened in the 1880s and farmers soon followed. Several small, thriving towns, including Hanford, White Bluffs, and Ringold, grew up along the riverbanks in the early 20th century. Other ferries were established at Wahluke and Richmond. The towns and nearly all other structures were razed after the U.S. Government acquired the land for the Hanford Nuclear Reservation in the early 1940s (Chatters 1989; Ertec Northwest, Inc. 1981; Rice 1980).

Historic archaeological sites totaling 202 and 11 other historic localities have been recorded by the Hanford Cultural Resources Laboratory on the Hanford Site. Localities include the Allard Pumping Plant at Coyote Rapids, the Hanford Irrigation Ditch, the Hanford townsite, Wahluke Ferry, the White Bluffs townsite, the Richmond Ferry, Arrowsmith townsite, a cabin at East White Bluffs ferry landing, the White Bluffs road, the old Hanford High School, and the Cobblestone Warehouse at Riverland (Rice 1980). Archaeological sites including the East White Bluffs townsite and associated ferry landings and an assortment of trash scatters, homesteads, corrals, and dumps have been recorded by the Hanford Cultural Resources Laboratory since 1987. Ertec Northwest, Inc. was responsible for minor test excavations at some of the historic sites, including the Hanford townsite locality. In addition to the recorded sites, numerous unrecorded site areas of gold mine tailings along the river bank and the remains of homesteads, farm fields, ranches, and abandoned Army installations are scattered over the entire Hanford Site. Of these historic sites, one is included in the National Register as an historic site, and 56 are listed as archeological sites.

More recent locations are the defense reactors and associated materials processing facilities that now dominate the site. The first reactors (B, D, and F) were constructed in 1943 as part of the Manhattan Project. Plutonium for the first atomic explosion and the bomb that destroyed Nagasaki to end World War II was produced in the B Reactor. Additional reactors and processing facilities were constructed after World War II during the Cold War. All reactor containment buildings still stand, although many ancillary structures have been removed. The B Reactor has been listed on the National Register of Historic Places. A historic context for Manhattan Project facilities has been created as part of a Multiple Property Document. Until a full evaluation of all Manhattan Project buildings and facilities has been completed, statements about National Register status cannot be made.

4.4.4 200 Areas

An archaeological survey has been conducted of all undeveloped portions of the 200-East Area, and a 50 percent random sample has been conducted of undeveloped portions of the 200-West Area. The old White Bluffs freight road (see Rice 1984) crosses diagonally through the 200-West Area. The road, formerly a Native American trail, has been in continuous use since antiquity and has played a role in Euro-American immigration, development, agriculture, and Hanford Site operations. The road has been found to be eligible for listing on the National Register of Historic Places. A 100-m easement has been created to protect the road from uncontrolled disturbance. Historic buildings that have not been evaluated for National Register eligibility occur in both the 200-East and 200-West Areas.

4.5 Aesthetic and Scenic Resources

The land in the vicinity of the Hanford Site is generally flat with little relief. Rattlesnake Mountain, rising to 1060 meters (3477 feet) above mean sea level, forms the western boundary of the site. Gable Mountain and Gable Butte are the highest land forms within the site. The view toward Rattlesnake Mountain is visually pleasing, especially in the springtime when wildflowers are in bloom. Large rolling hills are located to the west and far north. The Columbia River, flowing across the northern part of the site and forming the eastern boundary, is generally considered scenic, with its contrasting blue against a background of brown basaltic rocks and desert sagebrush. The White Bluffs, steep whitish-brown bluffs adjacent to the Columbia River and above the northern boundary of the river in this region, are a striking feature of the landscape.

The potential project site (under all alternatives except No Action) is characterized by large sagebrush, desert grasses, and shrubs. Immediate views to the east include the 200-East Area facilities, views in the distant north area of reactors. Somewhat hidden by a slight rise in the land are stacks for facilities in 200-West Area to the west of the project site. To the south southwest are gravel borrow pit and radio and meteorological towers. This site is of low sensitivity in terms of aesthetic and scenic resources.

4.6 Geology

This section summarizes the geologic setting, including potential geologic hazards, at the Hanford Site. Physiography, structure, soils, and seismicity and volcanic hazards are briefly discussed. A more detailed discussion of these subjects can be found in Cushing (1992).

4.6.1 General Geology

The Hanford Site lies within the Columbia Intermontane physiographic province, bordered on the north and east by the Rocky Mountains and on the west by the Cascade Range. The dominant geologic characteristics of the Hanford Site have resulted from basaltic volcanism and ancient catastrophic flooding.

Fluvial and lacustrine processes associated with the ancestral Columbia River system, including the ancestral Snake and Yakima rivers, have been active since the late Miocene. Deposits of these rivers and lakes are represented by the Ringold Formation and indicate that deposition was almost continuous from about 10.5 million years before present until about 3.9 million years before present (DOE 1988). At some time before 900,000 years ago, a major change in regional base level resulted in fluvial incision of as much as 150 meters (500 feet). The post-Ringold erosional surface was partially filled with locally derived alluvium and fluvial sediment before and possibly between periods of Pleistocene flooding. However, in most areas of the Columbia Basin subprovince, the record of Pleistocene fluvial activity was destroyed by cataclysmic flooding. Loess (buff-colored silt) occurs in sheets that mantle much of the upland areas of the Columbia Basin subprovince.

Quaternary(a) volcanism has been limited to the extreme western margin of the Columbia Basin subprovince and is associated with the Cascade Range Province. Airfall tephra(b) from at least three Cascade volcanoes has blanketed the central Columbia Plateau since the late Pleistocene. This tephra includes material from several eruptions of Mount St. Helens before the May 1980 eruption. Other volcanoes have erupted less frequently; two closely spaced eruptions from Glacier Peak about 11,200 years ago, and the eruption of - Mount Mazama about 6,600 years ago. Generally tephra layers have not exceeded more than a few centimeters in thickness, with the exception of the Mount Mazama eruption when as much as 10 centimeters (3.9 inches) of tephra fell over eastern Washington (DOE 1988).

4.6.1.1 Physiography. The Hanford Site, located within the Pasco Basin of

the Columbia Plateau, is defined generally by a thick accumulation of basaltic lava flows that extend laterally from central Washington eastward into Idaho and southward into Oregon (Tallman et al. 1979).

The Hanford Site overlies the structural low point of the Pasco Basin near the confluence of the Yakima and Columbia rivers. The boundaries of the Pasco Basin are defined by anticlinal structures of basaltic rock. These structures are the Saddle Mountains to the north; the Umtanum Ridge, Yakima Ridge, and Rattlesnake Hills to the west; and the Rattlesnake Hills and a series of doubly plunging anticlines merging with the Horse Heaven Hills to the south.

The terrain within the Pasco Basin is relatively flat. Its surface features were formed by catastrophic floods and have undergone little modification since, with the exception of more recently formed sand dunes (DOE 1986a).

The elevations of the alluvial plain that covers much of the site vary from 105 meters (345 feet) above mean sea level in the southeast corner to 245 meters (803 feet) in the northwest. The 200-Area plateau in the central part of the site varies in elevation from 190 to 245 meters (623 to 803 feet).

The major geologic units of the Hanford Site are (in ascending order): subbasalt rocks (inferred to be sedimentary and volcanoclastic rocks), the Columbia River Basalt Group with intercalated sediments of the Ellensburg formation, the Ringold formation, the Plio-Pleistocene unit, and the Hanford formation. Locally, sand and silt exist as surface material. A generalized stratigraphic column is shown in Figure 4.3.

Knowledge of the subbasalt rocks is limited to studies of exposures along the margin of the Columbia Plateau and to a few deep boreholes drilled in the interior of the plateau (DOE 1988). No subbasalt rocks are exposed within the central interior of the Columbia Plateau, including the Pasco Basin. Interpretation of data from wells drilled in the 1980s by Shell Oil Company in the northwestern Columbia Plateau indicates that in the central part of the Columbia Plateau the Columbia River Basalt Group is underlain predominantly by Tertiary continental sediments (Campbell 1989).

The Hanford formation lies on the eroded surface of the Plio-Pleistocene unit, on the Ringold formation, or locally on the basalt bedrock. The Hanford formation consists of catastrophic flood sediments that were deposited when ice dams in western Montana and northern Idaho were breached and massive volumes of water spilled abruptly across eastern and central Washington. The floods scoured the land surface, locally eroding the Ringold formation, the basalts, and sedimentary interbeds, leaving a network of buried channels crossing the Pasco Basin (Tallman et al. 1979). Thick sequences of sediments were deposited by several episodes of flooding with the last major flood sequence dated at about 13,000 years before the present (Myers et al. 1979).

Figure 4-3. A generalized stratigraphic column of the major geologic units of the Hanford Site.

4.6.1.2 Structure. The Columbia Plateau is tectonically a part of the

North American continental plate, and is separated from the Pacific and Juan de Fuca oceanic plates to the west by the Cascade Range, Puget-Willamette Lowland, and Coast Range geologic provinces. It is bounded on the north by the Okanogan Highlands, on the east by the Northern Rocky Mountains and Idaho Batholith, and on the south by the High Lava plains and Snake River plain. The tectonic history of the Columbia Plateau has included the eruption of the continental flood basalts of the Columbia River Basalt Group during the period of about 17 to 6 million years before present, as well as volcanic activity in the Cascade Range to the west (DOE 1988).

Structurally, the Columbia Plateau can be divided into three informal

---

a. Quaternary- A geologic period beginning approximately two million years ago and extending to the present.

b. Tephra- A collective term for all clastic materials ejected from a volcano and transported through air.

subprovinces: the Palouse, Blue Mountains, and Yakima Fold Belt. All but the easternmost part of the Pasco Basin is within the Yakima Fold Belt structural subprovince (DOE 1988). The Yakima Fold Belt contains four major structural elements: the Yakima Folds, Cle Elum-Wallula disturbed zone, Hog Ranch-Naneum anticline, and northwest-trending wrench faults.

The Yakima Folds are a series of continuous, narrow, asymmetric anticlines that have wavelengths between about 5 and 30 kilometers (3 to 19 miles) and amplitudes commonly less than 1 kilometers (less than 0.6 miles). The anticlinal ridges are separated by broad synclines or basins. The Yakima Folds are believed to have developed under generally north-south compression, but the origin and timing of the deformation along the fold structures are not well known (DOE 1988). Thrust or high-angle reverse faults are often found along both limbs of the anticlines, with the strike of the fault planes parallel or subparallel to the axis of the anticlines. Very little direct field evidence indicates quaternary movement along these anticlinal ridges. One of three cases of suspected Quaternary faulting is along the central Gable Mountain fault in the Pasco Basin. This fault is on the Hanford Site. It was considered by the NRC to be presumed capable, but not demonstrated to be capable for licensing purposes of the WNP plant.

The Cle Elum-Wallula disturbed zone is the central part of a larger topographic alignment called the Olympic-Wallowa lineament that extends from the northwestern edge of the Olympic Mountains to the northern edge of the Wallowa Mountains in Oregon. The Cle Elum-Wallula disturbed zone is a narrow zone about 10 kilometers (6 miles) wide that transects the Yakima Fold Belt and has been divided informally into three structural domains: a broad zone of deflected or anomalous fold and fault trends extending south of Cle Elum, Washington to Rattlesnake Mountain; a narrow belt of aligned domes and doubly plunging anticlines (called The Rattles) extending from Rattlesnake Mountain to Wallula Gap; and the Wallula fault zone, extending from Wallula Gap to the Blue Mountains. Evidence for quaternary deformation has been reported for 14 localities in or directly associated with the Cle Elum-Wallula disturbed zone. However, no evidence has been reported northwest of the Finley Quarry location (DOE 1988), about 60 kilometers (36 miles) southeast of the approximate center of the Hanford Site.

The Hog Ranch-Naneum Ridge anticline is a broad structural arch that extends from southwest of Wenatchee, Washington to the Yakima Ridge. This feature defines part of the northwestern boundary of the Pasco Basin, but little is known about the structural geology of this portion of the feature, and the southern extent of the feature is not known.

Northwest-trending wrench (strike-slip) faults have been mapped west of 120yW longitude in the Columbia Plateau (DOE 1988). The mean strike direction of the dextral wrench faults is 320y, but northeast-trending sinistral wrench faults that strike 013y are less numerous. These structures are not known to exist in the central Columbia Plateau.

Most known faults within the Hanford area are associated with anticlinal fold axes, are thrust or reverse faults although normal faults do exist, and were probably formed concurrently with the folding (DOE 1988). Existing known faults within the Hanford area include wrench (strike-slip) faults as long as 3 kilometers (1.9 miles) on Gable Mountain and the Rattlesnake-Wallula alignment, which has been interpreted as a right-lateral strike-slip fault. The faults in Central Gable Mountain are considered NRC capable by the U.S. Nuclear Regulatory Commission criteria (10 CFR 100) in that they have slightly displaced the Hanford formation gravels, but their relatively short lengths give them low seismic potential. No seismicity has been observed on or near Gable Mountain. The Rattlesnake-Wallula alignment is interpreted as possibly being capable, in part because of lack of any distinct evidence to the contrary and because this structure continues along the northwest trend of faults that appear active at Wallula Gap, some 56 kilometers (35 miles) southeast of the central part of the Hanford Site (DOE 1988).

Strike-slip faults have not been observed crosscutting the Pasco Basin. Anticlinal ridges that bound the Pasco Basin have been mapped in detail, and except for some component of dextral movement on the Rattlesnake-Wallula alignment, no strike-slip faults similar to those in the western Yakima Fold Belt have been observed (DOE 1988). Wrench (strike-slip) faults have been observed along the ridges at boundaries between geometrically coherent segments of the structures, as in the Saddle Mountains, but these faults are confined to the individual structures and formed as different geometries developed in the fold. Similar type faults have been mapped on Gable Mountain and studied in detail. These features are also interpreted as wrench (stike-slip) faults that are a response to folding.

In general, for structures within the Hanford Site area, the greatest deformation occurs in the hinge area of the anticlinal ridges and decreases with distance from that area; that is, the greatest amount of tectonic jointing and faulting occurs in the hinge zone and decreases toward the gently dipping limbs. The faults usually exhibit low dips with small displacements, may be confined to the layer in which they occur, and die out to no recognizable displacement in short lateral distances (DOE 1988).

4.6.1.3 Soils. Hajek (1966) lists and describes 15 different soil types on

the Hanford Site. The soil types vary from sand to silty and sandy loam. Various classifications, including land use, are also given in Hajek (1966). The proposed SNF facility site does not contain prime or unique farmland.

Section 4.8.2.1 (Groundwater Hydrology) provides a full discussion on ranges of thickness of the various geological units/soil types across the Hanford Site (Figures 4-3 and 4-11). The surface Hanford Formation varies in thickness across the Hanford Site from approximately 15 to 100 meters (49 to 328 feet) thick (Figure 4-11). The Middle Ringold Formation varies from 10 to 100 meters (32 to 328 feet) thick. The Lower Ringold and Basal Ringold Formations only extend eastward from the western boundary of the Hanford Site approximately 11 kilometers (6.8 miles). The former is rather uniform in thickness at 20 meters (65 feet), while the latter demonstrates a maximum thickness of 40 meters (131 feet) at the far western boundary of the Hanford Site. Groundwater movement within these layers is also discussed in Section 4.8.2.1.

There is a rather thick vadose zone on the Hanford Site. However, conclusions drawn from studies conducted at several locations vary from no downward percolation of precipitation on the 200 Area Plateau, where soil texture is varied and layered with depth (all moisture penetrating the soil is removed by evaporation) to observations of downward water movement below the root zone in the 300 Area, where soils are coarse textured and where precipitation was above normal (DOE 1987).

4.6.2 Mineral Resources

Sand, gravel, and cobble deposits are ubiquitous components of the soils over the Columbia Basin in general and the Hanford Site in particular: therefore, any possible economic impact to these resources resulting from the siting of the proposed SNF facility or an access road would be considered negligible. However, because gravel pits occur near the proposed SNF facility site, from which the DOE has been extracting gravel for many uses on the Hanford Site, these deposits could have economic value.

4.6.3 Seismic and Volcanic Hazards

The following discussion briefly summarizes seismic and volcanic hazards on the Hanford Site. A more detailed discussion of seismic and volcanic hazards can be found in Cushing (1992).

4.6.3.1 Seismic Hazards. The historic record of earthquakes in the Pacific

Northwest dates from about 1840. The early part of this record is based on newspaper reports of structural damage and human perception of the shaking, as classified by the Modified Mercalli Intensity scale, and is probably incomplete because the region was sparsely populated. Seismograph networks did not start providing earthquake locations and magnitudes of earthquakes in the Pacific Northwest until about 1960. A comprehensive network of seismic stations that provides accurate locating information for most earthquakes larger than magnitude 2.5 was installed in eastern Washington in 1969. A summary of the seismicity of the Pacific Northwest, a detailed review of the seismicity in the Columbia Plateau region and the Hanford Site, and a description of the seismic networks used to collect the data are provided in DOE (1988).

Large earthquakes (magnitude greater than 7 on the Richter scale) in the Pacific Northwest have occurred in the vicinity of Puget Sound, Washington, and near the Rocky Mountains in eastern Idaho and western Montana. A large earthquake of uncertain location occurred in north-central Washington in 1872. This event had an estimated maximum ranging from VIII to IX and an estimated magnitude of approximately 7. The distribution of intensities suggests a location within a broad region between Lake Chelan, Washington and the British Columbia border. Figure 4-4 shows the known faults occurring in the region.

Figure 4.4. Map of the Columbia Basin region showing the known faults. Seismicity of the Columbia Plateau, as determined by the rate of earthquakes per area and the historical magnitude of these events, is relatively low when compared to other regions of the Pacific Northwest, the Puget Sound area and

western Montana/eastern Idaho. Figure 4-5 shows the locations of all earthquakes that occurred in the Columbia Plateau before 1969 with IV or larger and with a magnitude of 3 or larger. Figure 4-6 shows the locations of all earthquakes that occurred from 1969 to 1986 with magnitudes of 3 or greater. The largest known earthquake in the Columbia Plateau occurred in 1936 around Milton-Freewater, Oregon. This earthquake had a magnitude of 5.75 and a maximum of VII, and was followed by a number of aftershocks that indicate a northeast-trending fault plane. Other earthquakes with magnitudes of 5 or larger and/or intensities of VI are located along the boundaries of the Columbia Plateau in a cluster near Lake Chelan extending into the northern Cascade Range; in northern Idaho and Washington; and along the boundary between the western Columbia Plateau and the Cascade Range. Three VI earthquakes have occurred within the Columbia Plateau, including one in the Milton-Freewater region in 1921, one near Yakima, Washington in 1892, and one near Umatilla, Oregon in 1893.

In the central portion of the Columbia Plateau, the largest earthquakes near the Hanford Site are two that occurred in 1918 and 1973. These two earthquakes had magnitudes of 4.4 and an intensity of V and were located north of the Hanford Site. Earthquakes often occur in spatial and temporal clusters in the central Columbia Plateau, and are termed earthquake swarms. The region north and east of the Hanford Site is a region of concentrated earthquake swarm activity, but earthquake swarms have also occurred in several locations within the Hanford Site.

Earthquakes in a swarm tend to gradually increase and decay in frequency of events, and usually no one outstanding large event is present within the sequence. These earthquake swarms occur at shallow depths, with 75 percent of the events located at depths less than 4 kilometers (2.5 miles). Each earthquake swarm typically lasts several weeks to months, consists of several to 100 or more earthquakes, and is clustered in an area 5 to 10 kilometers (3 to 6 miles) in lateral dimension. Often, the longest dimension of the swarm area is elongated in an east-west direction. However, detailed locations of swarm earthquakes indicate that the events occur on fault planes of variable orientation, and not on a single, throughgoing fault plane.

Earthquakes in the central Columbia Plateau also occur to depths of about 30 kilometers (18 miles). These deeper earthquakes are less clustered and occur more often as single, isolated events. Based on seismic refraction surveys in the region, the shallow earthquake swarms are occurring in the Columbia River Basalts, and the deeper earthquakes are occurring in crustal layers below the basalts.

Figure 4-5. Historical seismicity of the Columbia Plateau and surrounding areas. All earthquakes between 1850 and 1969 with a Modified Mercalli Intensity of IV or larger with a magnitude of 3 or greater are shown (Rohay 1989).

Figure 4-6. Recent seismicity of the Columbia Plateau and surrounding areas as measured by seismographs. All earthquakes between 1969 and 1986 with a Modified Mercalli Intensity of IV or larger with a magnitude of 3 or greater are shown (Rohay 1989).

The spatial pattern of seismicity in the central Columbia Plateau suggests an association of the shallow swarm activity with the east-west-oriented Saddle Mountains anticline. However, this association is complex, and the earthquakes do not delineate a throughgoing fault plane that would be consistent with the faulting observed on this structure.

Earthquake mechanisms in the central Columbia Plateau generally indicate reverse faulting on east-west planes, consistent with a north-south-directed maximum compressive stress and with the formation of the east-west-oriented anticlinal fold of the Yakima Fold Belt (Rohay 1987). However, earthquake focal mechanisms indicate faulting on a variety of fault plane orientations.

Earthquake focal mechanisms along the western margin of the Columbia Plateau also indicate north-south compression, but here the minimum compressive stress is oriented east-west, resulting in strike-slip faulting (Rohay 1987). Geologic studies indicate an increased component of strike-slip faulting in the western portion of the Yakima Fold Belt. Earthquake focal mechanisms in the Milton-Freewater region to the southeast indicate a different stress field, one with maximum compression directed east-west instead of north-south.

Estimates for the earthquake potential of structures and zones in the central Columbia Plateau have been developed during the licensing of nuclear power plants at the Hanford Site. In reviewing the operating license application for a Washington Public Power Supply System project, the Nuclear Regulatory Commission (NRC 1982) concluded that four earthquake sources should be considered for the purpose of seismic design: the Rattlesnake-Wallula alignment, Gable Mountain, a floating earthquake in the tectonic province, and a swarm area.

For the Rattlesnake-Wallula alignment, which passes along the southwest boundary of the Hanford Site, the estimated maximum magnitude is 6.5, and for Gable Mountain, an east- west structure that passes through the northern portion of the Hanford Site, the estimated maximum magnitude is 5.0. These estimates were based upon the inferred sense of slip, the fault length, or the fault area. The floating earthquake for the tectonic province was developed from the largest event located in the Columbia Plateau, the magnitude 5.75

Milton-Freewater earthquake. The maximum swarm earthquake for the purpose of seismic design was a magnitude 4.0 event. Figures 4-7 through 4-11 demonstrate the ranges of frequencies versus the acceleration across the Hanford Site (Geomatrix Consultants, Inc. 1993).

The seismic design is based upon a Safe-Shutdown Earthquake of 0.25 gravity (g; acceleration). The potential earthquake risk associated with the Gable Mountain structure dominated the risks associated with other potential sources that were considered. For DOE site comparison purposes, a maximum horizontal ground surface acceleration of 0.17-0.20g at the Hanford Site is estimated to result from an earthquake that could occur once every 2,000 years (DOE 1994c). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities could be evaluated on a facility specific basis consistent with DOE orders and standards and site specific procedures.

4.6.3.2 Volcanic Hazards. Several major volcanoes are located in the

Cascade Range west of the Hanford Site. The nearest volcano, Mount Adams, is about 165 kilometers (102 miles) from the Hanford Site, and the most active is Mount St. Helens, approximately 220 kilometers (136 miles) west-southwest from Hanford.

A period of renewed volcanic activity at Mount St. Helens began in March 1980 and climaxed in a major eruption on May 18, 1980. This eruption resulted in about 1 millimeter (0.039 inches) of ash fall over a 9-hour period at the Hanford Site, which was near the southern edge of the ash dispersal plume. Smaller eruptions of steam and ash occurred through October 1980, but none of these deposited measurable amounts of ash at the site. Because of their close proximity, the volcanic mountains of the Cascades are the principal volcanic hazard at Hanford.

The major concern is how ash fall might affect the operation of communications equipment and electronic devices, as well as the movement of truck and automobile traffic in and out the project site area.

4.7 Air Resources

This section addresses the general air resources at the Hanford Site and surrounding region. Included in this section are discussions on climate and meteorology, ambient air quality, and atmospheric dispersion.

Figure 4-7. Computed mean and 5th to 95th percentile hazard curves for the 200-West Area of the Hanford Site. Shown are results for peak horizontal acceleration and 5 percent-damped spectral acceleration at 0.3 and 2.0 seconds (Geomatrix Consultants, Inc. 1993).

Figure 4-8. Computed mean and 5th to 95th percentile hazard curves for the 200-East Area of the Hanford Site. Shown are results for peak horizontal acceleration and five percent-damped spectral acceleration at 0.3 and 2.0 seconds (Geomatrix Consultants, Inc. 1993).

Figure 4-9. Computed mean and 5th to 95th percentile hazard curves for the 300 Area of the Hanford Site. Shown are results for peak horizontal

acceleration and five percent-damped spectral acceleration at 0.3 and 2.0 seconds (Geomatrix Consultants, Inc. 1993).

Figure 4-10. Computed mean and 5th to 95th percentile hazard curves for the 400 Area of the Hanford Site. Shown are results for peak horizontal acceleration and five percent-damped spectral acceleration at 0.3 and 2.0 seconds (Geomatrix Consultants, Inc. 1993).

Figure 4-11. Computed mean and 5th to 95th percentile hazard curves for the 100-K Area of the Hanford Site. Shown are results for peak horizontal acceleration and five percent-damped spectral acceleration at 0.3 and 2.0 seconds (Geomatrix Consultants, Inc. 1993).

4.7.1 Climate and Meteorology

The climate of the Hanford Site, located in southcentral Washington

State, can be classified as mid-latitude semiarid or mid-latitude desert, depending on the climatological classification scheme used. Summers are warm and dry with abundant sunshine. Large diurnal temperature variations result from intense solar heating during the day and radiational cooling at night. Daytime high temperatures in June, July, and August periodically exceed 38yC (100yF). Winters are cool with occasional precipitation. Outbreaks of cold air associated with modified arctic air masses can reach the area and cause temperatures to drop below -18yC (0yF). Overcast skies and fog occur periodically (Stone et al. 1983).

Topographic features have a significant impact on the climate of the Hanford Site. All air masses that reach the region undergo some modification resulting from their passage over the complex topography of the Pacific Northwest. The climate of the region is strongly influenced by the Pacific Ocean and the Cascade Range to the west. The relatively low annual average rainfall of 16.1 centimeters (6.3 inches) at the Hanford Meteorological Station is caused largely by the rain shadow created by the Cascade Range. These mountains limit much of the maritime influence of the Pacific Ocean, resulting in a more continental-type climate than would exist if the mountains were not present. Maritime influences are experienced in the region during the passage of frontal systems and as a result of movement through gaps in the Cascade Range (such as the Columbia River Gorge).

The Rocky Mountains to the east and the north also influence the climate of the region. These mountains play a key role in protecting the region from the more severe winter storms and the extremely low temperatures associated with the modified arctic air masses that move southward through Canada. Local and regional topographical features, such as the Yakima Ridge and the Rattlesnake Hills, also impact meteorological conditions across the Hanford Site (Glantz and Perrault 1991). In particular, these features have a significant impact on wind directions, wind speeds, and precipitation levels.

Climatological data are collected for the Hanford Site at the Hanford Meteorological Station. The station is located between the 200-West and 200-East Areas and is in close proximity to the proposed project site. Data have been collected at this location since 1945 and are summarized in Stone et al. (1983). Beginning in the early 1980s, data have also been collected at a series of automated monitoring sites located throughout the Hanford Site and the surrounding region (Glantz et al. 1990). This Hanford Meteorological Monitoring Network is described in detail in Glantz and Islam (1988).

4.7.1.1 Wind. Prevailing wind directions on the 200-Area plateau are

from the northwest in all months of the year. Secondary maxima occur for southwesterly winds. Summaries of wind direction indicate that winds from the northwest quadrant occur most often during the winter and summer. During the spring and fall, the frequency of southwesterly winds increases with a corresponding decrease in northwest flow. Winds blowing from other directions (for instance, the northeast) display minimal variation from month to month. Monthly average wind speeds are lowest during the winter months, averaging 2.8 to 3.1 meters per second (6.2 to 6.8 miles per hour)--, and highest during the summer, averaging 3.9 to 4.4 meters per second (8.7 to 9.9 miles per hour). Summertime drainage winds are generally northwesterly and can frequently gust to 14 meters per second (31 miles per hour). A wind rose for the Hanford Site is shown in Figure 4-12.

4.7.1.2 Temperature and Humidity. Eight separate temperature

measurements are made at the 122-meter (400-foot) tower at the Hanford Meteorological Station. As of May 1987, temperatures are also measured at the 2-meter (6.6-foot) level on the twenty-two 9.1-meter (30-foot) towers located on and around the Hanford Site. The three 61-meter (200-foot) towers have temperature-measuring instrumentation at the 2-, 9.8-, and 61-meter (6.6-, 32-, and 200-foot) levels. The temperature data from the 9.1- and 61-meter (30- and 200-foot) towers are telemetered to the Hanford Meteorological Station.

Diurnal and monthly averages and extremes of temperature, dew point, and humidity are contained in Stone et al. (1983). Ranges of daily maximum and minimum temperatures vary from normal maxima of 2yC (36yF) in early January to 35yC (95yF) in late July. On the average, 55 days during the summer months have maximum temperatures greater than or equal to 32yC (90yF), and 13 days have maxima greater than or equal to 38yC (100yF). From mid-November through mid-March, minimum temperatures average less than or equal to 0yC (32yF), with the minima in early January averaging -6yC (21yF). During the winter, on average, four days have minimum temperatures less than or equal to -18yC (0yF); however, only about one winter in two experiences such temperatures. The record maximum temperature is 46yC (115yF), and the record minimum temperature is -33yC (-27yF). For the period 1912 through 1980, the average monthly temperatures ranged from a low of -1.5yC (29yF) in January to a high of 24.7yC (77yF)

Figure 4-12. Wind rose for the Hanford Site using data collected from January 1982 to December 1989 (Glantz et al. 1990). The direction of each of the petals of the wind rose indicates the wind direction, and the petal length is representative of the percentage of time the wind was from that direction. Petal thickness represents measured wind-speed category. The velocity categories, from thinnest line (near the center of the rose) to thickest line (near the edge of the rose), are 0.4-1.3 meters per second (1-3 miles per hour), 1.8-3.1 meters per second (4-7 miles per hour), 3.6-5.4 meters per second (8-12 miles per hour), 5.8-8.0 meters per second (13-18 miles per hour), 8.5-10.7 meters per second (19-24 miles per hour), 11.2-13.9 meters per second (25-31 miles per hour), respectively.

in July. During the winter, the highest monthly average temperature at the Hanford Meteorological Station was 7yC (45yF), and the record lowest was -5.9yC (21yF), both occurring during February. During the summer, the record highest monthly average temperature was 27.9yC (82yF, in July), and the record lowest was 17.2yC (63yF, in June).

Relative humidity/dew point temperature measurements are made at the Hanford Meteorological Station and at the three 61-meter (200-foot) tower locations. The annual average relative humidity at the Hanford Meteorological Station is 54 percent. It is highest during the winter months, averaging about 75 percent, and lowest during the summer, averaging about 35 percent. Wet bulb temperatures greater than 24yC (75yF) had not been observed at the Hanford Meteorological Station before 1975; however, on July 8, 9, and 10 of that year, seven hourly observations indicated wet bulb temperatures greater than or equal to 24yC (75yF).

Fog reduces the visibility to 6 miles during an average of 42 days each year and to less than 0.25 mile during an average of 25 days per year.

4.7.1.3 Precipitation. The average annual precipitation at the Hanford

Meteorological Station is 16.1 centimeters (6.3 inches). Most of the precipitation occurs during the winter with nearly half of the annual amount occurring in the months of November through February. Days with greater then 1.3 centimeters (0.5 inches) precipitation occur less than 1 percent of the year. A rainfall intensity of at least 1.3 centimeters per hour (0.5 inches per hour) persisting for 1 hour has only a 10 percent probability of occurring in any given year. A rainfall intensity of at least 2.5 centimeters per hour (1 inch per hour) has only a 0.2 percent probability of occurring in any given year. Winter monthly average snowfall ranges from 0.8 centimeters (0.3 inches) in March to 13.5 centimeters (5.3 inches) in January. The record snowfall of 53 centimeters (21 inches) occurred in December 1992. During the months of December, January, and February, snowfall accounts for about 38 percent of all precipitation.

4.7.1.4 Severe Weather. A discussion of severe weather may include a

variety of meteorological events, including, but not limited to, severe winds, dust and blowing dust, hail, fog, glaze, ash falls, extreme temperatures, temperature inversions, and blowing and drifting snow. These are described in detail in Stone et al. (1983). For many facilities, estimates of severe winds are of particular concern. The Hanford Meteorological Station's climatological summary and the National Severe Storms Forecast Center's database list only 24 separate tornado occurrences within 160 kilometers (100 miles) of the Hanford Site from 1916 to 1992 (Cushing 1992). Only one of these tornadoes was observed within the boundaries of the Hanford Site (on its extreme western edge), and no damage resulted. The estimated probability of a tornado striking a point at Hanford is 9.6 x 10-6 per year (Cushing 1992). Because tornadoes are infrequent and generally small in the Pacific Northwest (and hurricanes do not reach this area), risks from severe winds are generally associated with thunderstorms or the passage of strong cold fronts. The greatest peak wind gust recorded at 15 meters (50 feet) above ground level at the Hanford Meteorology Station was 36 meters per second (80 miles per hour). Projections on the return periods for peak gusts exceeding a specified speed are given in Stone et al. (1983). Extrapolations based on 35 years of observations indicate a return period of about 200 years for a peak gust in excess of 40 meters per second (90 miles per hour) at 15 meters (50 feet) above ground level.

4.7.1.5 Atmospheric Stability. The transport and diffusion of airborne

pollutants is dependent on the horizontal and vertical distribution of temperature, moisture, and wind velocity in the atmosphere. Greater amounts of turbulence or mixing in an atmospheric layer lead to greater rates of diffusion. The highest rates of diffusion are found in thermally unstable layers, moderate rates of diffusion are found in neutral layers, and the lowest rates of diffusion are found in thermally stable layers. There are a number of methods for estimating the "stability" of the atmosphere. Using a method based on the vertical temperature gradient (NRC 1980) and measurements made at the Hanford Meteorology Station, thermally unstable conditions are estimated to occur an average of about 25% of the time, neutral conditions about 31% of the time, and thermally stable conditions about 44% of the time. Detailed information on Hanford's atmospheric stability and associated wind conditions are presented in Glantz et al. (1990).

4.7.2 Nonradiological Air Quality

National ambient air quality standards (NAAQS) have been set by the EPA as mandated in the 1970 Clean Air Act. Ambient air is that portion of the atmosphere, external to buildings, to which the general public has access. For DOE facilities, this is interpreted to mean the site boundary or other publicly accessible location, e.g., highways on the site. The standards define levels of air quality that are necessary, with an adequate margin of safety, to protect the public health (primary standards) and the public welfare (secondary standards). Standards exist for sulfur oxides (measured as sulfur dioxide), nitrogen dioxide, carbon monoxide, particles with an aerodynamic diameter less than or equal to 10 micrometers (PM10), lead, and ozone. The standards specify the maximum pollutant concentrations and frequencies of occurrence that are allowed for specific averaging periods (that is, the concentration of carbon monoxide when averaged over 1 hour is allowed to exceed 40 milligrams per cubic meter only once per year). The averaging periods vary from 1 hour to 1 year, depending on the pollutant.

In addition to ambient air quality standards, the EPA has established standards for the Prevention of Significant Deterioration (PSD) of air quality. The PSD standards differ from the NAAQS in that the NAAQS provide maximum allowable concentrations of pollutants, while PSDs provide maximum allowable increases in concentrations of pollutants for areas already in compliance with NAAQS. Prevention of Significant Deterioration standards are expressed as allowable increments in atmospheric concentrations of specific pollutants (nitrogen dioxide, sulfur dioxide, and PM10) (40 CFR 52.21, "Prevention of Significant Deterioration of Air Quality"). Different PSD standards exist for Class I areas (where degradation of ambient air quality is to be severely restricted), and Class II areas (where moderate degradation of air quality is allowed) (Wark and Warner 1981). The PSD standards are presented in Table 4.7-1. The nitrogen oxide emissions from the Plutonium and Uranium Recovery through EXtraction (PUREX) plant and the Uranium Oxide (UO3) plant are permitted by the EPA under the PSD program (Cushing 1992).

State and local governments have the authority to impose standards for ambient air quality that are stricter than the national standards. Washington State has established more stringent standards for sulfur dioxide. In addition, Washington has established standards for volatile organic compounds, arsenic, fluoride, total suspended particulates, and other pollutants that are not covered by national standards. The state standards for carbon monoxide and nitrogen dioxide are identical to the national standards. At the local level, the Benton-Franklin Counties Clean Air Authority has the authority to establish more stringent air standards, but has not done so. Table 4.7-2 summarizes Washington State standards, and background and ambient concentrations for Hanford.

4.7.2.1 Background Air Quality. The closest Class I areas to the

Hanford Site are Mount Rainier National Park, located approximately 160 kilometers (100 miles) west of the site; Goat Rocks Wilderness Area, located approximately 145 kilometers (90 miles) west of the site;

b. The standard is not to be exceeded more than twice in any seven consecutive days.
c. The TSP standards have been replaced by the PM10 standards, but the former are

serving as interim standards.

d. Arithmetic mean of the quarterly arithmetic means for the four calendar quarters of the year.

e. Maximum concentrations were measured in 1992 at Columbia Center in Kennewick. This value includes background concentration and site concentrations.

Mount Adams Wilderness Area, located approximately 150 kilometers (95 miles) southwest of the site; and Alpine Lakes Wilderness Area, located approximately 175 kilometers (110 miles) northwest of the site.

Air quality in the Hanford region is well within the state and federal standards for criteria pollutants, except that short-term particulate concentrations occasionally exceed the 24-hour PM10 standard (Table 4.7-2). Concentrations of toxic chemicals, as listed in 40 CFR Part 60.01, are not available for the Hanford Site. Because the highest concentrations of airborne particulate material are generally a result of natural events, the area has not been designated non-attainment(a) with respect to the PM10 standard. However, the local clean air authority is currently completing discussions with EPA and the Department of Ecology regarding plans to conduct additional evaluations of potential sources and mitigation measures, if any, that might be implemented to reduce the short-term particulate loading.

Particulate concentrations can reach relatively high levels in eastern Washington because of exceptional natural events (dust storms, volcanic eruptions, and large brushfires) that occur in the region. Washington ambient air quality standards do not consider rural fugitive dust from exceptional natural events when estimating the maximum background concentrations of particulate in the area east of the Cascade Mountain crest. Similarly, the EPA also exempts the rural fugitive dust component of background concentrations when considering permit applications and enforcement of air quality standards (Cushing 1992).

4.7.2.2 Source Emissions. Emissions inventories for permitted pollution

sources in Benton, Franklin, and Walla Walla counties are routinely compiled by the Tri-County Air Pollution Control Board. The annual emission rates for stationary sources within the Hanford Site boundaries were reported to the Washington State Department of Ecology by the U.S. Department of Energy and are provided in Table 4.7-3.

The EPA's ISC/ST model was used for baseline modeling of stationary sources projected to be in operation in 1995 (Hadley 1991). Projected baseline conditions (presented in Table 4.7-2) are estimated to be well below any current national or state standards (Hadley 1991).

---

a. An attainment area is an area where measured concentrations of a pollutant are below the primary and secondary National Ambient Quality Standards (NAAQS).

Table 4.7-3. Emission rates (tons per year) for stationary emission sources within the Hanford Site for 1992a.

Source	Operation (hours per year)	TSP	PM10	Sulfur Dioxide	Nitrogen Oxides	Volatile Organic Compounds	Carbon Monoxide

4.7.2.3 Nonradiological Air Quality Monitoring.

4.7.2.3.1 Onsite Monitoring-The most recent monitoring data

available were obtained in 1992. Details of the monitoring program are described in Woodruff and Hanf (1993). The only onsite air quality monitoring conducted during 1991 was for nitrogen oxides. These oxides were sampled at three locations on the Hanford Site with a bubbler assembly operated to collect 24-hour integrated samples. The highest annual average concentration was <0.006 parts per million by volume, well below the applicable federal and Washington State annual ambient standard of 0.05 parts per million by volume (Cushing 1992). Monitoring of total suspended solids was discontinued in early 1988 when the Basalt Waste Isolation Project, for which those measurements were required, was concluded. In 1992 sampling was done at Rattlesnake Springs (near the southwestern edge of the site) for polychlorinated biphenyls (PCBs) and volatile organic compounds. Levels of PCB concentrations were found to be <0.27 to <0.29 nanogram per cubic meter (Woodruff and Hanf 1993). These values are well below the EPA limit of 1 nanogram per cubic meter. The volatile organic compounds tested for were halogenated alkanes and alkenes, benzene, and alkylbenzenes. All volatile organic compound concentrations were well below the occupational maximum allowable concentrations of air contaminants.

4.7.2.3.2 Offsite Monitoring-During the past 10 years, carbon

monoxide, sulfur dioxide, and nitrogen dioxide have been monitored periodically in communities and commercial areas southeast of Hanford. These urban measurements are typically used to estimate the maximum background pollutant concentrations for the Hanford Site because of a lack of specific onsite monitoring. Because these measurements were made in the vicinity of local sources of pollution, they will overestimate maximum background concentrations for the Hanford Site or at the site boundaries.

The only offsite monitoring in the vicinity of the Hanford Site in 1990 was conducted by the Washington Department of Ecology for particulates (WDOE 1991). Total suspended particulate (TSP) monitoring at Tri-Cities locations was discontinued in early 1989. Monitoring at the remaining two locations, Sunnyside and Wallula, continued during 1990. The annual geometric means of measurements at Sunnyside and Wallula for 1990 were 71 micrograms per cubic meter and 80 micrograms per cubic meter, respectively; both of these values exceeded the Washington State annual standard of 60 micrograms per cubic meter. The Washington State 24-hour standard, 150 micrograms per cubic meter, was exceeded six times during the year at Sunnyside and seven times at Wallula (Cushing 1992).

Particulate matter (PM10) was also monitored at three locations: Columbia Center in Kennewick, Walla Walla Fire Station, and Wallula. During 1992, the 24-hour PM10 standard adopted by Washington State, 150 micrograms per cubic meter, was exceeded two times at the Columbia Center monitoring location. The maximum 24-hour concentration at Columbia Center was 596 micrograms per cubic meter. The maximum 24-hour concentration at the Walla Walla Fire Station was 67 micrograms per cubic meter. The maximum 24-hour concentration at Wallula was 124 micrograms per cubic meter. None of the sites exceeded the annual primary standard, 50 micrograms per cubic meter (Cushing in preparation). As noted previously, the Benton-Franklin counties area has not been designated nonattainment with respect to PM10 standards because the particulate concentrations result from natural events.

4.7.2.4 Summary of Nonradiological Air Quality. The Hanford Site is

currently considered an attainment area for criteria pollutants. However, PM10 concentrations are high enough that the designation may change. There are no Class I areas close enough to the site to be affected by emissions at Hanford. Carbon monoxide concentrations are at 65 percent of the allowed concentration (for an eight-hour averaging time). Current PM10 concentrations are at 52 percent of the allowed ambient standard. Nitrogen dioxide concentrations are at 36 percent of the allowed values. All other pollutants, for which ambient air quality standards exist, are below 25 percent of the allowed values.

4.7.3 Radiological Air Quality

Radionuclide emissions to the atmosphere from the Hanford Site have been steadily decreasing over the last few years as site operations have changed emphasis from the historical mission of materials production and processing to energy and waste management research. During 1992, all operations at the Hanford Site released less than 100 Ci of radionuclides to the atmosphere, most of which consisted of tritium and noble gases (Woodruff and Hanf 1993). Of that total, fission and activation products accounted for less than 0.036 Ci, uranium isotopes accounted for less than 1 x 10-6 Ci, and transuranics contributed less than 0.005 Ci. These releases resulted in a dose to the maximally exposed offsite resident of less than 0.005 mrem, which is several orders of magnitude less than the current EPA standard of 10 mrem per year for DOE facilities.

Ambient air monitoring for radionuclides consisted of sampling at 42 onsite and offsite locations during 1992. Total concentrations of alpha- and beta-emitting radionuclides at the site perimeter were indistinguishable from those at distant locations that are unaffected by Hanford emissions. Concentrations of two specific radionuclides (tritium and iodine-129) were elevated relative to background; however, their contribution to the total airborne activity was small.

4.8 Water Resources

4.8.1 Surface Water

4.8.1.1 Surface Water Hydrology. The Pasco Basin occupies about

4900 square kilometers (1900 square miles) and is located centrally within the Columbia Basin. Elevations within the Pasco Basin are generally lower than other parts of the plateau, and surface drainage enters it from other basins. Within the Pasco Basin, the Columbia River is joined by three major tributaries: the Yakima River, the Snake River, and the Walla-Walla River.

The Hanford Site occupies approximately one-third of the land area within the Pasco Basin. Primary surface-water features associated with the Hanford Site are the Columbia and Yakima rivers. Several surface ponds and ditches are present, and they are generally associated with fuel- and waste-processing activities. Several small spring-streams occur on the Arid Land Ecology site on the western side of the Hanford Site.

A network of dams and multipurpose water resources projects is located along the course of the Columbia River. The principal dams are shown in Figure 4-13. Storage behind Grand Coulee Dam, combined with storage upstream in Canada, totals 3.1 x 1010 cubic meters (1.1 x 1012 cubic feet) of usable storage to regulate the Columbia River for power, flood control, and irrigation of land within the Columbia Basin project.

Figure 4-13. Locations of major surface water resources and principal dams within the Columbia Plateau.

Approximately two-thirds of the surface runoff, if there were any from Hanford, would drain directly into the Columbia River along the Hanford Reach, which extends from the upstream end of Lake Wallula to the Priest Rapids Dam. One-third of the surface runoff would drain into the Yakima River, which flows into the Columbia River below the Hanford Site. The flow has been inventoried and described in detail by the U.S. Army Corps of Engineers (DOE 1986a). Flow along this reach is controlled by the Priest Rapids Dam. Several drains and intakes are also present along this reach. These include irrigation outfalls from the Columbia Basin Irrigation Project and Hanford Site intakes for the onsite water export system.

Recorded flow rates of the Columbia River have ranged from 4500 to 18,000 cubic meters per second (~158,900 to 635,600 cubic feet per second) during the runoff in spring and early summer, to 1000 to 4500 cubic meters per second (35,300 to 158,900 cubic feet per second) during the low flow period of late summer and winter. The average annual Columbia River flow in the Hanford Reach, based on records from 65 years, is about 3400 cubic meters per second (120,100 cubic feet per second) (DOE 1988). A minimum flow of about 1020 cubic meters per second (35,000 cubic feet per second) is maintained along the Hanford Site. Normal river elevations within the site range from 120 meters (394 feet) above mean sea level where the river enters the Hanford Site near Vernita to 104 meters (341 feet) where it leaves the site near the 300-Area.

The Yakima River, near the southern portion of the Hanford Site, has a low annual flow compared to the Columbia River. For 57 years of record, the average annual flow of the Yakima River is about 104 cubic meters per second (3673 cubic feet per second) with monthly maximum and minimum flows of 490 cubic meters per second (17,305 cubic feet per second) and 4.6 cubic meters per second (162 cubic feet per second), respectively.

Cold Creek and its tributary, Dry Creek, are ephemeral streams within the Yakima River drainage system along the southern boundary of the Hanford Site. Both streams drain areas to the west of the Hanford Site and cross the southwestern part of the site toward the Yakima River.

Surface flow, when it occurs, infiltrates and disappears into the surface sediments in the western part of the Hanford Site (refer to subsection 4.6.1.3 for a discussion of soil types and moisture percolation). Rattlesnake Springs, located on the western part of the site, forms a small surface stream that flows for about 3 kilometers (1.8 miles) before disappearing into the ground. Approximately one-third of the Hanford Site is drained by the Yakima River system.

Total estimated precipitation over the Pasco Basin is about 9 x 106 cubic meters (318 x 106 cubic feet) annually, averaging less than 20 centimeters per year (~8 inches per year). Mean annual runoff from the basin is estimated to be less than 3.1 x 107 cubic meters per year (109 x 107 cubic feet per year), or approximately 3 percent of the total precipitation. The basin-wide runoff coefficient is zero for all practical purposes. The remaining precipitation is assumed to be lost through evapotranspiration, with a small component (perhaps less than 1 percent) recharging the groundwater system (DOE 1988).

Water use in the Pasco Basin is primarily from surface diversion with groundwater diversions accounting for less than 10 percent of the use. A listing of surface water diversions, volumes, types of usage, and the populations served is given in DOE (1988). Industrial and agricultural usage represent about 32 percent and 58 percent, respectively, and municipal use about 9 percent. The Hanford Site uses about 81 percent of the water withdrawn for industrial purposes. However, because of the N Reactor shutdown and considering the data in DOE (1988), these percentages now approximate 13 percent for industrial, 75 percent for agricultural, and 12 percent for municipal use, with the Hanford Site accounting for about 41 percent of the water withdrawn for industrial use.

Approximately 50 percent of the wells in the Pasco Basin are for domestic use and are generally shallow (less than 150 meters [500 feet]). Agricultural wells, used for irrigation and stock supply, make up the second-largest category of well use, about 24 percent for the Pasco Basin. Industrial users account for only about 3 percent of the wells (DOE 1988).

Most of the water used by the Hanford Site is withdrawn from the Columbia River. The principal users of groundwater within the Hanford Site are the Fast Test Flux Facility, with a 1988 use of 142,000 cubic meters (5.0 x 106 cubic feet) from two wells in the unconfined aquifer, and the PNL Observatory, with a water supply from a spring on the side of Rattlesnake Mountain.

Regional effects of water-use activities are apparent in some areas where the local water tables or potentiometric levels have declined because of withdrawals from wells. In other areas, water levels in the shallow aquifers have risen because of artificial recharge mechanisms, such as excessive application of imported irrigation water or impoundment of streams. Wastewater ponds on the Hanford Site have artificially recharged the unconfined aquifer below the 200-East and 200-West Areas. The increase in water table elevations was most rapid from 1950 to 1960, and apparently had nearly reached equilibrium between the unconfined aquifer and the recharge during 1970 to 1980 when only small increases in water table elevations occurred. Wastewater discharges from the 200-West Area were significantly reduced in 1984 (DOE 1988), with an accompanying decline in water table elevations.

4.8.1.2 Flood Plains. Large Columbia River floods have occurred in the past (DOE 1987), but the likelihood of recurrence of large-scale flooding has been reduced by the construction of several flood control/water storage dams upstream of the site. Major floods on the Columbia River are typically the result of rapid melting of the winter snowpack over a wide area augmented by above-normal precipitation. The maximum historical flood on record occurred June 7, 1894, with a peak discharge at the Hanford Site of 21,000 cubic meters per second (742,000 cubic feet per second). The flood plain associated with the 1894 flood is shown in Figure 4-14. The largest recent flood took place in 1948 with an observed peak discharge of 20,000 cubic meters per second (706,280 cubic feet per second) at the Hanford Site. The probability of flooding at the magnitude of the 1894 and 1948 floods has been greatly reduced because of upstream regulation by dams.

The Federal Emergency Management Agency has not prepared flood plain maps for the Hanford Reach of the Columbia River because that agency prepares maps only for developing areas (a criteria that specifically excludes the Hanford Reach).

Evaluation of flood potential is conducted in part through the concept of the probable maximum flood, determined from the upper limit of precipitation falling on a drainage area and other hydrologic factors, such as antecedent moisture conditions, snowmelt, and tributary conditions, that could result in maximum runoff. The probable maximum flood for the Columbia River below Priest Rapids Dam has been calculated to be 40,000 cubic meters per second (1.4 million cubic feet per second) and is greater than the 500-year flood. The flood plain associated with the probable maximum flood is shown in Figure 4-15. This flood would inundate parts of the 100-Areas located adjacent to the Columbia River, but the central portion of the Hanford Site where the SNF facility would be located would remain unaffected (DOE 1986a).

Figure 4-14. Flood area during the 1894 flood.

Figure 4-15. Flood area for the probable maximum flood.

The U.S. Army Corps of Engineers (1989) has derived the Standard Project Flood with both regulated and unregulated peak discharges given for the Columbia River below Priest Rapids Dam. Frequency curves for both natural (unregulated) and regulated peak discharges are also given for the same portion of the Columbia River. The regulated Standard Project Flood for this part of the river is given as 15,200 cubic meters per second (54,000 cubic feet per second) and the 100-year regulated flood as 12,400 cubic meters per second (440,000 cubic feet per second). No maps for the flooded areas are provided.

Potential dam failures on the Columbia River have been evaluated (DOE 1986a; ERDA 1976). Upstream failures could arise from a number of causes, with the magnitude of the resulting flood depending on the degree of breaching at the dam. The U.S. Army Corps of Engineers evaluated a number of scenarios on the effects of failures of Grand Coulee Dam, assuming flow conditions of the order of 11,000 cubic meters per second (400,000 cubic feet per second). For purposes of emergency planning, they hypothesized that 25 percent and 50 percent breaches, the instantaneous disappearance of 25 percent or 50 percent of the center section of the dam, would result from the detonation of nuclear explosives in sabotage or war. The discharge or floodwave resulting from such an instantaneous 50 percent breach at the outfall of the Grand Coulee Dam was determined to be 600,000 cubic meters per second (21 million cubic feet per second). In addition to the areas inundated by the probable maximum flood (see Figure 4-15), the remainder of the 100 Areas, the 300 Area, and nearly all of Richland, Washington, would be flooded (DOE 1986a; ERDA 1976). Determinations were not made for failures of dams upstream, for associated failures downstream of Grand Coulee, or for breaches greater than 50 percent of Grand Coulee for two principal reasons: the 50 percent scenario was believed to represent the largest realistically conceivable flow resulting from either a natural or human-induced breach (DOE 1986a); that is, it was hard to imagine that a structure as large as the Grand Coulee Dam would be 100 percent destroyed instantaneously. It was also assumed that such a scenario as the 50 percent breach would only occur as the result of direct explosive detonation, not because of a natural event such as an earthquake. Even a 50 percent breach under these conditions would indicate an emergency situation where other overriding major concerns might be present.

The possibility of a landslide resulting in river blockage and flooding along the Columbia River has also been examined for an area bordering the east side of the river upstream from the city of Richland (DOE 1986a). The possible landslide area considered was the 75-meter- (250-foot-) high bluff generally known as White Bluffs. Calculations were made for an 8 x 105 cubic meter (1 x 106 cubic yards) landslide volume with a concurrent flood flow of 17,000 cubic meters per second (600,000 cubic feet per second) (a 200-year flood) resulting in a flood wave crest elevation of 122 meter (400 foot) above mean sea level. Areas inundated upstream from such a landslide event would be similar to those shown in Figure 4-15.

A flood risk analysis of Cold Creek was conducted in 1980 as part of the characterization of a basaltic geologic repository for high-level radioactive waste. Such design work is usually done to the criteria Standard Project Flood or Probable Maximum Flood rather than the worst case or 100-year flood scenario. Therefore, in lieu of 100- and 500-year floodplain studies, a probable maximum flood evaluation was made for a reference repository location directly west of the 200-East Area and encompassing the 200-West Area (Skaggs and Walters 1981). Figure 4-16 shows the extent of this evaluation.

4.8.1.3 Surface Water Quality.

4.8.1.3.1 Water Quality of the Columbia River-The Department of

Ecology classifies the Columbia River as Class A (excellent) between Grand Coulee Dam and the mouth of the river near Astoria, Oregon (DOE 1986a). The Hanford Reach of the Columbia River is the last free-flowing portion of the river in the United States.

Pacific Northwest Laboratory conducts routine monitoring of the Columbia River for both radiological and nonradiological water quality parameters. A yearly summary of results has been published since 1973 (Woodruff and Hanf 1993). Numerous other water quality studies have been conducted on the Columbia River relative to the impact of the Hanford Site during the past 37 years. Currently, eight outfalls are covered by National Pollutant Discharge Elimination System (NPDES) permits at the Hanford Site: two at the 100-K Area, five at the 100-N Area, and one at the 300 Area. These discharge locations are monitored for various measures of water quality, including nonradioactive and radioactive pollutants. The dose from any radionuclide releases is estimated for the Annual Environmental Monitoring Report for the Hanford Site. In 1993, monitored liquid discharges resulted in a dose of 0.012 mrem to the downstream maximally exposed individuals (Dirkes et al. 1994). Permit applications have been submitted to EPA Region 10 for three new facilities (outfalls) planned for the 100 and 300 Areas. These new facilities include a treatment facility for process wastewater (1325-N), a filter backwash/ash sluicing wastewater disposal facility (315/384), and the 300 Area Treated Effluent Disposal Facility.

Figure 4-16. Extent of probable maximum flood in Cold Creek area.

Radiological monitoring shows low levels of radionuclides in samples of Columbia River water. Tritium, iodine-129, and uranium are found in somewhat higher concentrations downstream of the Hanford Site than upstream (Woodruff and Hanf 1993), but well below concentration guidelines established by DOE and EPA drinking-water standards (Table 4.8-1). Cobalt-60 and iodine-131 were not consistently found in measurable quantities during 1989 in samples of Columbia River water from Priest Rapids Dam, the 300-Area water intake, or the Richland city pumphouse (Woodruff and Hanf 1991). In 1989, the average annual strontium-90 concentrations were essentially the same at Priest Rapids Dam (upstream of the Hanford Site) and the Richland Pumphouse (Woodruff and Hanf 1991).

Nonradiological water quality parameters measured during 1989 were similar to those reported in previous years and were within Washington State Water Quality Standards (Woodruff and Hanf 1991). Under Federal Water Pollution Control Act Amendments of 1972 (as amended by the Clean Water Act of 1972) the NPDES can regulate permits issued to DOE-RL for discharges of nonradioactive effluents made to the Columbia River.

Table 4.8-1. Annual average concentrations of radionuclides in Columbia River water during 1992.

Radionuclides	Water concentrations (pCi/L) Upstream concentration (Priest Rapids Dam)	Downstream concentration (Richland Pumphouse)	EDA drinking water standard
H-3	50	101	20,000
Sr-90	0.09	0.09	8.0
Uranium	0.42	0.51	NA
Tc-99	0.10	0.21	900
I-129	<2.3 x 10-5	<1.4 x 10-4	1

a. Data taken from Woodruff and Hanf (1993).

4.8.1.3.2 Water Quality of the Unconfined Aquifer-As part of the continuing environmental

monitoring program, groundwater monitoring reports have been issued since 1956 and are now published in the Hanford Site Environmental Report, which is issued by calendar year. The shallow, unconfined aquifer in the Pasco Basin and on the Hanford Site contains waters of a dilute (less than or approximately 350 milligrams per liter total dissolved solids) calcium bicarbonate chemical type. Other principal constituents include sulfate, silica, magnesium, and nitrate. Variability in chemical composition exists within the unconfined aquifer in part because of natural variation in the composition of the aquifer material; in part because of agricultural and irrigation practices north, east, and west of the Hanford Site; and, on the Hanford Site, in part because of liquid waste disposal.

Graham et al. (1981) compared analyses of unconfined aquifer water samples taken by the U.S. Geological Survey in the Pasco Basin, but off the Hanford Site, with samples taken by PNL and the USGS on the Hanford Site for the years 1974 through 1979. In general, Hanford Site groundwater analyses showed higher levels of chemical constituents and temperatures than were reflected in the analyses of offsite samples.

Elevated levels of some constituents in the Hanford groundwater result from releases of various liquid wastes from disposal facilities, primarily in the 100 Areas (formerly the site of production reactor operations) and 200 Areas (formerly the spent fuel reprocessing and defense materials production site). Mobile contaminants, such as tritium and nitrate, from the 200 Areas are present in a groundwater plume that extends across the southeastern quadrant of the Hanford Site and enters the Columbia River along a broad front north of the 300 Area. Contaminants having lower mobility are generally confined to smaller localized plumes in the vicinity of the disposal facilities and migrate more slowly toward the Columbia River (Dirkes et al. 1994). Some longer-lived radionuclides, such as strontium-90 and cesium-137, have reached the groundwater, primarily through liquid waste disposal cribs. Minor quantities of longer-lived radionuclides have also reached the water table via a failed groundwater monitoring well casing and through reverse well injection, a disposal practice that was discontinued at Hanford in 1947 (Smith 1980).

Of the contaminants found in groundwater, several radionuclides and nonradioactive chemicals were present in concentrations that exceeded EPA drinking water standards or DOE Derived Concentration Guides (DCG) in 1993 (Dirkes et al. 1994). These quantities are used as a relative measure of contamination, although with one exception, groundwater beneath the site is not used for human consumption or food production. Groundwater utilized for drinking at the FFTF visitor center contains above-background quantities of tritium and iodine-129 from the 200 Area plume; however, these levels are well below the EPA drinking water standards. There is little opportunity for contaminated groundwater to migrate to locations where members of the public might utilize it directly for domestic purposes or irrigation. Groundwater in the unconfined aquifer beneath the Hanford Site is relatively isolated, and generally flows toward the north and east where it discharges to the Columbia River. Normal hydraulic gradients within the unconfined aquifer beneath the Hanford Site prevent southward migration of groundwater toward populated areas near Richland, and recharge to the Columbia River from aquifers in Franklin County to the north and east prevents radionuclides in the Columbia River from migrating to groundwater across the river from Hanford.

Groundwater monitoring at the 100 Areas detected concentrations of cobalt-60, strontium-90, antimony-125, and uranium that were above the EPA drinking water standards. Tritium concentrations exceeded both the EPA drinking water standard and the DOE DCG at one sample well in each of the 100-N and 100-K Areas. In 200 Area wells, cobalt-60, technetium-99, iodine-129, cesium-137, uranium, and plutonium were occasionally found in concentrations that exceeded the EPA drinking water standard; tritium and strontium-90 exceeded both the EPA drinking water standard and the DOE DCG in some locations. Only uranium exceeded the EPA drinking water standard in 300 Area wells, a result of liquid waste disposal at former fuel fabrication facilities.

Three nonradiological constituents - nitrate, chromium, and trichloroethylene - exceeded EPA drinking water standards in both 100 and 200 Area groundwater. In addition to those constituents, some 200 Area wells exceeded EPA drinking water standards for cyanide, fluoride, carbon tetrachloride, and chloroform. Only trichloroethylene was found above the drinking water limits in the 300 Area.

The occurrence and consequences of leaks from waste storage tanks and of radioactive materials in soils have been described elsewhere (ERDA 1975). These occurrences have not resulted, and are not expected to result, in radiation exposure to the public (ERDA 1975; DOE 1987). Leakage from the 105-KE fuel storage basin results in groundwater contamination with several radionuclides, as noted previously. The more mobile radionuclides reach the Columbia River via springs near the 100-K Area, although radionuclides in the springs were below the EPA drinking water standard in 1993 (Dirkes et al. 1994).

Radioactive and nonradioactive effluents are discharged to the environment from Westinghouse Hanford Company facilities in the 200 Area (Cooney et al. 1988). These effluents, in general, are discharged to the soil column. Cooling water represents by far the largest volume of potentially radioactive liquid effluent. Additional treatment systems for these effluents are being designed and installed pursuant to the schedule set forth in the Hanford Federal Facility Agreement and Consent Order, which was jointly issued by DOE, EPA, and the Washington Department of Ecology in May 1989. Under the provisions of the Comprehensive Environmental Response Compensation and Liability Act, remedial investigations/feasibility studies will be conducted for groundwater operable units at Hanford.

Springs are common on basalt ridges surrounding the Pasco Basin. Geochemically, spring waters are of a calcium or sodium bicarbonate type with low dissolved solids (approximately 200 to 400 milligrams per liter) (DOE 1986a). Compositionally these waters are similar to shallow local groundwaters (unconfined aquifer and upper Saddle Mountains basalt). However, they are readily distinguishable from waters of the lower Saddle Mountains (Mabton interbed) and the Wanapum and Grande Ronde basalts, which are of sodium bicarbonate to sodium chloride bicarbonate (or sodium chloride sulfate) type. Currently, no evidence suggests these spring waters contain any significant component of deeper groundwater.

4.8.1.3.3 Water Quality of the Confined Aquifer-Areal and stratigraphic changes in

groundwater chemistry characterize basalt groundwaters beneath the Hanford Site (Graham et al. 1981). The stratigraphic position of these changes is believed to delineate flow-system boundaries and to identify chemical evolution taking place along groundwater flow paths. Using these data, some potential mixing of groundwaters has also been located; however, the rate of mixing is unknown. According to Woodruff and Hanf (1993), no evidence of contamination was observed in the groundwater of the confined aquifer on Rattlesnake Ridge. Groundwater in one well in this aquifer contained 8,800 micrograms of nitrate per liter in 1992. The well was located near an erosional window in the confining basalt flow. In another well, tritium levels were elevated (maximum of 7,830 picocuries per liter) in 1992. In the same well, elevated levels of iodine-129 (0.15 picocuries per liter) were observed in 1992.

4.8.2 Groundwater

4.8.2.1 Groundwater Hydrology. The regional geohydrologic setting of the Pasco Basin is based on the stratigraphic framework consisting of numerous Miocene tholeiitic flood basalts of the Columbia River Basalt group; relatively minor amounts of intercalated fluvial and volcanoclastic Ellensburg Formation sediments; and fluvial, lacustrine, and glaciofluvial suprabasalt sediments. The vertical order of the geological units from the surface downward is Hanford formation, Middle Ringold Formation, Lower Ringold Formation, Basal Ringold Formation, and bedrock, e.g., basalt. Figure 4-3 illustrates the stratigraphic layering of the hydrogeologic units underlying the Hanford Site, and Figure 4-17 shows the order of the geological units. The surface Hanford formation varies in thickness across the Hanford Site from approximately 15 to 100 meters (49 to 328 feet) thick (Figure 4-17). The Middle Ringold Formation varies from 10 to 110 meters (33 to 361 feet) thick. The Lower Ringold and Basal Ringold Formations extend eastward from the western boundary of the site approximately 1.1 kilometers (6.8 miles). The Lower Ringold Formation is rather uniform in thickness at 20 meters (66 feet), while the Basal Ringold Formation demonstrates a maximum thickness of 40 meters (131 feet) at the far western boundary of the site (interpolated from Woodruff and Hanf 1993). Lateral groundwater movement is known to occur within a shallow, unconfined aquifer consisting of fluvial and lacustrine sediments lying on top of the basalts, and within deeper confined-to-semiconfined aquifers consisting of basalt flow tops, flow bottom zones, and sedimentary interbeds (DOE 1988). These deeper aquifers are intercalated with aquitards consisting of basalt flow interiors. Vertical flow and leakage between geohydrologic units is inferred and estimated from water level or potentiometric surface data but is not quantified, and direct measurements are not available (DOE 1988).

Figure 4-17. Geologic cross section of the Hanford Site (modified from Tallman et al. 1979).

The multiaquifer system within the Pasco Basin has been conceptualized as consisting of four geohydrologic units: (1) the Grande Ronde Basalt; (2) Wanapum Basalt; (3) Saddle Mountain Basalt; and (4) suprabasalt Hanford and Ringold Formation sediments. Geohydrologic units older than the Grande Ronde Basalt are probably of minor importance to the regional hydrologic dynamics and system.

The Grande Ronde Basalt is the most voluminous and widely spread formation within the Columbia River Basalt group and has a thickness of at least 2745 meters (9000 feet). The Grande Ronde Basalt geohydrologic unit is composed of the Grande Ronde Basalt and minor intercalated sediments equivalent to or part of the Ellensburg Formation (DOE 1988). More than 50 flows of Grande Ronde Basalt underlie the Pasco Basin, but little is known of the lower 2200 to 2500 meters of this geohydrologic unit. This unit is a confined-to-semiconfined flow system that is recharged along the margins of the Columbia Plateau where the unit is at or close to the land surface, and by surface-water and groundwater inflow from lands adjoining the plateau. Vertical movement into and out of the unit is known to occur. Groundwater within the unit in the eastern Pasco Basin is believed to be derived from groundwater inflow from the east and northeast.

The Wanapum Basalt geohydrologic unit consists of basalt flows of the Wanapum Basalt intercalated with minor and discontinuous sedimentary interbeds of the Ellensburg Formation or equivalent sediments. In the Pasco Basin, the Wanapum Basalt consists of three members, each consisting of multiple flows. The geohydrologic unit underlies the entire Pasco Basin and has a maximum thickness of 370 meters (1215 feet). Groundwater within the Wanapum Basalt geohydrologic unit is confined to semiconfined. Recharge is believed to occur from precipitation where the Wanapum Basalt is not overlain by great thicknesses of younger basalt, leakage from adjoining formations, and surface-water and groundwater inflow from lands adjoining the plateau. Local recharge is derived from irrigation. Within the Pasco Basin, recharge occurs along the anticlinal ridges to the north and west, with recharge in the eastern basin being from groundwater inflow from the east and northeast (DOE 1988). Interbasin transfer and vertical leakage are also believed to contribute to the recharge.

The Saddle Mountains Basalt geohydrologic unit is composed of the youngest formation of the Columbia River Basalt Group and several thick sedimentary beds of the Ellensburg Formation or equivalent sediments that comprise up to 25 percent of the unit. Within the Pasco Basin, the Saddle Mountains Basalt contains seven members, each with one or more flows. This geohydrologic unit underlies most of the Pasco Basin, attaining a thickness of about 290 meters (950 feet), but is absent along the northwest part of the basin and along some anticlinal ridges. Groundwater in the Saddle Mountains geohydrologic unit is confined to semiconfined, with recharge and discharge believed to be local (DOE 1988).

The rock materials that overlie the basalts in the structural and topographic basins within the Columbia Plateau generally consist of Miocene-Pliocene sediments, volcanics, Pleistocene sediments (including those from catastrophic flooding), and Holocene sediments consisting mainly of alluvium and eolian deposits. The suprabasalt geohydrologic unit (referred to as the Hanford/Ringold unit) consists principally of the Miocene-Pliocene Ringold Formation stream, lake, and alluvial materials, and the Pleistocene catastrophic flood deposits informally called the Hanford formation. Groundwater within the suprabasalt geohydrologic unit is generally unconfined, with recharge and discharge usually coincident with topographic highs and lows (DOE 1988). The Hanford/Ringold unit is essentially restricted to the Pasco Basin with principal recharge occurring along the periphery of the basin from precipitation and ephemeral streams.

Little if any natural recharge occurs within the Hanford Site, but artificial recharge occurs from liquid waste disposal activities (Woodruff and Hanf 1993). Recharge from irrigation occurs east and north of the Columbia River and in the synclinal valleys west of the Hanford Site. Upward leakage from lower aquifers into the unconfined aquifer is believed to occur in the northern and eastern sections of the Hanford Site. Groundwater discharge is primarily to the Columbia River.

Groundwater under the Hanford Site occurs under unconfined and confined conditions (Figure 4-17). The unconfined aquifer is contained within the glaciofluvial sands and gravels of the Hanford formation and within the Ringold Formation. It is dominated by the middle member of the Ringold Formation, consisting of sands and gravels with varying amounts of cementation. The bottom of the unconfined aquifer is the basalt surface or, in some areas, the clay zones of the Lower Ringold. A semiconfined aquifer occurs in areas where the coarse-grained Basal Ringold lies between the basalt and the fine-grained Lower Ringold. The confined aquifers consist of sedimentary interbeds and/or interflow zones that occur between dense basalt flows in the Columbia River Basalt Group. The main water-bearing portions of the interflow zones occur within a network of interconnecting vesicles and fractures of the flow tops or flow bottoms.

4.8.2.2 Vadose Zone Hydrology. Sources of natural recharge to the unconfined aquifer are rainfall and

runoff from the higher bordering elevations, water infiltrating from small ephemeral streams, and river water along influent reaches of the Yakima and Columbia rivers. In order to define the movement of water in the vadose zone, the movement of precipitation through the unsaturated (vadose) zone has been studied at several locations on the Hanford Site. Conclusions from these studies are varied depending on the location studied. Some investigators conclude that no downward percolation of precipitation occurs on the 200-Area

Plateau where soil texture is varied and is layered with depth, and that all moisture penetrating the soil is removed by evaporation. Others have observed downward water movement below the root zone in tests conducted near the 300 Area, where soils are coarse textured and precipitation was above normal (DOE 1987).

From the recharge areas to the west, the groundwater flows downgradient to the discharge areas, primarily along the Columbia River. This general west-to-east flow pattern is interrupted locally by the groundwater mounds in the 200 Areas. From the 200 Areas, a component of groundwater also flows to the north, between Gable Mountain and Gable Butte. These flow directions represent current conditions; the aquifer is dynamic, and responds to changes in natural and artificial recharge.

Local recharge to the shallow basalts is believed to result from infiltration of precipitation and runoff along the margins of the Pasco Basin. Regional recharge of the deep basalts is thought to result from interbasin groundwater movement originating northeast and northwest of the Pasco Basin in areas where the Wanapum and Grande Ronde Basalts crop out extensively (DOE 1986a). Groundwater discharge from the shallow basalt is probably to the overlying unconfined aquifer and the Columbia River. The discharge area(s) for the deep groundwaters is presently uncertain, but flow is believed to be generally southeastward with discharge speculated to be south of the Hanford Site (DOE 1986a).

4.8.3 Existing Radiological Conditions

This section relates to the hydrology of the Hanford Site in general and to the hydrology of the 200 Area specifically because it is the location of the proposed SNF facility.

4.8.3.1 Hydrology of the Hanford Site. Groundwater quality on the Hanford Site has been affected by

defense-related activities to produce nuclear materials. Due to the arid nature of the climate, natural recharge of the groundwater on the site is normally low. Artificial recharge has occurred in the past from the disposal of liquid waste associated with processing operations in the 100, 200, and 300 Areas that created mounds of water underlying discharge points. While most of the site does not have contaminated groundwater, large areas underlying the site do have elevated levels of both radiological and nonradiological constituents. The liquid effluents discharged into the ground have carried with them certain radionuclides and chemicals that move through the soil column at varying rates, eventually enter the groundwater, and form plumes of contamination (see Figure 5.54 in DOE 1992a).

Groundwater monitoring is conducted on an annual basis on the Hanford Site as part of the Hanford Ground-Water Environmental Surveillance Program and other monitoring programs to study the movement of plumes, groundwater quality, and the concentration of certain constituents as regulated by the EPA, the DOE, and Washington State. In 1992, several groundwater samples were taken from approximately 720 wells, of which 50 percent were sampled at least quarterly or more frequently. The remainder were sampled either once or twice. Figure 5.49 in DOE (1992a) illustrates the locations of these monitoring wells.

Results indicate that total alpha, total beta, tritium, cobalt-60, strontium-90, technetium-99, iodine-129, cesium-137, and uranium concentrations in wells in or near operating areas exceeded Drinking Water Standards (DWS) (see Tables C2 and C3 in Appendix C of DOE [1992a]). Concentrations of uranium in the 200-West Area, tritium in the general 200 Area, strontium-90 in the 100-N and 200-East Areas exceeded the Derived Concentration Guides (DCGs) [see Table C6 in Appendix C of DOE (1992b)]. Tritium continues to slowly migrate downgradient with the groundwater flow where it enters the Columbia River; 1 curie of tritium was discharged to the Columbia River from the 100 Areas in 1992 (Woodruff and Hanf 1993).

Nitrate concentrations also exceeded DWS at various locations in the 100, 200, and 300 Areas and at several 600 Area locations. Elevated concentrations were also detected for chromium, cyanide, carbon tetrachloride, chloroform, and trichloroethylene in various sample wells in the 100 and 200 Areas. For further information regarding groundwater quality on the Hanford Site, refer to DOE (1992b).

4.8.3.2 Hydrology of the 200 Areas. The unconfined aquifer beneath the Hanford Site is contained

within the Ringold Formation and the overlying Hanford formation. The unconfined aquifer is affected by wastewater disposed to surface and subsurface disposal sites. The depth to groundwater ranges from 55 to 95 meters (180 to 310 feet) on the 200 Area Plateau. The bottom of the unconfined aquifer is the uppermost basalt surface or, in some areas, the clays of the Lower Ringold Member. The thickness of the unconfined aquifer in the 200 Areas ranges from less than 15 to 61 meters (50 to 200 feet). Beneath the unconfined aquifer is a confined aquifer system consisting of sedimentary interbeds or interflow zones that occur between dense basalt flows or flow units.

The sources of natural recharge to the unconfined aquifer are rainfall from areas of high relief to the west of the Hanford Site and two ephemeral streams, Cold Creek and Dry Creek. From the areas of recharge, the groundwater flows downgradient and discharges into the Columbia River. This general flow pattern is modified by basalt outcrops and subcrops in the 200 Areas and by artificial recharge.

The unconfined aquifer beneath the 200 Areas receives artificial recharge from liquid disposal areas. Cooling water disposed to ponds has formed groundwater mounds beneath two former and one continuing high-volume disposal sites: U Pond in the 200-West Area, B Pond east of the 200-East Area, and Gable Mountain Pond north of the 200-East Area. The water table rose approximately 20 meters (65 feet) under U Pond and 9 meters (30 feet) under B Pond compared with pre-Hanford conditions (Newcomb et al. 1972). However, U Pond and Gable Mountain Pond have been eliminated and, with no further recharge from them, the water levels will decline over the coming years. U Pond was deactivated in 1984 and Gable Mountain Pond was decommissioned and backfilled in 1987. The volume of B Pond increased after the elimination of Gable Mountain Pond.

The dry nature (for example, climate, waste form, and depth to water) of the low-level burial ground and the limited natural surface recharge available from precipitation minimize the probability of leachate formation and migration from these facilities.

Additional characterization and enhanced groundwater monitoring of the 200 Areas are currently being conducted pursuant to requirements established under the Resources Conservation and Recovery Act. When complete, this work will supply additional information on the 200 Areas.

4.8.4 Water Rights

The Hanford Site, situated along the Columbia River and near the Yakima River, lies within a region traditionally concerned about water rights. Typical water uses in this region include cooling a commercial nuclear power plant, irrigation, and municipal and industrial uses. Cooling water was withdrawn from the Columbia River to cool the defense reactors at Hanford. The DOE continues to assert a federally reserved water withdrawal right with respect to its existing Hanford operations. Current activities use water withdrawn from the Columbia River under the Department's federally reserved water right.

4.9 Ecological Resources

The Hanford Site is a relatively large, undisturbed area (1450 square kilometers [~560 square miles]) of shrub-steppe that contains numerous plant and animal species adapted to the region's semiarid environment. The site consists of mostly undeveloped land with widely spaced clusters of industrial buildings located along the western shoreline of the Columbia River and at several locations in the interior of the site. The industrial buildings are interconnected by roads, railroads, and electrical transmission lines. The major facilities and activities occupy about 6 percent of the total available land area, and their impact on the surrounding ecosystems is minimal. Most of the Hanford Site has not experienced tillage or livestock grazing since the early 1940s. The Columbia River flows through the Hanford Site, and although the river flow is not directly impeded by artificial dams within the Hanford Site, the historical daily and seasonal water fluctuations have been changed by dams upstream and downstream of the site (Rickard and Watson 1985). The Columbia River and other water bodies on the Hanford Site provide habitat for aquatic organisms. The Columbia River is also accessible for public recreational use and commercial navigation.

Topography of the proposed SNF facility site is level to gently sloping to the northeast. Substrate on the subject area is primarily Burbank loamy sand intergraded with Rupert sand. The latter consists of broad, stabilized sand dunes. Several used and unused unpaved roads cross the project area (Figure 4-18) with resulting disturbance to the plant community. The subject area outside the disturbed area is primarily a mature stand of big sagebrush with an understory of cheatgrass, an alien weed species, and Sandberg's bluegrass (Figure 4-18); there are approximately 494 square kilometers (191 square miles) of this community on the Hanford site. Sagebrush-bitterbrush/cheatgrass comprises the second largest plant community. Cover of big sagebrush increases rapidly from 10-25 percent near Route 4 to 25-50 percent over the remainder of the site. Cover of cheatgrass and Sandberg's bluegrass is mostly uniform across the subject area at 25-50 percent and 10-20 percent, respectively.

4.9.1 Terrestrial Resources

4.9.1.1 Vegetation. The Hanford Site, located in southeastern Washington, has been botanically char-

acterized as a shrub-steppe. Because of the site's aridity, the productivity of both plants and animals is relatively low compared with other natural communities. In the early 1800s, the dominant plant in the area was big sagebrush with an understory of perennial bunchgrasses, especially Sandberg's bluegrass and bluebunch wheatgrass. With the advent of settlement that brought livestock grazing and crop raising, the natural vegetation mosaic was opened to a persistent invasion by alien annuals, especially cheatgrass. Today cheatgrass is the dominant plant on fields that were cultivated 50 years ago. Cheatgrass is also well established on rangelands at elevations less than 244 meters (800 feet) (Rickard and Rogers 1983). Wildfires in the area are common; the most recent extensive fire in 1984 significantly altered the shrub component of the vegetation. The dryland areas of the Hanford Site were treeless in the years before land settlement; however, for several decades before 1943, trees were planted and irrigated on most of the farms to provide windbreaks and shade. When the farms were abandoned in 1943, some of the trees died but others have persisted, presumably because their

Figure 4-18. Distribution of vegetation types on the Hanford Site.

roots are deep enough to

contact groundwater. Today these trees serve as nesting platforms for several species of birds, including hawks, owls, ravens, magpies, and great blue herons, and as night roosts for wintering bald eagles (Rickard and Watson 1985). The vegetation mosaic of the Hanford Site currently consists of 10 major kinds of plant communities:

1) thyme buckwheat/Sandberg's bluegrass
2) sagebrush/bluebunch wheatgrass
3) sagebrush/cheatgrass or sagebrush/Sandberg's bluegrass
4) sagebrush-bitterbrush/cheatgrass
5) greasewood/cheatgrass-saltgrass
6) winterfat/Sandberg's bluegrass
7) cheatgrass-tumble mustard
8) willow or riparian
9) spiny hopsage/Sandberg's bluegrass
10) sand dunes.

The dominant plant community on the proposed SNF site is sagebrush/Sandberg's bluegrass, with cheatgrass-tumble mustard occurring in the southern portion of the site. A table listing common plants on the Hanford Site can be found in Cushing (1992).

Almost 600 species of plants have been identified on the Hanford Site (Sackschewsky et al. 1992). The dominant plants on the 200 Area Plateau are big sagebrush, rabbitbrush, cheatgrass, and Sandberg's bluegrass, with cheatgrass providing half of the total plant cover. More than 100 species of plants have been identified in the 200 Area Plateau. Cheatgrass and Russian thistle, annuals introduced to the United States from Eurasia in the late 1800s, invade areas where the ground surface has been disturbed. Certain desert plants have roots that grow to depths approaching 10 meters (33 feet) (Napier 1982); however, root penetration to these depths has not been demonstrated for plants in the 200 Areas. Rabbitbrush roots have been found at a depth of 2.4 meters (8 feet) near the 200 Areas (Klepper et al. 1979). Mosses and lichens appear abundantly on the soil surface; lichens commonly grow on the shrub stems. The important desert shrubs, big sagebrush and bitterbrush, are widely spaced and usually provide less than 20 percent canopy cover. The important understory plants are grasses, especially cheatgrass, Sandberg's bluegrass, Indian ricegrass, June grass, and needle-and-thread grass.

As compared to other semiarid regions in North America, primary productivity is relatively low and the number of vascular plant species is also low. This situation is attributed to the low annual precipitation (16 centimeters [~6 inches]), the low water-holding capacity of the rooting substrate (sand), and the droughty summers and occasionally very cold winters.

Sagebrush and bitterbrush are easily killed by summer wildfires, but the grasses and other herbs are relatively resistant and usually recover in the first growing season after burning. Fire usually opens the community to wind erosion. The severity of erosion depends on the severity and areal extent of the fire. Hot fires incinerate entire shrubs and damage grass crowns. Less intensive fires leave dead stems standing, and recovery of herbs is prompt. The most recent and extensive wildfire occurred in the summer of 1984.

Bitterbrush shrubs provide browse for a resident herd of wild mule deer. Bitterbrush shrubs are slow to recolonize burned areas because invasion is by seeds. Bitterbrush does not sprout even when fire damage is relatively light.

Certain passerine birds (such as sage sparrow, sage thrasher, and loggerhead shrike) rely on sagebrush or bitterbrush for nesting. These birds are not expected to nest in places devoid of shrubs. Jackrabbits also appear to avoid burned areas without shrubs. Birds that nest on the ground in areas without shrubs included longbilled curlews, horned larks, Western meadowlarks, and burrowing owls.

An ecological inventory of the vegetation on the proposed SNF facility site revealed two primary vegetation types: burned and unburned sagebrush/cheatgrass. Two species predominated in the burned area: cheatgrass and tarweed fiddleneck; the unburned vegetation comprised mainly cheatgrass and big sagebrush. During the one-day survey, approximately 43 species were identified.

4.9.1.2 Insects. More than 300 species of terrestrial and aquatic insects have been found on the Hanford

Site. Grasshoppers and darkling beetles are among the more conspicuous groups and, together with other species, are important in the food web of the local birds and mammals. Most species of darkling beetles occur throughout the spring to fall period, although some species are present only during two or three months in the fall (Rogers and Rickard 1977). Grasshoppers are evident during the late spring to fall. Both beetles and grasshoppers are subject to wide annual variations in abundance.

4.9.1.3 Reptiles and Amphibians. Among amphibians and reptiles, 12 species are known to occur on the

Hanford Site (Fitzner and Gray 1991). The occurrence of these species is infrequent when compared with similar fauna of the southwestern United States. The side-blotched lizard is the most abundant reptile and can be found throughout the Hanford Site. Short-horned and sagebrush lizards are also common in selected habitats. The most common snakes are the gopher snake, the yellow-bellied racer, and the Pacific rattlesnake, all found throughout the Hanford Site. Striped whipsnakes and desert night snakes are rarely found, but some sightings have been recorded for the site. Toads and frogs are found near the permanent water bodies and along the Columbia River. Cushing (1992) contains a list of all the reptiles and amphibians occurring on the Hanford Site.

4.9.1.4 Birds. Fitzner and Gray (1991) and Landeen et al. (1992) have presented data on birds observed

on the Hanford Site. The horned lark and western meadowlark are the most abundant nesting birds in the shrub-steppe. A list of some of the more common birds present on the Hanford Site can be found in Cushing (1992).

4.9.1.4.1 Birds Inhabiting Terrestrial Habitats-The game birds inhabiting terrestrial

habitats at Hanford are the chukar, gray partridge, and mourning dove. The chukar and partridge are year-round residents, but mourning doves are migrants. Although a few doves overwinter in south-eastern Washington, most leave the area by the end of September. Mourning doves nest on the ground and in trees all across the Hanford Site. Chukars are most numerous in the Rattlesnake Hills, Yakima Ridge, Umtanum Ridge, Saddle Mountains, and Gable Mountain areas of the Hanford Site. A few birds also inhabit the 200-Area Plateau. Gray partridges are not as numerous as chukars, and their numbers also vary greatly from year to year. Sage grouse populations have declined on the Hanford Site since the 1940s, and it is probable there are no grouse nests on the site at this time. The nearest viable population is located on the U.S. Army's Yakima Training Center, located to the north and west of the Hanford Site.

In recent years, the number of nesting ferruginous hawks has increased, at least in part because the hawks have accepted steel powerline towers as nesting sites. Only about 50 pairs are believed to be nesting in Washington. Other raptors that nest on the Hanford Site are the prairie falcon, northern harrier, red-tailed hawk, Swainson's hawk, and kestrel. Burrowing owls, great horned owls, barn owls, and long-eared owls also nest on the site but in smaller numbers.

4.9.1.5 Mammals. Approximately 39 species of mammals have been identified on the Hanford Site (Fitzner

and Gray 1991), and a complete list can be found in Cushing (1992). The largest vertebrate predator inhabiting the Hanford Site is the coyote, which ranges all across the site. Coyotes have been a major cause of destruction of Canada goose nests on Columbia River islands, especially islands upstream from the abandoned Hanford townsite. Bobcats and badgers also inhabit the Hanford Site in low numbers.

Black-tailed jackrabbits are common on the Hanford Site, mostly associated with mature stands of sagebrush. Cottontails are also common but appear to be more closely associated with the buildings, debris piles, and equipment laydown areas associated with the onsite laboratory and industrial facilities.

Townsend's ground squirrels occur in colonies of various sizes scattered across the Hanford Site but marmots are scarce. The most abundant mammal inhabiting the site is the Great Basin pocket mouse. It occurs all across the Columbia River plain and on the slopes of the surrounding ridges. Other small mammals include the deer mouse, harvest mouse, grasshopper mouse, montane vole, vagrant shrew, and Merriam's shrew.

The Hanford Site has seven species of bats that are known to be or are potential inhabitants, arriving mostly as fall or winter migrants. The pallid bat frequents deserted buildings and is thought to be the most abundant of the various species. Other species include the hoary bat, silver-haired bat, California brown bat, little brown bat, Yuma brown bat, and Pacific western big-eared bat.

A herd of Rocky Mountain elk is present on the ALE Reserve. It is believed these animals immigrated to the reserve from the Cascade Mountains in the early 1970s. This herd had grown from approximately 6 animals in 1972 to 119 animals in the spring of 1992. Elk frequently move off the ALE Reserve to private lands located to the north and west, particularly during late spring, summer, and early fall. However, while the elk are on the Hanford Site, they restrict their activities to the ALE Reserve. Lack of water and the high level of human activity presumably restrict the elk from using other areas of the Hanford Site. Despite the arid climate and their unusual habitat, these elk appear to be very healthy; antler and body size for given age classes are among the highest recorded for this species (McCorquodale et al. 1989). In addition, reproductive output is also among the highest recorded for this species. Elk remain on the ALE Reserve because of the protection it provides from human disturbance.

Mule deer are found throughout the Hanford Site, although areas of highest concentrations are on the ALE Reserve and along the Columbia River. Deer populations on the Hanford Site appear to be relatively stable. The herd is characterized by a large proportion of very old animals (Eberhardt et al. 1982) and high fawn mortality. Islands in the Hanford Reach of the Columbia River are used extensively as fawning sites by the deer (Eberhardt et al. 1979) and thus are a very important habitat for this species. Hanford Site deer frequently move offsite and are killed by hunters on adjacent public and private lands (Eberhardt et al. 1984).

The ecological survey conducted on an area adjacent to the proposed SNF facility site recorded (by presence or sign) 12 bird, 7 mammal, and 3 reptile species.

4.9.2 Wetlands

Several habitats on the Hanford Site could be considered as wetlands. The largest wetland habitat is the riparian zone bordering the Columbia River. The extent of this zone varies, but it includes extensive stands of willows, grasses, various aquatic macrophytes, and other plants. The zone is extensively impacted by both seasonal water level fluctuations and daily variations related to power generation at Priest Rapids Dam immediately upstream from the site.

Other extensive areas of wetlands can be found within the Saddle Mountain National Wildlife Refuge and the Wahluke Wildlife Refuge Area. These two areas encompass all the lands extending from the north bank of the Columbia River northward to the site boundary and east of the Columbia River down to Ringold

Springs. Wetland habitat in these areas consists of fairly large ponds resulting from irrigation runoff. These ponds have extensive stands of cattails (Typha sp.) and other emergent aquatic vegetation surrounding the open water regions. They are extensively used as resting sites by waterfowl.

Some wetlands habitat exists in the riparian zones of some of the larger spring streams on the ALE Reserve. These areas are not extensive and usually amount to less than a hectare in size, although the riparian zone along Rattlesnake Springs is probably about 2 kilometers (1.2 miles) in length and consists of peachleaf willows, cattails, and other plants. No wetlands are on or in the vicinity of the proposed project site area.

4.9.3 Aquatic Resources

There are two types of natural aquatic habitats on the Hanford Site: one is the Columbia River, which flows along the northern and eastern edges of the Hanford Site, and the other is provided by the small spring-streams and seeps located mainly in the Rattlesnake Hills. Several artificial water bodies, both ponds and ditches, have been formed as a result of wastewater disposal practices associated with the operation of the reactors and separation facilities. These bodies of water are temporary and will vanish with cessation of activities, but while present, they form established aquatic ecosystems (except West Pond) complete with representative flora and fauna (Emery and McShane 1980). West Pond is created by a rise in the water table in the 200 Areas and is not fed by surface flow; thus, it is alkaline and has a greatly restricted complement of biota.

4.9.3.1 The Columbia River. The Columbia River is the dominant aquatic ecosystem on the Hanford Site

and supports a large, diverse community of plankton, benthic invertebrates, fish, and other communities. It is the fifth largest river in North America and has a total length of about 2000 kilometers (~1240 miles) from its origin in British Columbia to its mouth at the Pacific Ocean. The Columbia has been dammed both upstream and downstream from the Hanford Site, and the reach flowing through the area is the last free-flowing, but regulated, reach of the Columbia River in the United States. Plankton populations in the Hanford Reach are influenced by communities that develop in the reservoirs of upstream dams, particularly Priest Rapids Reservoir, and by manipulation of water levels below by dam operations in downstream reservoirs. Phytoplankton and zooplankton populations at Hanford are largely transient, flowing from one reservoir to another. Generally, insufficient time does not allow characteristic endemic groups of phytoplankton and zooplankton to develop in the Hanford Reach. No tributaries enter the Columbia during its passage through the Hanford Site. Gray and Dauble (1977) list 43 species of fish in the Hanford Reach of the Columbia River. Since 1977, the brown bullhead (Ictalurus nebulosus) has also been collected, bringing the total number of fish species identified in the Hanford Reach to 44. Of these species, the chinook salmon, sockeye salmon, coho salmon, and steelhead trout use the river as a migration route to and from upstream spawning areas and are of the greatest economic importance. Both the fall chinook salmon and steelhead trout also spawn in the Hanford Reach. The relative contribution of upper river bright stocks to fall chinook salmon runs in the Columbia River increased from about 24 percent of the total in the early 1980s to 50 percent to 60 percent of the total by 1988 (Dauble and Watson 1990). The destruction of other main-stream Columbia spawning grounds by dams has increased the relative importance of the Hanford Reach spawning (Watson 1970, 1973). Fish migrating from the Columbia River up the Snake River would not be expected to pass through the Hanford area because the confluence of the two rivers lies downstream from the Hanford Site.

4.9.3.2 Spring Streams. The small spring streams, such as Rattlesnake and Snively springs, contain diverse biotic communities and are extremely productive (Cushing and Wolf 1984). Dense blooms of watercress occur and are not lost until one of the major flash floods occurs. The aquatic insect production is fairly high as compared to that in mountain streams (Gaines 1987). The macrobenthic biota varies from site to site and is related to the proximity of colonizing insects and other factors.

4.9.4 Threatened, Endangered, and Sensitive Species

Threatened and endangered plants and animals identified on the Hanford Site, as listed by the federal government (50 CFR 17) and Washington (Washington Natural Heritage Program 1994), are shown in Table 4.9-1. No plants or mammals on the federal list of endangered and threatened wildlife and plants (50 CFR 17.11, 17.12) are known to occur on the Hanford Site. However, several species of both plants and animals are under consideration for formal listing by the federal government and Washington.

4.9.4.1 Plants. Four species of plants are included in the Washington listing. Columbia milk-vetch (Astragalus columbianus Barneby) and Hoover's desert parsley (Lomatium tuberosum) are listed as threatened, and Columbia yellowcress (Rorippa columbiae Suksd.) and northern wormwood (Artemisia campestris ssp. borealis var. wormskioldii) are designated as endangered. Columbia milk-vetch occurs on dry land benches along the Columbia River in the vicinity of Priest Rapids Dam, Midway, and Vernita. It also has been found on top of Umtanum Ridge and in Cold Creek Valley near the present vineyards. Hoover's desert parsley grows on steep talus slopes in the vicinity of Priest Rapids Dam, Midway, and Vernita. Yellowcress occurs in the wetted zone of the water's edge along the Columbia River. Northern wormwood is known to occur near Beverley and could inhabit the northern shoreline of the Columbia River across from the 100 Areas.

Table 4.9-1. Threatened (T) and endangered (E) species known or possibly occurring on the Hanford Site.

Common name	Scientific name	Federal	State
Plants			
Columbia milk-vetch	Astragalus columbianus		T
Columbia yellowcress	Rorippa columbiae		E
Hoover's desert parsley	Lomatium tuberosum		T
Northern wormwood	Artemisia campestris borealis var. wormskioldii		E
Birds			
Aleutian Canada goose	Branta canadensis leucopareia	T	E
Peregrine falcon	Falco peregrinus	E	E
Bald eagle	Haliaeetus leucocephalus	T	T
White pelican	Pelecanus erythrorhychos		E
Sandhill crane	Grus canadensis		E
Ferruginous hawk	Buteo regalis		T
Mammals			
Pygmy rabbit	Brachylagus idahoensis		T
Insects			
Oregon silverspot butterfly	Speyerra zerene hippolyta	T	T

4.9.4.2 Animals. The federal government lists the Aleutian Canada goose (Branta canadensis leucopareia) and the bald eagle (Haliaeetus leucocephalus) as threatened and the peregrine falcon (Falco peregrinus) as endangered. In addition to the peregrine falcon, Aleutian Canada goose, and bald eagle, Washington lists the white pelican (Pelecanus erythrorhynchos) and sandhill crane (Grus canadensis) as endangered and the ferruginous hawk (Buteo regalis) as threatened. The peregrine falcon is a casual migrant to the Hanford Site and does not nest here. The Oregon silverspot butterfly (Speyerra zerene hippolyta) has recently been classified as a threatened species by both the state and federal governments. The bald eagle is a regular winter resident and forages on dead salmon and waterfowl along the Columbia River; nesting attempts have been made on the Hanford Site, but those have not been successful to date.   does not nest on the Hanford Site. Increased use of power poles for nesting sites by the ferruginous hawk on the Hanford Site has been noted. Washington State Bald Eagle Protection Rules were issued in 1986 (WAC-232-12-292). These rules require DOE to prepare a management plan to mitigate eagle disturbance; this has been done by Fitzner and Weiss (DOE/RL 1994). The Endangered Species Act of 1973 also requires that Section 7 consultation be undertaken when any action is taken that may jeopardize the existence of, destroy, or adversely modify habitat of the bald eagle or other endangered species.

Table 4.9-2 lists the designated candidate species that are under consideration for possible addition to the threatened or endangered list. Table 4.9-3 lists the plant species that are of concern in the state of Washington and are presently listed as sensitive or are in one of three monitor groups (Washington Natural Heritage Program 1994).

Sagebrush habitat is considered priority habitat by Washington because of its relative scarcity in the state and its requirement as nesting/breeding habitat by loggerhead shrikes (federal and state candidate species), sage sparrows (state candidate), burrowing owls (state candidate), pygmy rabbits (federal candidate and state threatened), sage thrashers (state candidate), western sage grouse (federal and state candidate), and sagebrush voles (state monitored). Although the last five species were not discovered during the present survey of the proposed SNF site, the habitat should be considered potentially suitable for their use. Pygmy rabbits and western sage grouse have only rarely been seen on the Hanford Site, and then primarily in upland regions. Loggerhead shrikes have been seen frequently on the proposed SNF facility site and are known to select tall big sagebrush as nest sites (Poole 1992). Although this species begins migration at the beginning of August (Poole 1992), one individual was observed during the present survey of the proposed SNF site. However, no nests were located. Ground squirrel burrows used by burrowing owls and owl pellets were observed during the present survey of the proposed SNF site. Numerous sage sparrows were also observed on the proposed SNF site. Pygmy rabbits would not have been observed during this survey because they are primarily crepuscular and nocturnal and may have already begun hibernation. However, this species is not known from lowland portions of the Hanford Site. The closest known ferruginous hawk (federal candidate and state threatened species) nest is approximately 8.9 kilometers (5.3 miles) northwest of the subject area. The subject area should be considered as comprising a portion of the foraging range of this species. No other species listed as endangered or threatened, or candidates for such listing by Washington or federal governments, or species listed as monitor species by Washington State, were observed on the proposed SNF site.

Table 4.9-2. Candidate species.

Common Name	Scientific Name	Federal	State
Mollusks			
Shortfaced lanx	Fisherola (=Lanx) nuttalli		X
Columbia pebble snail	Fluminicola (=Lithoglyphus) columbiana	X	X
Birds			
Common loon	Gavia immer		X
Swainson's hawk	Buteo swainsoni		X
Ferruginous hawk	Buteo regalis	X	
Western sage grouse	Centocrcus urophasianus phaios	X	X
Sage sparrow	Amphispiza belli		X
Burrowing owl	Athene cunicularia		X
Loggerhead shrike	Lanius ludovicianus	X	X

Northern goshawk	*Accipter gentilis*	X	
Harlequin duck	*Histrionicus histrionicus*	X	
Lewis' woodpecker	*Melanerpes lewis*		X
Long-billed curlew	*Numenius americanus*	X	
Sage thrasher	*Oreoscoptes montanus*		X
Flammulated owl	*Otus fammeolus*		X
Western bluebird	*Sialia mexicana*		X
Tricolored blackbird	*Agelaius tricolor*	X	
Golden eagle	*Aquila chrysaetos*		X
Black tern	*Chlidonius niger*	X	
Mammals			
Merriam's shrew	*Sorex merriami*		X
Pacific western big-eared bat	*Plecotus townsendii townsendii*	X	
Pygmy rabbit	*Brachylagus idahoensis*	X	
Insects			
Columbia River tiger beetle	*Cinindela columbica*		X
Plants			
Columbia milk-vetch	*Astragalus columbianus*	X	
Columbia yellowcress	*Rorippa columbiae*	X	
Hoover's desert parsley	*Lomatium tuberosum*	X	
Northern wormwood	*Artemisia campetis borealis* var. *wormskioldii*	X	

Table 4.9-3. Washington plant species of concern occurring on the Hanford Site.

Common Name	Scientific Name	Status[a]
Dense sedge	*Carex densa*	S
Gray cryptantha	*Cryptantha leucophaea*	S
Bristly cyptantha	*Cryptantha interrupta*	S
Shining flatsedge	*Cyperus rivularis*	S
Piper's daisy	*Erigeron piperianus*	S
Southern mudwort	*Limosella acaulis*	S
False-pimpernel	*Lindernia anagallidea*	S
Dwarf desert primrose	*Oenothera pygmaea*	S
Desert dodder	*Cuscuta denticulata*	M1
Thompson's sandwort	*Arenaria franklinii* v. *thompsonii*	M2
Robinson's onion	*Allium robinsonii*	M3
Columbia River mugwort	*Artemisia lindleyana*	M3
Stalked-pod milkvetch	*Astragalus sclerocarpus*	M3
Medick milkvetch	*Astragalus speirocarpus*	M3
Crouching milkvetch	*Astragalus succumbens*	M3
Rosy balsamroot	*Balsamorhiza rosea*	M3
Palouse thistle	*Cirsium brevifolium*	M3
Smooth cliffbrake	*Pellaea glabella*	M3
Fuzzy beardtongue penstemon	*Penstemon eriantherus*	M3
Squill onion	*Allium scillioides*	M3

The following species may inhabit the Hanford Site, but have not been recently collected, and the known collections are questionable in terms of locations or identification.

Palouse milkvetch	*Astragalus arrectus*	S
Few-flowered blue-eyed Mary	*Collinsia sparsiflora*	S
Coyote tobacco	*Nicotiana attenuata*	S

a. Abbreviations: S, sensitive; taxa vulnerable or declining, and could become endangered or threatened without active management or removal of threats. M1, Monitor group 1; taxa for which there are insufficient data to support listing as threatened, endangered, or sensitive. M2, Monitor group 2; taxa with unresolved taxonomic questions. M3, Monitor group 3; taxa that are more abundant or less threatened than previously assumed.

4.9.5 Radionuclide Levels in Biological Resources

Samples of vegetation and wildlife are routinely collected as part of the site environmental monitoring program and analyzed for various radionuclides. The following summarizes the levels reported in Woodruff and Hanf (1993).

A single sample of vegetation collected on the Hanford Site contained 0.015 picocuries strontium-90 per gram dry weight and 0.0059 picocuries cesium-137 per gram dry weight. These values are lower by nearly an order of magnitude from those reported for the previous five years. Mean values of cesium-137 in upland gamebird muscle (n = 4) in 1992 were 0.02 picocuries per gram wet weight and were about an order of magnitude higher than similar samples collected off of the Hanford Site the previous five years (n = 42). Mean values of cesium-137 in rabbit muscle (n = 12) were 0.09 picocuries per gram wet weight and exceed those collected on the Hanford Site the previous five years (n = 27) by about threefold, and were an order of magnitude higher than samples collected off of the Hanford Site. Values for strontium-90 in rabbit bone (n = 12) had a mean value of 4.08 picocuries per gram wet weight; mean values collected on the Hanford Site for the previous five years (n = 37) were 43 picocuries per gram wet weight, an order of magnitude higher. Mean strontium-90 concentrations in the bones of rabbits (n = 20) collected off of the Hanford Site were 0.37 picocuries per gram wet weight. One sample of muscle collected from a deer in the 200-Areas contained 0.006 picocuries cesium-137 per gram wet weight, nearly two orders of magnitude less than a similar sample collected off of the Hanford Site. Fish populations are safe for human consumption. Radionuclide levels of fish from the Hanford Reach are not significantly higher than those of fish found upstream. Because the confluence of the Snake and Columbia Rivers is downstream from the Hanford Site, the Snake River salmon runs do not migrate through the Hanford reach.

4.10 Noise

Noise is technically defined as sound waves perceptible to the human ear. Sound waves are characterized by frequency, measured in Hertz (Hz), and sound pressure expressed as decibels (dB). Noise levels are often reported as the equivalent sound level (Leq), which normally refers to the equivalent continuous sound level for an intermittent sound, such as traffic noise. The Leq is expressed in A-weighted decibels (dBA) over a specified period of time and is a frequency-weighted measure of sound level related to human hearing characteristics and the concept of equal loudness.

4.10.1 Hanford Site Sound Levels

Most industrial facilities on the Hanford Site are located far enough away from the site boundary that noise levels at the boundary are not measurable or are barely distinguishable from background noise levels. Modeling of environmental noises has been performed for commercial reactors and State Highway 240 through the Hanford Site. These data are not concerned with background levels of noise and are not reviewed here. Two studies of environmental noise were done at Hanford, as described in subsections 4.10.2 and 4.10.3. One study reported environmental noise measurements taken in 1981 during site characterization of the Skagit/Hanford Nuclear Power Plant Site (NRC 1982). The second was a series of site characterization studies performed in 1987 that included measurement of background environmental noise levels at five places on the Hanford Site. Additionally, such activities as well drilling and sampling have the potential for producing noise in the field apart from major permanent facilities. Noise can be disruptive to wildlife and studies have been done to compile noise data in remote areas.

4.10.2 Skagit/Hanford Data

Preconstruction measurements of environmental noise were taken in June 1981 on the Hanford Site (NRC 1982). Monitoring was conducted at 15 sites, showing point noise level reading ranging from 30 to 60.5 dBA. The corresponding values for more isolated areas ranged from 30 to 38.8 dBA. Measurements taken in the vicinity of the sites where the Washington Public Power Supply System was constructing nuclear power plants ranged from 50.6 to 64 dBA, reflecting operation of construction equipment. Measurements taken along the Columbia River near the intake structures for WNP-2 were 47.7 and 52.1 dBA, compared to more remote river noise levels of 45.9 dBA (measured about three miles upstream of the intake structures). Community noise levels from point measurements in North Richland (3000 Area at Horn Rapids Road and Stevens Road [Route 240]) were 60.5 dBA, largely attributed to traffic. North Richland is about 20 miles from the proposed site for SNF facilities.

4.10.3 Basalt Waste Isolation Project Data

Background noise levels were determined at five sites located within the Hanford Site. Noise levels are expressed as equivalent sound levels for 24 hours (Leq-24). The average noise level for these five sites was 38.8 dBA on the dates tested. Wind was identified as the primary contributor to background noise levels with winds exceeding 12 mph significantly affecting noise levels. This study concluded that background noise levels in undeveloped areas at Hanford can best be described as a mean Leq-24 of 24 to 36 dBA (Cushing 1992). Periods of high wind, which normally occur in the spring, would elevate background noise levels.

4.10.4 Noise Levels of Hanford Field Activities

In the interest of protecting Hanford workers and complying with Occupational Safety and Health Administration (OSHA) standards for noise in the workplace, the Hanford Environmental Health Foundation has monitored noise levels resulting from several routine operations performed in the field at Hanford. These included well drilling, pile driving, compressor operations, and water wagon operation. Occupational sources of noise propagated in the field from outdoor activities ranged from 93.4 to 96 dBA.

4.10.5 Noise Related to the Spent Nuclear Fuel Facility

Ambient noise levels at the proposed project SNF site just west of the 200-East Area on the Hanford Site are very low and would be expected to be less than 40 dBAs. The land is currently vacant, and no vehicular traffic transverses the site. A lightly used road borders the eastern side of the proposed SNF site and occasional traffic generates moderate amounts of vehicular noise, but only for those personnel near the road. Existing traffic noise on the Hanford Site is centered primarily on the main arteries leading into the site. These are Route 4 South, which connects with the Richland Bypass (Route 240) and eventually with Interstate 182. Another main road is Route 10, which also connects with Route 240 and leads into the 200 Areas in the site center. It is estimated that 3,300 privately owned vehicles travel to and from the site each day using these roads. The vast majority of the privately owned vehicle movement occurs during the rush hours of 6 to 8 a.m. and 3:30 to 6 p.m. In addition, it is estimated that 3,600 oncoming truck shipments, 445 oncoming rail shipments, and 837 intrasite truck shipments occur each day on the Hanford Site. The movement of all this vehicular traffic generates noise along these affected road corridors. However, little, if any, population exists along these roadways because of the geographic remoteness of work areas on the Hanford Site. Information on noise contours generated by peak rush hour traffic in terms of community Leqs and dBAs is not available at this time.

4.10.6 Background Information

Studies at Hanford of noise propagation have been concerned primarily with occupational noise at work sites. Environmental noise levels have not been extensively evaluated due to the remoteness of most Hanford activities and their isolation from receptors that are covered by federal or state statutes. The Noise Control Act of 1972 and its subsequent amendments (Quiet Communities Act of 1978, 42 USC 4901-4918, 40 CFR 201-211) empower the state to direct. The State of Washington has adopted RCW 70.107, which authorizes the Washington Department of Ecology to implement rules consistent with federal noise control legislation. The Hanford Site is currently in compliance with state and federal noise regulations.

4.11 Traffic and Transportation

4.11.1 Regional Infrastructure

This section discusses the existing transportation environment at and around the Hanford Site. Personnel and most material shipments are transported by road. Bulk materials or large items are shipped by barge. Rail transportation is used only to move irradiated fuel, certain high-level radioactive solid wastes, equipment, and materials (primarily coal). High-level and low-level wastes from spent fuel stabilization are transported to waste management facilities by pipeline.

The regional transportation network in the Hanford vicinity includes the areas in Benton and Franklin Counties from which 93 percent of the commuter traffic associated with the site originates. Interstate highways that serve the area are I-82, I-182, and I-90 (Figure 4-19). Interstate-82 is 8 kilometers (5 miles) south-southwest of the site. Interstate-182, a 24-kilometer (15-mile) long urban connector route 8 kilometers (5 miles) south-southeast of the site, provides an east-west corridor linking I-82 to the Tri-Cities area. Interstate-90 (not shown in Figure 4-19), located north of the site, is the major link to Seattle and Spokane and extends to the east coast; SR 224 (not shown in Figure 4-19), also south of the site, serves as a 16-kilometers

Figure 4-19. Transportation routes in the Hanford vicinity.

(10-mile) link between I-82 and SR 240. State Route 243 exits the northwestern boundary of the site and serves as a primary link between Hanford and I-90. State Route 24 enters the site from the west, continues eastward across the northernmost portion of the site, and intersects SR 17 approximately 24 kilometers (15 miles) east of the site boundary. State Route 17 is a north-south route that links I-90 to the Tri-Cities and joins U.S. Route 395, which continues south through the Tri-Cities. State Route 14 (not shown in Figure 4-19) connects with I-90 at Vantage, Washington, and provides ready access to I-84 (not shown in Figure 4-19) at several locations along the Oregon and Washington border.

General weight, width, and speed limits have been established for highways in the Hanford vicinity. However, no unusual laws or restrictions that have been identified would significantly influence general regional transportation.

Airline passenger and air freight service is provided at the Tri-Cities Airport owned and operated by the Port of Pasco, at Pasco, Washington. The air terminal is located approximately 16 kilometers (10 miles) from the Hanford Site. Delta Airlines provides domestic Boeing-737 and 727 service to Salt Lake City where multiple major airline service is available for domestic and international travel. Two feeder airlines service

the Tri-Cities:
United Express, a subsidiary of United Airlines, and Horizon Airlines, a subsidiary of Alaska Airlines, provide service to Seattle, Portland, and several other regional cities. Federal Express serves the Tri-Cities by charter airplane from Spokane to Pasco and Airborne Express serves the Tri-Cities with charter airplane from Seattle to the Richland airport, Richland, Washington.

4.11.2 Hanford Site Infrastructure

Hanford's onsite road network consists of rural arterial routes (see Figure 4-20). Only 104 of the 461 kilometers (65 of the 288 miles) of paved roads at Hanford are accessible to the public. Most onsite employee travel occurs along Route 4, with controlled access at the Yakima and Wye barricades. State Route 240 is the main public route through the site. Public highways SR 24 and SR 243 also traverse the site.

The highway network is in excellent condition. A recently completed major highway improvement project involved repavement and widening of the four-lane access route to the Wye Barricade. The highway network has been used extensively for transporting large equipment items, construction materials, and radioactive materials. Resurfacing, sealing, and restoration programs are currently planned for segments of SR 17, SR 224, SR 240, and U.S. Route 395.

Figure 4-20. Transportation routes on the Hanford Site.

In 1988 about 32 percent of the work force at Hanford worked in offices in Richland. The remaining work force was on the site. Approximately 80 percent of the work force resides in the Tri-Cities: Richland (45 percent), Kennewick (28 percent), and Pasco (7 percent). Approximately 1600 of the employees on the site use bus transportation.

In 1988 nearly 12 million miles were logged by DOE vehicles at Hanford. In addition, an estimated 3,300 privately owned vehicles were driven onsite each weekday and 560 were driven onsite each weekend day. Assuming a round-trip distance of 30 miles onsite for each of these vehicles, a total of about 40 million miles were driven annually by workers onsite.

The primary highways used by commuters are SR 24, SR 240, and I-182; 10, 90, and 10 percent of the work force use these routes, respectively (totals to more than 100 percent because some commuters use two of the routes). With these commuting patterns, workers annually travel about 27 million miles offsite. Trucks used for material shipment to Hanford compose about 5 percent of the vehicular traffic on and around the site. At present there are periods of moderate traffic congestion, some of which is expected to be alleviated by a new road to the 200 Areas.

During 1988, 169 accidents were reported onsite, with 20 involving DOE vehicles. The other accidents involved privately owned vehicles and included seven injury accidents and one fatal accident on SR 240. Among offsite highway segments of concern, most accidents occurred along I-82. According to available data, the 15 accidents involving trucks in 1987 in the Benton/ Franklin county study area resulted in 13 injuries and 3 fatalities.

Onsite rail transport is provided by a short-line railroad owned and operated by DOE. This line connects just south of the Yakima River with the Union Pacific line, which in turn interchanges with the Washington Central and Burlington Northern railroads at Kennewick. AMTRAK passenger rail service is provided in the Tri-Cities at the Burlington Northern depot at Pasco. Approximately 145,000 rail miles were logged at Hanford in 1988, primarily transporting coal to steam plants. Two noninjury rail accidents occurred at Hanford in 1988.

The Hanford Site infrequently uses the Port of Benton dock facilities on the Columbia River for off-loading large shipments. Overland wheeled trailers are then used to transport those shipments to the site. No barge accidents were reported in 1988.

4.12 Occupational and Public Health and Safety

This section summarizes the Hanford Site programs designed to protect the health and safety of workers and the public. It also describes existing radiological and nonradiological conditions and provides a historical perspective on worker and public exposures and potential health effects.

The section is based on existing documentation and generic descriptions. Reference is made to policies, orders, guidance documents, annual occupational exposure and environmental reports, and to other site descriptive documents. The parameters of greatest interest are the history of radiological releases and worker radiation doses, particularly those associated with the storage of SNF.

The DOE, the DOE-RL, and all Hanford Site contractors have established policies to help ensure a safe and healthful workplace for all employees and visitors and to protect the environment and public health and safety. The DOE-RL manager has the overall responsibility for safety and health at the Hanford Site. Each contractor develops and enforces occupational and public health and safety programs that meet or exceed the requirements of DOE orders, other federal agencies, and Washington State.

4.12.1 Occupational Health and Safety

Programs are in place at the Hanford Site to protect workers from radiological and nonradiological hazards. Radiological protection (health physics) programs are based on requirements in regulations and DOE orders, and on guidance in radiological control manuals. Occupational nonradiological health and safety programs are composed of industrial hygiene programs and occupational safety programs.

4.12.1.1 Radiological Health and Safety/Health Physics Program. In order to help ensure that

workers at DOE facilities are adequately protected from ionizing radiation, the DOE promulgates radiation protection standards for occupational workers. These standards include radiation dose limits to control worker dose from both external radiation and internally deposited radionuclides. The current radiation dose limits were promulgated in 10 CFR Part 835, "Occupational Radiation Protection," which was enacted in 1993. This regulation includes limits on total effective dose equivalent to workers, dose to individual organs, and dose to members of the public (including minors and unborn children of workers) that may be incidentally exposed while at DOE facilities.

Hanford contractors base their radiological protection programs, procedures, and manuals primarily on 10 CFR Part 835. This regulation establishes the criteria for radiation protection for occupational workers. It lists allowable doses, establishes a policy on keeping doses as low as reasonably achievable, and specifies training requirements for radiation protection personnel and other workers. The DOE Radiological Control Manual, DOE/EH-0256T, issued by DOE Headquarters, establishes practices for conducting radiological control activities at all DOE sites. The DOE requires monitoring and reporting of radiation exposure records for individual workers and certain visitors. Monitoring is required by 10 CFR Part 835 when the potential exists for an individual to receive an annual effective dose equivalent above 100 millirem (1 millisievert), or an annual dose equivalent to an individual organ greater than 10 percent of DOE occupational exposure limits. Personnel to be monitored are assigned a thermoluminescent dosimeter that is worn at all times during radiation work on the Hanford Site. This instrument measures the amount and type of external radiation dose the worker receives. Dosimeters for all DOE and contractor personnel are processed by Pacific Northwest Laboratory. The centralized operational dosimetry program reads, records, and summarizes results of dosimetry data as required. Records of occupational exposure are maintained, and reports of radiation dose are provided annually to each worker. Summary reports are also provided to DOE and published periodically (Smith et al. 1992)

4.12.1.2 Radiation Doses to Workers. The reported cumulative doses to all Hanford Site workers and

visitors for all activities are given as a baseline for site operations.

In 1993, about 14,500 workers were monitored at the Hanford Site. Of those monitored, 11,000 were classified as radiation workers, with an average annual dose equivalent of 0.02 rem per individual (Lyon). This dose is well below the 10 CFR Part 835 dose limit of 5 rem per year and the DOE Administrative Control Level of 2 rem per year for occupational exposure.

For 1993, the estimated collective dose-equivalent was 200 person-rem for all Hanford Site radiation workers. Based on standard dose-to-health effects conversion factors (ICRP 1991), no health effects would be expected to result among workers so exposed.

The worker radiation dose of most interest in this document is the cumulative collective dose to SNF workers, which is described in the following subsection. The SNF management alternatives considered in this document are similar to those current work activities associated with maintenance and storage of SNF at the Hanford Site.

4.12.1.3 Radiation Dose to K-Basin Workers. On the Hanford Site the bulk of the SNF is stored in the

105-KE and 105-KW Basins, which are collectively referred to as the K-Basins. The K-Basins are located within the 100-K Area of the Hanford Site. The basins are filled with recirculating water to cool the fuel and to provide radiological shielding for personnel working in the facility. Westinghouse Hanford Company (WHC) operates the K Basins for DOE. Therefore the best measure of radiation dose from SNF is the dose to WHC employees assigned to work at the K Basins. The collective radiation dose to WHC K Basin workers over the 2-year period 1991 and 1992 averaged 22 person-rem per year, or approximately 0.4 rem per year for each worker. An average of 58 workers were assigned to the K-Basin during 1991 and 1992, or approximately 29 workers per basin (Holloman and Motzco 1992, 1993).

The nominal collective radiation dose per year of operation of each SNF basin in the 100-K Area is estimated to be 11 person-rem. During the plutonium production mission, each reactor at the Hanford Site had a similar nuclear fuel storage basin associated with its operation. This resulted in an estimated total radiation dose of 2000 person-rem, assuming 179 total operating reactor years plus six years of K-Basin operation following shutdown of the production reactors (Bergsman 1994). Therefore, operation of nuclear fuel storage basins has accounted for approximately 2.4 percent of the total radiological dose received by all Hanford Site workers from 1945 through 1985, 86,100 rem (Gilbert et al. 1993). Based on standard dose-to-health effects conversion factors (ICRP 1991), the dose to SNF workers since Hanford start up would statistically relate to one fatal cancer among these workers.

4.12.1.4 Worker Safety and Accidents. No incidents of overexposure to radiation have been reported to

DOE during 1990 and 1991 in association with SNF storage activities at the Hanford Site. Overexposures are defined as any exposure over regulatory limits established by the DOE (WHC 1990; Lansing et al. 1992).

In the four-year period from 1991 through 1994, industrial-type accidents resulted in 98 lost working days at the K Basins out of a total of approximately 70,000 days worked.

4.12.1.5 Industrial Hygiene Program. Occupational nonradiological health and safety programs at

Hanford are composed of industrial hygiene and occupational safety programs. Industrial hygiene programs address such subjects as toxic chemicals and physical agents, carcinogens, noise, biological hazards, lasers, asbestos, and ergonomic factors. Occupational safety programs address such subjects as machine safety, hoisting and rigging, electrical safety, building codes, welding safety, and compressed gas cylinders.

The governing document is DOE 5480.10, "Contractor Industrial Hygiene Program," dated 6-26-85. The DOE-RL implementing procedure for DOE 5480.10 is RLIP 5480.10 "Industrial Hygiene Program," dated 7-30-90. The procedure establishes additional requirements and direction for implementation of an industrial hygiene program for DOE-RL and its contractors. In addition to the program requirements of DOE 5480.10, the RL Industrial Health Program addresses the following subject areas:

(1) Use of respiratory equipment
(2) Asbestos material
(3) Regulated carcinogen or suspect carcinogenic materials
(4) Sanitation
(5) Control of hazardous materials
(6) Filter testing
(7) Hearing conservation
(8) Indoor air quality
(9) Human factors
(10) Hazardous waste site safety/health management.

The responsibilities and authorities of the Occupational Medical Services Contractor (contracted by DOE to Hanford Environmental Health Foundation) of the Industrial Health Program are also described in DOE 5480.10. These are 1) to provide technical industrial health support services, that is, air and water monitoring; 2) to evaluate, recommend, and train workers in the use of respiratory devices, as requested by DOE-RL and its contractors; 3) to provide an industrial health analytical laboratory; 4) to conduct work environment surveys; 5) to support noise abatement and hearing conservation; and 6) to maintain permanent records of personal exposure monitoring data. Hanford Environmental Health Foundation maintains centralized records and provides DOE-RL and its contractors with the results of monitoring efforts.

The RL contractors are required to do the following:

- Conduct an effective program to educate employees on the potential health hazards in their work environment, the control measures, and the protection necessary to reduce those risks to acceptable levels.

- Inform employees of health hazards and the results from monitoring of harmful toxic or physical agents in the work environment, and document this action.

Records are maintained in accordance with DOE 1324.2, DOE 5483.1A, and DOE 5484.1. Contractors of DOE-RL are required to maintain records of employee toxic and physical agent exposure and potential personal exposure data. Contractors of DOE-RL are also required to maintain Hanford Site material safety data sheets.

The DOE requires that as low as reasonably achievable (ALARA) principles for radiological and nonradiological hazardous materials be applied in the preparation of all health and safety plans, and that all such ALARA criteria are followed during the course of the work.

Training requirements consistent with 29 CFR 1910.120 for entry into sites potentially containing toxic or hazardous material are specified by DOE (29 CFR OSHA 1991).

The DOE-RL requires that all work (including preliminary investigation activities) be conducted in such a manner that it conforms to applicable federal and state safety and health standards and that all operating equipment meets all safety and operability standards and requirements.

4.12.2 Public Health and Safety

The DOE has the responsibility under the Atomic Energy Act to establish the necessary standards to protect members of the public from radiation exposures resulting from DOE activities. In addition, Presidential Order 12088, "Federal Compliance with Pollution Control Standards," requires all federal facilities to comply with the legislative acts and regulations relating to the prevention, control, and abatement of environmental pollution. The Hanford Site is also in compliance with EPA's National Emission Standards for Hazardous Air Pollutants for Radionuclides, 40 CFR 61, Subpart H. The EPA offsite air emissions limiting standard is 10 millirem/year effective dose equivalent to the public. The National Primary Drinking Water Regulations of the Safe Drinking Water Act apply to the drinking water supplies at the Hanford Site. Several radionuclides are included in these water standards (40 CFR 141, 142; 56 FR 33050-33127, 1991) For 1993, the Hanford Site Environmental Report (Dirkes et al. 1994) relates that the facility is in compliance with these requirements.

4.12.2.1 Environmental Programs. DOE 5400.1, "General Environmental Protection Program,"

establishes the requirement for environmental protection programs. The Hanford Site Environmental Report is prepared annually pursuant to DOE 5400.1 to summarize environmental data that characterize Hanford Site environmental management performance and regulatory compliance status. The most recent report summarizes the status in 1993 of compliance with environmental regulations, describes programs at the Hanford Site, discusses estimates of radiation dose to the public from Hanford activities, and presents information on effluent monitoring and environmental surveillance, including groundwater monitoring (Dirkes et al. 1994). In 1993, environmental programs were conducted at the Hanford Site to restore environmental quality, manage waste, develop appropriate technology for cleanup activities, and study the environment.

4.12.2.2 Environmental Monitoring/Surveillance Information. Environmental monitoring at the

Hanford Site consists of effluent monitoring and environmental surveillance, including groundwater monitoring. Effluent monitoring is performed by the operators at the facility or at the point of release to the environment. Environmental surveillance consists of sampling and analyzing environmental media on and off the Hanford Site to detect and quantify potential contaminants and to assess their environmental and human health significance. The annual Hanford Site Environmental Reports (Dirkes et al. 1994) present a summary of this information for the Hanford Site. The Hanford Site operations contractor, Westinghouse Hanford Company, also reports summary data annually on radioactive and nonradioactive materials released into the environment from facilities they manage (WHC 1993a). Several federal and state laws and regulations require the reporting of radioactive and nonradioactive releases. The Hanford Site reports pursuant to the federal Clean Air Act (Diediker et al. 1994) and Clean Water Act.

4.12.2.3 Natural Cancer Incidence. The probability of an American contracting cancer in their lifetime is 340 in 1000 (American Cancer Society 1993), and 20 percent of Americans will die from cancer, an estimated 526,000 cancer deaths in 1993. Table 4.12-1 shows the estimated 1993 cancer incidence for different types of cancer for the United States and for Washington State. For the United States the probability of contracting cancer in 1993 is 4.9 in 1000, and 2.2 in 1000 of dying from that cancer. For Washington State the probability of contracting cancer in 1993 is 3.2 in 1000, and 1.4 in 1000 of dying from that cancer.

The expected survival period for cancer victims has increased as detection and treatment technologies have improved. Currently, 40 percent of the victims of all forms of cancer survive for at least 5 years.

4.12.2.4 Potential Radiation Doses. Potential radiation doses and exposures to members of the public from releases of radionuclides to air and water at the Hanford Site are calculated and reported annually by the Surface Environmental Surveillance Project at the Pacific Northwest Laboratory.

Table 4.12-1. Estimated 1993 cancer incidence and cancer deaths in the United States and the state of Washington for different forms of cancer (American Cancer Society 1993).

	United States[a] 1993		Washington State[b] 1993	
Type of Cancer	Estimated new cases	Estimated deaths	Estimated new cases	Estimated deaths
All types & sites	1,170,000	526,000	14,825	6,350
Female breast	182,000	46,000	3,300	850
Colon & rectum	152,000	57,000	2,400	950
Lung	170,000	149,000	3,100	2,700
Oral	29,800	7,700	500	125
Uterus	44,500	10,100	600	125
Prostate	165,000	35,000	3,300	700
Skin melanoma	32,000	6,800	600	125
Pancreas	27,700	25,000	475	425
Leukemia	29,300	18,600	550	350

a. Total population 250 million.
b. Total population 5 million.

4.12.2.4.1 Maximally Exposed Individual (MEI) Dose.

The MEI is defined in the Hanford Site Environmental Report as "an hypothetical person who lives at a location and has a lifestyle such that it is unlikely that other members of the public would receive higher radiation doses" (Dirkes et al. 1994). The potential radiation doses to MEI have been published in annual Hanford Site Environmental Reports since 1957. For 1993, the total potential dose (via air and water pathways) to the MEI from Hanford operations was calculated to be 0.03 mrem (Dirkes et al. 1994). Estimates of the potential cumulative Effective Dose Equivalent (EDE) to the MEI from both air and water sources for the 28-year period 1994 through 1972 were reconstructed by the Hanford Environmental Dose Reconstruction (HEDR) Project (TSP 1994).

The highest cumulative dose to an adult resident for the years 1944 through 1972 from pathways associated with releases to the air was 1 rem; almost all of this dose was received during 1945. The highest cumulative dose to an adult resident for the years 1944 through 1971 from pathways associated with releases to the water was 1.5 rem; about one-half of this was received during the period from 1954 through 1964. Thus the total cumulative dose from both air and water releases was about 2.5 rem. For comparison, the dose received by an average resident during this 28-year period from natural background radiation was approximately 9 rem. Radiation doses received by the public from Hanford releases after 1972 were vanishingly small.

The maximum cumulative dose to the thyroid of a small child for the years 1944 through 1951 was estimated to be 240 rad; the majority of this dose was received during 1945.

4.12.2.4.2 Population Dose - Estimates of the potential cumulative dose to the population

within 50 miles (80 km) of the Hanford Site for 1944 through 1972 were estimated from the releases to air and water developed by the Hanford Environmental Dose Reconstruction (HEDR) project. Pathways of exposure associated with releases to the air dominated the population doses until after 1954 when their contribution decreased rapidly. The cumulative population dose during 1944 through 1972 was 100,000 person-rem; essentially all of this dose was received through air pathways in 1945. The cumulative population dose during 1944 through 1972 associated with water pathways was estimated to be about 6,000 person-rem; most of this dose was received during the decade between 1954 and 1964.

The total potential radiation dose to the population within 50 miles (80 km) for 1993 was 0.4 person-rem (Dirkes et al. 1994). By comparison, the total dose received in 1993 by this same population was about 110,000 person-rem.

About 50 cancer deaths would be implied by the total public radiation dose from Hanford activities since 1944 using standard dose-to-health-effects conversion factors (ICRP 91). Essentially all of these would have been a result of radiation exposures received during 1945. For perspective, the population within 50 miles (80 km) of the Site would have experienced about 75,000 cancer deaths in 1993 from all causes.

4.13 Site Services

4.13.1 Water Consumption

The principal source of water in the Tri-Cities and the Hanford Site is the Columbia River, from which the water systems of Richland, Pasco, and Kennewick draw a large portion of the average 4.3 x 107 cubic meters (11.38 billion gallons) used in 1991. Each city operates its own supply and treatment system. The Richland water supply system derives about 67 percent of its water from the Columbia River, approximately 15 to 20 percent from a well field in North Richland, and the remaining from groundwater wells. The city of Richland's total usage in 1991 was 2.1 x 107 cubic meters (5.65 billion gallons). This current usage represents approximately 58 percent of the maximum supply capacity. The city of Pasco system also draws from the Columbia River for its water needs; the 1991 estimate of consumption is 1.1 x 107 cubic meters (2.81 billion gallons). The Kennewick system uses two wells and the Columbia River for its supply. These wells serve as the sole source of water between November and March and can provide approximately 62 percent of the total maximum supply of 2.8 x 107 cubic meters (7.3 billion gallons). Total usage of those wells in 1991 was 1.1 x 107 cubic meters (2.92 billion gallons).

4.13.2 Electrical Consumption

Electricity is provided to the Tri-Cities by the Benton County Public Utility District, Benton Rural Electrical Association, Franklin County Public Utility District, and City of Richland Energy

Services Department.
All the power that these utilities provide in the local area is purchased from the Bonneville Power Administration, a federal power marketing agency. The average rate for residential customers served by the three local utilities is approximately $0.0396 per kilowatt hour. Electrical power for the Hanford Site is purchased wholesale from the Bonneville Power Administration. Energy requirements for the site during FY 1988 exceeded 550 average megawatts.

Natural gas, provided by the Cascade Natural Gas Corporation, serves a small portion of residents, with 4800 residential customers in June 1992.

In the Pacific Northwest, hydropower, and to a lesser extent, coal and nuclear power, constitute the region's electrical generation system. Total generating capacity is about 40,270 megawatts. Approximately 74 percent of the region's installed generating capacity is hydroelectric, which supplies approximately 65 percent of the electricity used by the region. Coal-fired generating capacity is 6,702 megawatts in the region, 16 percent of the region's electrical generating capacity. Two commercial nuclear power plants are in service in the Pacific Northwest, with a 2247-megawatt capacity of 6 percent of the region's generating capacity. Oil and natural gas account for about 3 percent of capacity.

The region's electrical power system, more than any other system in the nation, is dominated by hydropower. On average, the region's hydropower system can produce 16,400 megawatts. Variable precipitation and limited storage capabilities alter the system's output from 12,300 average megawatts under critical water conditions to 20,000 average megawatts in record high water years. The Pacific Northwest system's reliance on hydroelectric power means that it is more constrained by the seasonal variations in peak demand than in meeting momentary peak demand.

Throughout the 1980s, the Northwest had more electric power than it required and was operating with a surplus. This surplus has been exhausted, however, and there is only approximately enough power supplied by the existing system to meet the current electricity needs. Hydropower improvement projects currently under construction in the Northwest include about 150 megawatts of new capacity. The cost and availability of several other resources are currently being studied (Northwest Power Planning Council 1986). Approximate rates for current consumption of electricity, coal, propane, natural gas, and other utilities at the Hanford Site are shown in Table 4.13-1.

4.13.3 Waste Water Disposal

The major incorporated areas of Benton and Franklin counties are served by municipal wastewater treatment systems, whereas the unincorporated areas are served by onsite septic systems. Richland's wastewater treatment system is designed to treat a total capacity of 27 million cubic meters per year (a daily average flow of 8.9 million gallons per day with a peak flow of 44 million gallons per day). In 1991 the system processed an average of 4.83 million gallons per day. The Kennewick system similarly has significant excess capacity, with a treatment capability of 12 million cubic meters per year (8.7 million gallons per day); 1991 usage was 4.8 million gallons per day. Pasco's waste-treatment system processes an average of 2.22 million gallons per day, while the system could treat 4.25 million gallons per day or 16.2 liters per day.

4.14 Materials and Waste Management

This section discusses the management of materials and waste and presents both a historic overview and the current status of the various waste types being generated and stored at the Hanford Site. Regulatory requirements governing the management of these materials and wastes are discussed in Section 2.2.

Table 4.13-1. Approximate consumption of utilities and energy on the Hanford Site (1992).

Energy	Consumption	
Electricity	340,000 megawatt-hours	
Coal	45,000 metric tons	(50,000 tons)
Fuel Oil	83,000 cubic meters	(22,000,000 gallons)
Natural Gas	680,000 cubic meters	(24,000,00 cubic feet)
LPG-propane	110 cubic meters	(29,000 gallons)
Gasoline	3,600 cubic meters	(950,000 gallons)
Diesel	1,700 cubic meters	(450,000 gallons)
Other Utilities		
Water	15,000,000 cubic meters	(4,000+ million gallons)
Power Demand	57 megawatts	

In order for Hanford programs to meet operational and mission requirements, many hazardous materials are or have been used onsite. Hazardous materials are not waste, but when no longer useful, may become waste. Because of the potential for impacts to human health and the environment, hazardous materials have been included in Subsection 4.14.7.

Wastes at the Hanford Site are generated by both facility operations and environmental restoration activities. Facility operations include nuclear and non-nuclear research, materials testing, laboratory analysis, high-level waste stabilization, and nuclear fuel storage, manufacturing, repair and maintenance, and general office work. They also include operation of all waste management facilities for treatment, storage, or disposal of Hanford wastes, as well as any waste shipped to Hanford for storage or disposal. Environmental restoration operations include remediation (identifying and arranging for the cleanup of inactive waste sites) and decontamination and decommissioning of surplus facilities.

Wastes and materials handled at the Hanford Site are described in subsections 4.14.1 through 4.14.7. These wastes and materials have been classified as high-level waste (discussed in detail in subsection 4.14.1), transuranic waste (discussed in detail in subsection 4.14.2), mixed low-level waste (discussed in detail in subsection 4.14.3), low-level waste (discussed in detail in subsection 4.14.4), hazardous waste (discussed in detail in subsection 4.14.5), industrial solid waste (discussed in detail in subsection 4.14.6), and hazardous materials (discussed in detail in subsection 4.14.7). Table 4.14-1 shows expected waste disposal rates as of the year 2000, including the expected disposition.

The total amount of waste generated and disposed of at the Hanford Site has been, and is being, reduced through the efforts of the pollution prevention and waste minimization programs at the site. The Hanford Waste Minimization (and Pollution Prevention) Program is an ambitious program aimed at source reduction, product substitution, recycling, surplus chemical exchange, and waste treatment. The program is tailored to meet Executive Order 12780, DOE orders, RCRA, and EPA guidelines. All wastes on the Hanford Site, including radioactive, mixed, hazardous and non-hazardous regulated wastes are included in the Hanford Waste Minimization Program.

Table 4.14-1. Baseline waste quantities as of the year 2000 at Hanford[a].

Waste identification	Annual disposal volume from stabilization operations wastes (m3/yr)	Annual disposal volume from stabilization of stored wastes (m3/yr)	Total annual disposal volume from all waste stabilization (m3/yr)	Disposition
High-level waste	0	240	240[c]	Interim onsite solid[b] storage[d]
Transuranic waste	0	170	170[c]	Interim onsite solid[e] storage[f]
Low-level waste	13,000	7,000	20,000	Onsite solid[g]

disposal			
Mixed waste	300	0	300
Interim onsite			
solid[g]			
storage			
Hazardous waste	100	0	100
Offsite			
liquid and solid			
disposal			
Other waste			
nonhazardous			
liquid	2,000,000	10,000,000	12,000,000
Liquid effluent			
solid	38,000	0	38,000
Onsite disposal			
sewage			
liquid[h]	210,000	0	210,000
Liquid effluent			
solid[i]	4	0	4
Onsite disposal			

a. Baseline values are projected from 1988 data.
b. Liquid high-level waste (HLW) is held in interim storage and then processed to a solid form for disposal.
c. The baseline value is taken from 1988 data for planned future activities.
d. These wastes are targeted for disposal at a federal repository.
e. Liquids containing transuranics are processed as HLW.
f. These wastes are targeted for disposal at WIPP.
g. Solidified or absorbed-liquid-waste quantities are included in the solid waste quantity.
h. Liquid effluents from sewage treatment operations.
i. Solids from sewage treatment operations.

Reductions in the volumes of radioactive wastes generated have been achieved through methods such as intensive surveying, waste segregation, recycling, and use of administration and engineering controls. Some examples of waste reduction follow:

- Waste minimization efforts have reduced the volume of waste water discharged to process trenches in the 300 Area by more than 5,600 cubic meters (>1.5 million gallons) per day. By the end of 1992, waste reduction efforts had reduced liquid waste by more than 22,000 cubic meters (>5.8 million gallons) (Woodruff and Hanf 1993).

- In 1991, 440,645 kilograms (971,440 pounds) of ferrous metals, 49,323 kilograms (108,737 pounds) of nonferrous metals, 275 cubic meters (9,076 cubic feet) of wood scrap, and 136,077 kilograms (299,993 pounds) of scrap paper were recycled. During 1992, approximately 181,440 kilograms (400,000 pounds) of paper were recycled (Woodruff and Hanf 1993).

On-going projects include packaging reduction, waste minimization design, and technology transfer.

Databases are used at the Hanford Site to track and manage waste management information. These databases have been screened to ensure that the information supplied is supported by official databases, reports, or other public documents. Although the most reliable data available have been used to quantify and characterize waste volumes, past waste volumes are imprecise and may be subject to change as characterization of previously disposed waste is undertaken and completed.

4.14.1 High-Level Waste

High-level radioactive waste is defined in the Nuclear Waste Policy Act of 1982 (PL 97-425) as "(A) the highly radioactive material resulting from the reprocessing of SNF, including liquid waste produced directly in reprocessing and any solid material derived from such liquid waste that contains fission products in sufficient concentrations; and (B) other highly radioactive material that the [Nuclear Regulatory Commission], consistent with existing law, determines by rule requires permanent isolation."

High-level waste at Hanford was generated from the reprocessing of production reactor fuel for the recovery of plutonium, uranium, and neptunium for defense and other national programs of spent reactor fuel and irradiated targets. Radioactive waste generated on the Hanford Site from 1988 through 1990 is shown in Table 4.14-2.

4.14.1.1 Historic Overview. Until recently, the primary mission of the Hanford Site was production of special nuclear material for defense purposes. Since 1943, the Hanford Site has been involved in fabrication of reactor fuel elements, operation of production reactors, processing of irradiated fuel, separation and extraction of plutonium and uranium, preparation of plutonium metal, and decontamination and decommissioning activities. Between 1943 and 1964, 149 single-shell tanks were built to store liquid radioactive wastes. No new wastes have been added to these tanks since 1980; much of the liquid waste originally stored in the single-shell tanks has been transferred to some of the 28 one-million gallon double-shell tanks for safer storage (DOE 1993c).

Table 4.14-2. Radioactive waste generated on the Hanford Site from 1988-1990 in kilograms (excluding mixed waste).

Calendar Year	Low-Level Waste	Transuranic Waste	High-Level Waste
1988	3,800,000	21,900	0
1989	8,300,000	27,200	0
1990	3,600,000	24,500	0

Source: DOE 1991.

High-level waste has been accumulating at Hanford since 1944. Most of these high-level wastes have undergone one or more treatment steps (e.g., neutralization, precipitation, decantation, or evaporation) and will eventually require incorporation into a stable, solid medium (e.g., glass) for final disposal (DOE 1993d, 1992b).

Between 1956 and 1990, the Plutonium and Uranium Recovery through EXtraction (PUREX) plant processed irradiated reactor fuel to extract plutonium and uranium (DOE 1982). The wastes from the PUREX process were placed in double-shell tanks after 1970, and are the second high-level waste stream (DOE 1993c).

Cesium and Strontium Capsules: From 1968 to 1985, most of the high-heat emitting nuclides (strontium-90 and cesium-137, plus their daughters) were extracted from the old tank waste, converted to solids (strontium fluoride and cesium chloride), placed in double-walled metal cylinders (capsules) about 50 centimeters (20 inches) in length and 5 centimeters (2 inches) in diameter, which were stored in the Waste Encapsulation and Storage Facility in water-filled pools (DOE 1993d).

4.14.1.2 Current Status. There are two high-level waste streams at Hanford: the single-shell tank wastes and double-shell tank PUREX aging wastes. All wastes contained in double-shell tanks consist of mixtures of high-level wastes, transuranic waste, and several low-level wastes, and are managed as if they contain high-level waste. The single-shell tank wastes make up 95 percent of the Hanford Site high-level mixed waste (DOE 1993c).

There are currently 164,000 cubic meters (214,500 cubic yards) of wastes in the single-shell tanks, which are managed as high-level waste. The waste is multi-phased: most is sludge with interstitial liquids; some is in the form of crystalline solids, and there are some supernatant liquids present in the tanks. There are currently 92,000 cubic meters (120,000 cubic yards) of PUREX wastes in the double-shell tanks (DOE 1992e).

No known treatment is currently possible for these two waste streams, although it is planned to treat high-level wastes in the Hanford Waste Vitrification Plant, for which construction is scheduled to begin in 2002, with an operational start date in 2009 (DOE 1993c).

No high-level wastes are expected to be generated in 1995 from SNF management activities.

Cesium and Strontium Capsules: The total number of cesium capsules produced is 1,577. As of August 19, 1993, the number of known dismantled cesium capsules is 249; these have been put to beneficial use and are not expected to be returned. The total number of remaining capsules requiring disposal is 1,328. Of the 1,328 remaining capsules, 959 are in storage at Hanford, and 369 capsules have been leased for beneficial use. One of these capsules developed a small leak, and others have shown signs of bulging, so current plans are to bring all leased capsules back to the Hanford Site (DOE 1993d).

The total number of strontium capsules produced is 640. As of August 19, 1993, the number of known dismantled strontium capsules is 35; these have been put to beneficial use and are not expected to be returned. The total number of remaining capsules requiring disposal is 605. Of the 605, 601 are in storage at Hanford, and 4 have been leased offsite for beneficial use.

Therefore, at present 1,328 cesium capsules (2.47 cubic meters - 3.23 cubic yards) and 605 strontium capsules (1.08 cubic meters - 1.41 cubic yards) require storage. Nine-hundred and fifty-nine cesium capsules and 605 strontium capsules are stored in pools of water in the Waste Encapsulation and Storage Facility. The capsules will be stored at Hanford until they can be transported to a proposed national repository (DOE 1992d).

4.14.2 Transuranic Waste

Transuranic waste is defined in the Atomic Energy Act of 1954 (42 U.S.C. 2014[ee]) as "material contaminated with elements that have an atomic number greater than 92, including neptunium, plutonium, americium, and curium, and that are in concentrations greater than 10 nanocuries per gram, or in such other concentrations as the Nuclear Regulatory Commission may prescribe to protect the public health and safety."

Transuranic waste is primarily generated by research and development activities, plutonium recovery, weapons manufacturing, environmental restoration, and decontamination and decommissioning. Most transuranic waste exists in solid form (e.g., protective clothing, paper trash, rags, glass, miscellaneous tools, and equipment). Some transuranic waste is in liquid form (sludges) resulting from chemical processing for recovery of plutonium or other transuranic elements.

4.14.2.1 Historic Overview. Prior to 1970 all DOE-generated transuranic waste was disposed of onsite

in shallow, unlined trenches. From 1970 to 1986, transuranic wastes were segregated from other waste types and disposed in trenches designated for retrieval. Since 1986 all transuranic waste has been segregated and placed in retrievable storage pending shipment and final disposal in a permanent geologic repository (DOE 1992d, 1993g).

4.14.2.2 Current Status. Currently, all transuranic wastes are stored in above-grade storage

facilities in the Hanford Central Waste Complex and Transuranic Waste Storage and Assay Facility. The plan is to ship the stored transuranic waste to the Waste Isolation Pilot Plant near Carlsbad, New Mexico for final disposal.
The inventory of transuranic wastes is given in Table 4.14-3.

4.14.3 Mixed Low-Level Waste

Mixed low-level waste is defined as mixtures of low-level radioactive materials and (chemically and/or physically) hazardous wastes. Typically, mixed low-level waste includes a variety of contaminated materials, including air filters, cleaning materials, engine oils and grease, paint residues, photographic materials, soils, building materials, and decommissioned plant equipment.

Table 4.14-3. Transuranic waste inventory through 1991a.

Disposition of TRU Waste	Mass of TRU Nuclides (kilograms)	Volume (cubic meters)
Buried Waste	346	109,000b
Retrievable Storage	480	10,200

a. Source: DOE 1992d, Figures 3.3-3.6.
b. This number includes soils contaminated with TRUs.

4.14.3.1 Historic Overview. Between 1987 and 1991, 16,745 cubic meters (21,902 cubic yards) of mixed low-level waste were buried at the Hanford Site (between 1944 and 1986, no differentiation was made between low-level and low-level mixed wastes); all buried low-level wastes from that period are reported in subsection 4.14.4). Another 4,225 cubic meters (5,526 cubic yards) of mixed waste has been accumulating in storage in the Central Waste Complex, located in the 200-West Area (DOE 1993d).

The Hanford Site also receives defueled submarine reactor compartments, which are contaminated with PCBs and lead. These compartments are managed as mixed waste. Several compartments are received each year and placed in a trench in the 200-East Area (DOE 1993b).

4.14.3.2 Current Status. In 1992, 56,245 kilograms (124,000 pounds) of mixed low-level waste were generated. The 78 mixed low-level waste streams at Hanford make up 85,000 cubic meters (111,176 cubic yards) of waste (101,314,863 kilograms - 223,361,010 pounds). Ninety-six percent of the total is beta/gamma emitting waste in the form of mostly aqueous liquid in the double-shell tanks. One stream (double-shell tank miscellaneous waste) accounts for 40,000 cubic meters (52,318 cubic yards) of the mixed low-level wastes, and in combination, the double-shell tank Double-Shell Slurry Feed, double-shell tank Complex Concentrate and double-shell tank Double-Shell Slurry make up another 34,500 cubic meters (45,124 cubic yards). Three mixed low-level waste streams related to the 183-H Solar Evaporation Basin cleaning made up 2,500 cubic meters (3,270 cubic yards) of wastes. These inorganic sludge/particulate wastes have been neutralized and treated for packaging (DOE 1993c).

It is expected that of all the mixed low-level wastes at Hanford, 49 percent cannot be treated until the technology is modified or verified. The remaining 51 percent is to be processed through the 242A-Evaporator (a closed system in which distillates are passed through an ion-exchange system to remove cesium) (DOE 1993c).

In 1992, eight defueled submarine reactor compartment disposal packages were received and placed in Trench 94 of the 200-East Area Low-Level Waste Burial Grounds (Woodruff and Hanf 1993). The Naval Nuclear Propulsion Program will prepare an EIS for their proposal to bury additional reactor compartments at Hanford. As of November 1993, there were a total of 35 submarine reactor compartments stored in Trench 94.

Mixed low-level wastes generated in 1995 from SNF management activities will total 0.4 cubic meters (0.6 cubic yards).

4.14.4 Low-Level Waste

Low-level radioactive waste is defined in the Nuclear Waste Policy Act of 1982 (PL 97-425) as "radioactive material that (A) is not high-level radioactive waste, spent nuclear fuel, transuranic waste, or by-product material...; and (B) the [Nuclear Regulatory Commission], consistent with existing law, classifies as low-level radioactive waste." By-product material is defined in the Atomic Energy Act of 1954 [42 U.S.C. 2014(e)(2)] as "(1) any radioactive material (except special nuclear material) yielded in or made radioactive by exposure to the radiation incident to the process of producing or utilizing special nuclear material, and (2) the tailings or wastes produced by the extraction or concentration of uranium or thorium from any ore processed primarily for its source material content."

Commercial fuel low-level waste can be generated by fuel fabrication and reactor operations. Low-level waste also results from commercial operations by private organizations that are licensed to use radioactive materials. These include institutions engaged in research and various medical and industrial activities. Some low-level waste is also generated by DOE environmental restoration activities. Other low-level wastes will be generated in future years by routine decommissioning and decontamination operations.

4.14.4.1 Historic Overview. From 1944 to 1991, approximately 558,916 cubic meters (731,034 cubic

yards) of low-level waste was buried at Hanford (DOE 1993d). Between 1944 and 1986, no differentiation was made between low-level and low-level mixed wastes - all data from that period are reported in this section. Another 130 cubic meters (170 cubic yards) was placed into storage.

U.S. Ecology operates a licensed commercial low-level waste burial ground at Hanford on a site that is leased to the State of Washington. Although physically located on the Hanford Site, it is not considered part of the Hanford facility. The site area is 40 hectares (99 acres), of which 29.5 hectares (72.9 acres) is considered usable, with 11.9 hectares (29.4 acres) used by the end of 1991. Through 1991 338,500 cubic meters (442,741 cubic yards) of low-level wastes had been disposed of at this site (DOE 1992d).

4.14.4.2 Current Status. Solid low-level waste currently is placed in unlined, near-surface trenches

at the 200-Area Low-Level Waste Burial Grounds. Onsite sources at the Hanford Site generated about 4500 square meters of low-level waste in 1992. Table 4.14-4 lists quantities of radioactive materials received at the Hanford Site from offsite generators over 5 years. The site continues to receive low-level waste from offsite generators for disposal. Major sources of this waste have been the Puget Sound Naval Shipyard in Washington, Brookhaven National Laboratory in New York, and Lawrence Berkeley Laboratory in California. Other points of origin include DOE facilities at nuclear power stations in Shippingport, Pennsylvania; Bechtel in Albany, Oregon; and Wood River in Charleston, Rhode Island (DOE 1993d). The U.S. Ecology commercial low-level burial ground continues to operate.

Table 4.14-4. Offsite low-level waste receipts summary (from 1987 through 1991).

Year	Volume (m3)	Activity (curies)
1987	7,000	68,000
1988	5,000	107,000
1989	600	1,500
1990	5,500	240,000
1991	5,300	489,000

a. Source: Draft Environmental Restoration and Waste Management Fiscal Year 1993 Site-Specific Plan for the Richland Field Office (DOE 1993d). (Does not include waste quantities received at the U.S. Ecology low-level burial ground.)

In 1995, 174.5 cubic meters (228.3 cubic yards) of low-level wastes will be generated from SNF management activities. Of this amount, 167.2 cubic meters (218.7 cubic yards) are contact handled, and 7.3 cubic meters (9.6 cubic yards) are remote handled.

4.14.5 Hazardous Waste

Hazardous waste is defined in the State of Washington Dangerous Waste Regulations (WAC 173-303) as solid waste designated by 40 CFR Part 261 and regulated as hazardous wastes by the EPA. The State of Washington designates wastes as either "dangerous waste" or "extremely hazardous waste." Hazardous wastes are generated during normal facility operations and environmental restoration activities at the Hanford Site (Table 4.14-5).

Mixed wastes are wastes that contain both hazardous waste (regulated under the Resource Conservation and Recovery Act) and radioactive waste (regulated under the Atomic Energy Act). The following special nuclear material production and site restoration activities have generated or may generate mixed waste:

- fabrication of reactor fuel elements
- operation of the production reactors
- processing of irradiated fuel
- separation and extraction of plutonium and uranium
- preparation of plutonium metal
- environmental restoration (i.e., soil and groundwater cleanup)
- research and development support projects
- maintenance and operations support.

Table 4.14-5. Hazardous waste generated on the Hanford Site from 1988 through 1992 (including mixed waste).

Calendar year	Hazardous waste (t)	Mixed waste (t)	Total (t)
1988	80,000	25,000	105,000
1989	66,000	9400	75,000
1990	780	12,000	13,000
1991	330	4600	4900
1992	620	3400	4000

Tank wastes constitute 99 percent of the mixed wastes at the Hanford Site. The Hanford Site currently has 233,689 cubic meters (305,654 cubic yards) of mixed wastes stored in these tanks: 145,952 cubic meters (190,898 cubic yards) of high-level waste, 3,935 cubic meters (5,147 cubic yards) of mixed transuranic waste, and 84,802 cubic meters (110,917 cubic yards) of mixed low-level waste. These wastes consist of 108 different waste streams (2 high-level waste, 22 mixed transuranic waste, and 84 mixed low-level waste). Of the 108 identified waste streams, 97 are still being generated. Additional environmental restoration waste streams are expected. Their numbers and types remain to be determined (DOE 1993c).

The Resource Conservation and Recovery Act components of mixed waste at the Hanford Site are mainly the following listed wastes: D002B (alkaline liquids, 22 streams), D006B (cadmium, 29 streams), D007 (chromium, 34 streams), D008B (lead, 30 streams), and F003 (nonchlorinated solvents, 30 streams). Waste sources are primarily the separations and extraction processes that were used to produce special nuclear material (DOE 1993c).

4.14.5.1 Historic Overview. In the past, hazardous waste generated at Hanford was either shipped

offsite, recycled, or treated onsite. Hazardous waste was also disposed of onsite (e.g., buried in trenches, burial grounds, or discharged to cribs or directly to the soil). For example, from 1943 through 1945, acids from a pipe-cleaning operation were discharged to the soil through two side-by-side cribs in an area west of the old White Bluffs townsite. From 1955 through 1973, approximately 379-2,271 cubic meters (100,000-600,000 gallons) of organic liquids, including carbon tetrachloride, were discharged to the soil in the 200-West Area. Drums containing approximately 19 cubic meters (5,000 gallons) of organic solvent (primarily hexone) were buried at the 618-9 burial ground north of the 300 Area. Many of these disposal sites have been or will be closed under RCRA or remediated under CERCLA (DOE 1993d).

4.14.5.2 Current Status. As of March 15, 1993, the Hanford Site contained 64 interim status treatment, storage, or disposal units. Present plans are that final RCRA permits will be sought for 24 of these 64 interim status treatment, storage, or disposal units. Thirty-four units will be closed under interim status. Six units will be dispositioned through other regulatory options. Future circumstances may cause these numbers to change. The treatment, storage, or disposal units within the Hanford facility include, but are not limited to, tank systems, surface impoundments, container storage areas, waste piles, landfills, and miscellaneous units. Other RCRA permits, such as research, development, and demonstration permits (for example, the 200-Area Liquid Effluent Treatment Facility), are also being pursued (DOE 1993d).

The principal present waste management practice for newly generated nonradioactive hazardous waste is to ship it offsite for treatment, recycling, recovery, and/or disposal. The Nonradioactive Dangerous Waste Storage Facility (616 Building) and the 305-B Waste Storage Facility are the only active facilities storing nonradioactive hazardous waste (other than less than 90-day storage areas) (DOE 1992d, 1993d), other than two boxes (one containing mixed and one containing nonradioactive waste) stored in the 222-S laboratory complex.

Hazardous wastes generated in 1995 from SNF management activities will total 2.2 cubic meters (2.9 cubic yards).

4.14.6 Industrial Solid Waste

Solid wastes are generated in all areas of the Hanford Site. Nondangerous solid wastes include the following nonradioactive, nonhazardous wastes:

(a) construction debris, office trash, cafeteria waste/garbage, empty containers, and packaging materials, medical waste, inert materials, bulky items such as appliances and furniture, solidified filter backwash and sludge from the treatment of river water, failed and broken equipment and tools, air filters, uncontaminated used gloves and other clothing, and certain chemical precipitates such as oxalates

(b) nonradioactive friable asbestos (regulated under the Clean Air Act)

(c) ash generated from powerhouses

(d) nonradioactive demolition debris from decommission projects.

4.14.6.1 Historic Overview. Both prior to and after establishment of the reservation, a number of landfills have been used on the Hanford Site for solid waste disposal, including the Horn Rapids, Central, Original Central, White Bluffs, East White Bluffs, Wahluke Slope and Hanford Townsite Landfills.

The active Hanford Site Solid Waste Landfill, located in the 200-Area, began operation in 1973. Nondangerous wastes in category (a) above are buried in the solid waste section of the Solid Waste Landfill, located in the 200-Area. Nonradioactive friable asbestos is buried in designated areas at the

Solid Waste Landfill. The nonradioactive dangerous waste section of the landfill was closed to chemicals in January 1985, and closed to asbestos in May 1988. Ash generated at powerhouses in the 200-East and 200-West Areas is buried in designated sites near those powerhouses. Demolition waste from 100-Area decommissioning projects is buried in situ or in designated sites in the 100 Areas (Woodruff and Hanf 1993; WHC 1993b). Solid waste has also been sent to the City of Richland landfill.

4.14.6.2 Current Status. In 1992, 22,213 cubic meters (29,054 cubic yards) of solid waste and 1,017 cubic meters (1,330 cubic yards) of asbestos were deposited in the solid waste section of the Solid Waste Landfill. Pit 10 was opened for disposal of inert material as defined in Washington Administrative Code (WAC) 173-304, and a total of 11,389 cubic meters (14,986 cubic yards) were disposed of there. A summary of the solid waste disposed of at the Hanford Site from 1973 through 1992 is shown in Table 4.14-6. The landfill is currently scheduled for closure in 1997 (WHC 1993b). Quantities of solid waste disposed of at the City of Richland Landfill are not readily available.

4.14.7 Hazardous Materials

A hazardous chemical is any chemical that poses a physical or health hazard [as defined in 29 CFR 1900.1200(c)]. The Emergency Planning and Community Right-to-Know Act sets forth reporting requirements (Tier 1 and Tier 2) that provide the public with information on hazardous chemicals to enhance community awareness of chemical hazards and facilitate the development of state and local emergency response plans.

Table 4.14-6. 1973-1992: Historical annual volume of onsite buried solid sanitary waste in cubic meters per year.

Waste Type	Volume (m3/year)											
	73-81	82	83	84	85	86	87	88	87	90	91	92
Construction Debris[a]	4,149	5,819	9,494	10,378	10,789	14,254	14,316	12,842	12,469	10,088	5,666	7,330
Metals[b]	1,383	1,940	3,165	3,459	3,596	4,751	4,772	4,281	4,156	3,363	1,889	2,443
Paper	5,658	7,936	12,946	14,151	14,712	19,437	19,522	17,512	17,003	13,757	7,727	9,996
Miscellaneous[c]	1,383	1,940	3,165	3,459	3,569	4,751	4,772	4,281	4,156	3,363	1,889	2,443
Total	12,573	17,635	28,770	31,447	32,694	43,193	43,382	38,916	37,785	30,571	17,170	22,213

a. Construction Debris: Volume is calculated based on disposal volume (excluding asbestos) at the onsite landfill: Construction debris 33 percent; Metals 11 percent, Paper 45 percent, Miscellaneous Waste 11 percent.
b. Metals: See note b above. Category consists of large bulky items such as appliances and furniture.
c. Miscellaneous: Category includes garbage, packaging, empty containers, medical waste and inert materials.

4.14.7.1 Historic Overview. Hazardous chemicals are used throughout the Hanford Site in facility and environmental restoration operations. The types of chemicals in inventory onsite tend to be static since Hanford's mission involves mainly remediation and decontamination and decommissioning (as opposed to production or processing). The amount of chemicals actually onsite changes from day to day, and there is no requirement to keep a real- time inventory of the quantity of chemicals onsite at any one time. Also, the percentage of hazardous chemicals used onsite that eventually become hazardous waste cannot be determined.

4.14.7.2 Current Status. The Hazardous Materials Inventory Database currently being used to generate

Tier 2 data indicates that approximately 1484 hazardous chemicals are reported in inventory at over 783 locations on the Hanford Site. These 1484 chemicals are contained in approximately 2926 different hazardous materials, in weights that range from less than 0.5 kilograms (one pound) to a maximum inventory of 35,658,872 kilograms (78,614,420 pounds).

The DOE has prepared chemical inventory reports required by the Emergency Planning and Community Right-to-Know Act since 1988 (for calendar year 1987). In 1992 the Emergency Planning and Community Right-to-Know Act reporting threshold was exceeded for 53 hazardous chemicals.

5. ENVIRONMENTAL CONSEQUENCES

Descriptions of analyses for various potential environmental consequences as a result of implementing 1) No Action, 2) Decentralization, 3) 1992/1993 Planning Basis, 4) Regionalization, and 5) Centralization Alternatives for interim storage of SNF for the Hanford Site are presented in the following subsections. By and large these discussions are at the programmatic level because in many cases specific alternative treatments and locations, particularly for new facilities, have not been identified for the Hanford Site.

5.1 Overview

An overview of the various alternatives and a brief summary of potential environmental consequences of interest are provided in the following subsections. For purposes of this programmatic analysis, all new facilities were assumed to be constructed in a quarter section of land adjacent to the 200-East Area; commitment of that amount of land within the industrialized 200 Areas would be consistent with the site mission and would not represent a conflict on land use. Up to 15 percent of that area would be disturbed during construction of storage and support facilities where required. A survey of the area described revealed no threatened and endangered species or cultural resources. Routine operations under any of the alternatives would not add significantly to current occupational or near-zero public exposure to radiation. Although not quantified, no significant additions to current releases of criteria pollutants or other hazardous materials would be expected from implementing any of the alternatives. However, such implementation requires a small increase in Hanford's electrical power consumption; the largest increase would be less than 1.5 percent. The influx of workers would probably increase competition for desirable housing and strain teacher/student ratios in some local school districts, the extent of which (although small in any case) would depend on the option chosen.

5.1.1 No Action Alternative

The No Action Alternative identifies the minimum actions deemed necessary for continued safe and secure storage of SNF at the Hanford Site. Upgrade of the existing facilities would not occur other than as required to ensure safety and security. No receipt of fuels from offsite would occur. No research and development would take place; however, characterization of fuel would continue to establish a safety envelope for extended interim storage, fuel would be containerized at the 105-KE Basin, and the first 10 dry storage casks would be procured for FFTF fuel.

Results presented in the Hanford Site Environmental Report for 1992 (Woodruff and Hanf 1993) suggest that under normal conditions no significant environmental effects would be associated with the No Action Alternative. For example, the radiation dose to the maximally exposed individual in the Hanford environs from all Hanford sources was calculated to have been 0.02 mrem and the collective population dose was 0.8 person-rem during 1992. Continued storage of SNF contributed only a small portion of those doses. No health effects would be expected as a result of such small doses. For perspective, the Hanford Site doses for 1992 may be compared to annual individual doses of 300 mrem and an annual collective dose of about 100,000 person-rem from natural background radiation.

5.1.2 Decentralization Alternative

The Decentralization Alternative would consider additional facility upgrades over those considered in the No Action Alternative, specifically, new wet storage (for defense production fuel only) or dry storage facilities, fuel stabilization via shear/leach/calcination or shear/leach/ solvent extraction, with research and development activities to support SNF management.

Impacts from storage prior to implementation of new wet or dry storage or fuels stabilization would not differ from those indicated for the No Action Alternative. In the event new storage facilities are selected some impacts would be associated with construction of those facilities. A proposed site has been identified comprising one-quarter section of land adjacent to the 200-East Area where any new facilities associated with SNF storage or stabilization that might be necessary would be assumed to be built. The area has been surveyed both for threatened and endangered species and for the presence of cultural resources; none were found. However, one federal candidate species, the loggerhead shrike, and one state candidate species, the sage sparrow, were seen. Use of this area is consistent with the Hanford mission and would impact no threatened or endangered biota. Construction would take place on up to 15 percent of the selected site. Construction activities would result in dust generation and various amounts of pollutants released from diesel-fueled equipment; however, concentrations at points of public access are expected to be well below permissible levels. Impacts associated with SNF storage would be expected to be less than those in the No Action Alternative.

Research and development of technologies for SNF stabilization would be undertaken in existing hot cell facilities in the 300 Area. Although not examined in detail for this programmatic analysis, no important environmental consequences have resulted from work in these facilities and none would be anticipated for development activities related to fuel processing.

5.1.3 1992/1993 Planning Basis Alternative

The 1992/1993 Planning Basis Alternative differs from the Decentralization Alternative only in that TRIGA fuel currently stored at the Hanford Site would be shipped to INEL for storage. The storage and stabilization options identified for the Decentralization Alternative are also assumed for the 1992/93 Planning Basis Alternative and that discussion is not repeated here. The potential impacts of transportation of TRIGA fuel to INEL are covered in Appendix I.

5.1.4 Regionalization Alternative

The Regionalization Alternative as it applies to the Hanford Site contains the following options:

A) All SNF, except defense production SNF, would be sent to INEL.

B1) All SNF west of the Mississippi River, except Naval SNF would be sent to Hanford.

B2) All SNF west of the Mississippi River and Naval SNF would be sent to Hanford.

C) All Hanford SNF would be sent to INEL or Nevada Test Site (NTS).

Facilities and features of Regionalization A would be the same as those described for Hanford defense production fuel in the Decentralization Alternative. The facilities and features for all other Hanford SNF would be very similar to those described for that spent nuclear fuel in the Centralization Minimum Alternative.

Facilities and features of Regionalization B1 and B2 options would be incremental to those described for the Decentralization Alternative and would be similar, but not identical, to those described in the Centralization Maximum Alternative.

Facilities and features of Regionalization C would be equivalent to those described for the Centralization Minimum Alternative.

5.1.5 Centralization Alternative

Two options exist at the Hanford Site for the Centralization Alternative: 1) shipment of all fuel within the DOE complex to the Hanford Site for management and storage, and 2) shipment of all fuel off of the Hanford Site. In the former option, dry storage of all fuel sent to the Hanford Site from offsite would be assumed. A facility equivalent to the decentralization sub-options would be assumed for processing of SNF prior to storage; fuel received from offsite would have been stabilized for dry storage prior to receipt. The consequences of implementing this option would be larger than those of the Decentralization Alternative. In the option of transferring all Hanford fuel to another site, a fuel stabilization and packaging facility would need to be constructed to prepare existing fuel for shipment.

5.2 Land Use

Implications of implementing the alternatives for interim storage of SNF on land use at the Hanford Site are discussed in the following subsections.

5.2.1 No Action Alternative

No new SNF facilities would be built at the Hanford Site; thus, land use patterns would remain as described in Section 4.2 and have no impact on the existing environment. The Hanford Site would remain a federal facility dedicated to nuclear research and development and environmental cleanup. Other continuing activities would include waste management, commercial power production, ecological research, and wildlife management, as described in Section 4.2.

5.2.2 Decentralization Alternative

This alternative would require the construction of an SNF facility for fuel management and storage. Most SNF from the Hanford Site would be stored at that facility.

Historically, the Hanford Site has been used for nuclear materials production. The construction and operation of an SNF facility would be consistent with this historical use. Off-site land use would not be affected by construction and operations of an SNF facility, except to the extent that some undeveloped lands probably would be developed for worker housing. Such development would be subject to local land use and zoning controls, which vary by jurisdiction. No project facilities would be located offsite.

No direct or indirect effects would occur to wildlife refuges on the Hanford Site because SNF activities would not be close to these areas. Similarly, no direct or indirect effects would occur to the Columbia River. Although construction at the SNF site would disturb native vegetation (Section 5.9.1), on up to 7 hectares (18 acres) of the 65-hectare (160-acre) site, this would involve only a small part of similar natural habitat at Hanford. The use of Hanford as a National Environmental Research Park would not be significantly affected.

No impacts requiring mitigation would occur to land uses a result of construction or operation of an SNF facility at the Hanford Site.

5.2.3 1992/1993 Planning Basis Alternative

The 1992/1993 Planning Basis Alternative differs from the Decentralization Alternative only in that TRIGA fuel currently stored at the Hanford Site may be shipped to INEL for storage. Thus, land use would be essentially the same as in the Decentralization Alternative. Although construction at the SNF site would disturb native vegetation (Section 5.9.1), on up to 7 hectares (18 acres) of the 65-hectare (160-acre) site, this would involve only a small part of similar natural habitat at Hanford. The use of Hanford as a National Environmental Research Park would not be significantly affected.

5.2.4 Regionalization Alternative

Construction of facilities in support of the Regionalization Alternative as it applies to the Hanford Site would result in the following disturbance of native vegetation and land use commitments:

A) From about 2 to 7 hectares (6 to 18 acres) when all SNF, except defense production SNF would be sent to INEL.

B1) From about 14 to 17 hectares (36 to 43 acres) when all SNF west of the Mississippi River, except Naval SNF would be sent to Hanford.

B2) From about 24 to 27 hectares (61 to 68 acres) when all SNF west of the Mississippi River and Naval SNF would be sent to Hanford.

C) From about 2 to 5 hectares (6 to 12 acres) when all Hanford SNF would be sent to INEL or NTS.

These areas involve only a small part of similar natural habitat at Hanford. The use of Hanford as a National Environmental Research Park would not be significantly affected.

5.2.5 Centralization Alternative

If Hanford is selected as the site for implementing the Centralization Alternative, the SNF facility and its support facilities (including a new Expended Core Facility) would be constructed. The impacts of such construction would be essentially the same as those presented for the Decentralization Alternative. Although construction at the SNF site would disturb native vegetation (Section 5.9.1) on up to 37 hectares (93 acres) of the 65-hectare (160-acre) site, this would involve only a small part of similar natural habitat at Hanford. In addition to the above total, new construction would also include construction of a new Expended Core Facility for fuel from the Naval Nuclear Propulsion Program. The use of Hanford as a National Environmental Research Park would not be significantly affected.

If Hanford is not selected as the site for centralization of SNF, an SNF stabilization and packaging facility would be built to prepare the fuel for transport offsite. This facility would have somewhat smaller construction requirements than would be required for storage of all DOE SNF at Hanford. The land use impacts would be similar to those described for the Regionalization option C.

5.2.6 Effects of Alternatives on Treaty or Other Reserved Rights of Indian

Tribes and Individuals

The Yakama Indian Nation and the Confederated Tribes of the Umatilla Indian Reservation acquired certain rights and privileges in the 1855 treaty. These rights and privileges are also claimed by the Wanapum Tribe. In Article III, of the 1855 treaty it states that "The exclusive right of taking fish in all streams, where running through or bordering said reservation, is further secured to said confederated tribes and bands of Indians, as also the right of taking fish at all usual and accustomed places, in common with citizens of the

Territory, and of erecting temporary buildings for curing them; together with the privilege of hunting, gathering roots and berries, and pasturing their horses and cattle upon open unclaimed land.(a)"

Although access to the Hanford Site has been restricted, tribal members have expressed an interest in renewing their use of these resources in accordance with the Treaty of 1855, and the DOE is assisting them in this effort. In keeping with this effort, each of the alternatives would provide for the rights and privileges identified in the treaty:

- Taking Fish - The alternatives considered in this document would not reduce access to fishing locations on the Hanford Site.

- Hunting, Gathering Roots and Berries, and Pasturing Livestock - The No Action Alternative would not further reduce the areas potentially available for hunting, gathering roots and berries, or pasturing livestock. All existing fenced areas assigned for SNF storage and a suitable buffer zone would likely remain unavailable for these activities. All other alternatives would require the construction of new facilities. This would further reduce the land base available for hunting, gathering, and pasturing. This impact could be on the order of 18 acres.

5.3 Socioeconomics

The following section describes the socioeconomic impacts of the SNF project at the Hanford Site. For the analysis, a ten-county region of influence was identified. While the region of influence covers the counties of Adams, Benton, Columbia, Franklin, Grant, Walla Walla, and Yakima in the state of Washington; and Morrow, Umatilla, and Wallowa counties in the state of Oregon, the majority of the impacts would be confined to the Benton-Franklin County region and the Tri-Cities (Richland, Kennewick, and Pasco) (see Figure 4-2).

The socioeconomic impacts are classified in terms of direct and secondary effects. Changes in Hanford employment and expenditures are classified as direct effects, while changes that result from Hanford regional purchases, nonpayroll expenditures, and payroll spending by Hanford employees are classified as secondary effects. The total socioeconomic impact within the region is the sum of the direct and secondary effects.

Estimates of total employment impacts were calculated using the Regional Input-Output Modeling System developed for the Hanford region of influence by the U.S. Bureau of Economic Analysis. This assessment reports the changes in employment and earnings based on historic data, which indicate that 93 percent of Hanford employees reside in the Benton-Franklin county area. Table 4.3-1 in Section 4.3 presents the baseline projections from which comparisons can be made.

All employment comparisons are made relative to the regional employment projections and not current Hanford Site employment projections. While a down-turn in Hanford Site employment is anticipated, the extent of the down-turn is unknown. The effect of such a down-turn on the region's employment projection used in this analysis is expected to be minimal because the regional projection, released in 1992, assumed a more stable rate of growth than the actual "boom" experienced in recent years.

5.3.1 No Action Alternative

Under the No Action Alternative, only the minimum actions required for continued safe and secure storage of SNF would occur. No new facilities would be constructed, and only minimal facility upgrades would take place. It is assumed that existing personnel would be utilized under this alternative, and therefore no incremental socioeconomic consequences are anticipated. Socioeconomic conditions would continue as described in Section 4.3.

5.3.2 Decentralization Alternative

---

a. These treaty rights and priviledges are subject to diverse interpretations. None of the lands contemplated for use for SNF processing and/or storage at Hanford were on "open unclaimed land" when the government established the Hanford Site.

Under the Decentralization Alternative, significant facility development and upgrades are permitted, with various suboptions defined for processing and storage of the SNF. The socioeconomic consequences related to implementing the decentralization alternatives are described in this subsection. The employment and population impacts related to construction and operation of the Decentralization Alternative suboptions are presented in Table 5.3-1. It was assumed that up to 300 current Hanford workers could be reassigned to operation activities (this number excludes current workers at the Fast Flux Test Facility because it was assumed that they would be reassigned to activities related to the Hanford Waste Vitrification Plant). Construction activities were assumed to require new workers coming into the area. Estimates of direct jobs were provided by Bergsman (1995). For construction activity, direct jobs were reported as number of jobs in the peak year and total person-years because it was assumed that construction activities would "ramp-up" to the peak year, and then "ramp-down," with the total number of jobs related to construction activity equaling the total person-years required, as reported in Bergsman (1995). Increases in activity levels could strain an already tight housing market and add to school-capacity concerns. However, because construction activities are short-term relative to the total project time frame, impacts from construction activities may be overstated.

5.3.2.1 Employment. All construction activity is assumed to peak in

1998. Construction activity for storage options W, X, Y, and Z occurs in the years 1997-2000; construction activity for processing suboptions P and Q occurs in the years 1998-2001. Increases in employment range from 221 (suboption X) to 1,094 (suboptions Y and P) and equate to between 0.3 and 1.3 percentage points over baseline regional employment projections (see **Table 4.3-1).** All operations activity peaks in 2002, with incremental activity tapering off. Increases in employment range from 442 (suboptions Z and P) to 880 (suboptions Q and Small Vault) persons and equate to between 0.5 and 1.0 percentage points over baseline regional employment projections. Beyond 2004, operations activity will taper off as processing activities (suboptions P and Q) will occur only through 2005. Suboptions Y and Z each require only 50 workers beyond 2005 for operations activity. Because it is anticipated that up to 300 current workers could be reassigned, no incremental socioeconomic impacts are anticipated after 2005. This is also true with suboptions W and X because they are assumed to absorb between 200 and 210 current workers for the first two years of operation (2001-2002), with employment requirements falling to between 150 and 95

Table 5.3-1. Comparison of the socioeconomic impacts of spent nuclear fuel Decentralization Alternative suboptions.

Decentralization Alternative	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Suboption W										
Direct Jobs	0	0	216	251	216	181	0	0	0	0
Secondary Jobs	0	0	240	280	240	200	0	0	0	0
Population Change	0	0	590	680	590	490	0	0	0	0
Suboption X										
Direct Jobs	0	0	200	221	200	178	0	0	0	0
Secondary Jobs	0	0	220	240	220	200	0	0	0	0

workers in 2003 and 2004. For the remaining years (2005-2035), suboptions W and X each would require only 60 workers for operation activities.

5.3.2.2 Population. For construction-related activities, the

population is expected to peak in 1998, with increases in population ranging from 600 (suboption X) to 2,810 (suboptions Y and P) and equating to between 0.4 and 1.7 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off through 2007. Increases in population range from 1,310 (suboptions Z and P) to 2,610 (suboptions Q and Small Vault) persons and equate to between 0.7 and 1.5 percentage points over baseline projections for 2002.

5.3.3 1992/1993 Planning Basis Alternative

This alternative defines those activities that were already scheduled at the various sites for the transportation, receipt, processing, and storage of SNF. Under this alternative, no new spent fuel would be sent to the Hanford Site, but the TRIGA fuel would be shipped offsite. The upgrades of existing storage facilities, as defined in the Decentralization alternative, were already planned, so the impacts of the 1992/1993 Planning Basis Alternative are essentially the same as outlined in Subsection 5.3.2. Because of the shipment of TRIGA fuel, an additional two workers per year would be required over 3 years of operation; however, it was assumed that current personnel would be reassigned to fill these jobs; therefore, the incremental impacts would be the same as those presented in Table 5.3-1.

5.3.4 Regionalization Alternative

Under this alternative, SNF would be redistributed to candidate sites based on similarity of SNF types or region within the country. There are four possible cases: regionalization of SNF by fuel type (Regionalization A); regionalization in which all SNF currently stored in the western United States, or to be generated in the western United States, except Naval SNF would be sent to and stored at the Hanford Site (Regionalization B1); regionalization in which all SNF currently stored in the western United States, or to be generated in the western United States, and all Naval fuel would be sent to and stored at the Hanford Site (Regionalization B2); and regionalization in which all SNF currently located in the western United States, or to be generated in the western United States, including all Hanford SNF, would be sent to and stored at another location (Regionalization C).

5.3.4.1 Regionalization A. In this case, all SNF currently located at

Hanford, except defense production fuel, would be sent to INEL. For the Hanford Site, the facility requirements for the N reactor and single-pass reactor fuel would be the same as those described in the Decentralization Alternative. Facilities for all other Hanford Site fuel would be similar to those described within the Centralization minimum alternative. The population and employment impacts related to Regionalization A are presented in Table 5.3-2.

5.3.4.1.1 Employment.

All construction activity is assumed to peak in 1998. Construction activity for suboptions RAX, RAY, and RAZ occurs in the years 1997-2000 and construction activity for suboption P occurs in the years 1998-2001. Increases in employment range from 176 (suboption RAX) to 1,065 (suboption RAY and P) and equate to between 0.2 and 1.3 percentage points over baseline projections of regional employment (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off. Increases in employment range from 208 (suboption RAY and P) to 230 (suboption RAZ and P) persons and equate to between 0.2 and 0.3 percentage points over baseline projections. Beyond 2004, operations activity will taper off as processing activities (suboption P) will only occur through 2005. Suboptions RAY and RAZ each require only 50 workers beyond 2005 for operations activity. Because it is anticipated that up to 300 current workers could be reassigned, no incremental socioeconomic impacts are anticipated after 2005. This is also true with suboption RAX because it would require only 59 workers for operation activities after 2005.

5.3.4.1.2 Population.

For construction-related activities, the population is expected to peak in 1998, with increases in population ranging from 480 (suboption RAX) to 2,900 (suboption RAY and P) and equating to between 0.3 and 1.7 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off through 2006. Increases in population range from 620 (suboption RAX) to 680 (suboption RAY and P) persons and equate to between 0.3 and 0.4 percentage points over baseline projections for 2002.

Table 5.3-2. Comparison of socioeconomic impacts of spent nuclear fuel Regionalization A suboptions.

Regionalization A Suboptions	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004

Secondary Jobs	0	0	160	950	950	950	780	290	290	290
Population Change	0	0	410	2,360	2,360	2,360	1,950	680	680	680

5.3.4.2 Regionalization B1. In this case, all SNF currently stored or

to be generated in the western United States, except Naval SNF, would be sent to and stored at the Hanford Site. Facility requirements for this case would be incremental to those described for the Decentralization Alternative. Additional facilities include a storage facility for offsite fuel, a receiving and canning facility, and a technology development facility (RB1). The population and employment impacts related to regionalization B1 are presented in Table 5.3-3.

5.3.4.2.1 Employment.

All construction activity is assumed to peak in 2000. Construction activity for suboptions W, X, Y, and Z occurs in the years 1997-2000; construction activity for suboptions P and Q occurs in the years 1998-2001; and construction of the additional facilities (suboption RB1) for receiving and canning and technology development occurs in the years 1998-2001, with 90% of the storage facility being constructed during the years 2000-2010 and the remaining 10% being constructed during the years 2010-2035. Increases in employment range from 398 (suboption X and RB1) to 1,191 (suboption Y and P and RB1) and equate to between 0.5 and 1.4 percentage points over baseline projections of regional employment (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off. Increases in employment range from 73 (suboption X and RB1) to 1,050 (suboption Q and Small Vault and RB1) persons and equate to between 0.1 and 1.2 percentage points over baseline projections. Beyond 2004, operations activity will taper off as described in Section 5.3.2.2.1.

5.3.4.2.2 Population.

For construction-related activities, the population is expected to peak in 2000, with increases in population ranging from 1,090 (suboptions W and RB1 and X and RB1) to 3,250 (suboption Y and P and RB1) and equating to between 0.6 and 1.9 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off through 2006. Increases in population range from 200 (suboptions X and RB1) to 3,100 (suboptions Q, Small Vault, and RB1) persons and equate to between 0.1 and 1.7 percentage points over baseline projections for 2002.

5.3.4.3 Regionalization B2. In this case, all fuel currently stored or

to be generated in the western United States, including Naval fuel, would be sent to and stored at the Hanford Site. Facility requirements for this case would be essentially the same as those described in the Regionalization B1 case, as the only difference would be the presence of Naval fuel. The receiving and canning facility, offsite storage facility, and technology development facility are referred to as suboption RB2. Also required for this case is the Naval Nuclear Propulsion

Program's Expended Core Facility (ECF). Discussion on the relocation of the ECF to the Hanford Site is provided in Appendix D to the INEL Spent Nuclear Fuel PEIS and is not included here. Population and employment impacts of the Regionalization B2 case are presented in Table 5.3-4.

5.3.4.3.1 Employment.

All construction activity is assumed to peak in 2000. Construction activity for suboptions W, X, Y, and Z occurs in the years 1997-2000; construction activity for suboptions P and Q occurs in the years 1998-2001; and construction of the additional facilities (suboption RB1) for receiving and canning and technology development occurs in the years 1998-2001, with 35% of the storage facility being constructed during the years 2000-2010 and the remaining 65% being constructed during the years 2010-2035. Increases in employment range from 488 (suboptions X and RB2) to 1,281 (suboptions Y, P, and RB2) and equate to between 0.6 and 1.5 percentage points over baseline projections of regional employment (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off. Increases in employment range from 80 (suboptions X and RB2) to 1,085 (suboptions Q, Small Vault, and RB2) persons and equate to between 0.1 and 1.3 percentage points over baseline projections. Beyond 2004, operations activity will taper off as described in section 5.3.2.2.1.

5.3.4.3.2 Population.

For construction-related activities, the population is expected to peak in 2000, with increases in population ranging from 1,330 (suboptions X and RB2) to 3,490 (suboptions Y, P and RB2) and equating to between 0.8 and 2.0 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off through 2006. Increases in population range from 220 (suboption X and RB2) to 3,190 (suboptions Q, Small Vault, RB2) persons and equate to between 0.1 and 1.8 percentage points over baseline projections for 2002.

5.3.4.4 Regionalization C. In this case, all fuel currently stored or to be generated in the western United States, including all Hanford Site fuel, would be sent to and stored at INEL or NTS. Facility requirements for the Hanford Site in this case are identical to those described in the Centralization Minimum Alternative. Employment and population impacts of this case are provided in Table 5.3-5 and are discussed in Section 5.3.5.2.

Table 5.3-4. Comparison of socioeconomic impacts of spent nuclear fuel Regionalization B2 suboptions.

5.3.5 Centralization Alternative

Under this alternative, all current and future SNF would be stored at a centralized location. There are two possible options: the maximum option in which all fuel is stored at Hanford, and the minimum option in which all fuel at Hanford is shipped offsite. The socioeconomic consequences related to implementing the Centralization Alternative suboptions are described in this subsection. The employment and population impacts related to construction and operation of the maximum option are presented in Table 5.3-5. The population and employment impacts related to construction and operation of the minimum option are presented in Table 5.3-6. It was assumed that up to 300 current Hanford workers could be reassigned to operation activities (this number excludes current workers at the Fast Flux Test Facility, as it was assumed that they would be reassigned to activities related to the Hanford Waste Vitrification Plant). Construction activities were assumed to require new workers coming into the area. Estimates of direct jobs were provided by Bergsman (1995). For construction activity, direct jobs were reported as number of jobs in the peak year and total person-years because it was assumed that construction activities would "ramp-up" to the peak year, and then "ramp-down," with the total number of jobs related to construction activity equaling the total person-years required as reported in Bergsman (1995). Although the housing market is currently uncertain and beginning to turn downward, increases in activity levels could strain the housing market and add to school-capacity concerns. However, because construction activities are short-term relative to the total project time frame, impacts from construction activities may be overstated.

5.3.5.1 Centralization - Maximum Option. Under the maximum option,

Hanford SNF would be stabilized and stored under one of the options outlined in the decentralization alternative, with larger storage facilities. A facility would also be built to receive SNF from other sites. Additionally, the ECF would be relocated from the INEL site. The impacts of the ECF to regional population and employment are presented in Appendix D of Volume 1 of this EIS and are not discussed here. Table 5.3-5 presents the employment and population impacts of the options under the maximum centralization option.

5.3.5.1.1 Employment.

All construction activity is assumed to peak in 2000. Construction activity for suboptions W, X, Y, and Z occurs in the years 1997-2000; construction activity for suboptions P and Q occurs in the years 1998-2001; and construction activity for the

Table 5.3-6. Comparison of socioeconomic impacts of spent nuclear fuel Centralization Alternative - minimum case suboptions.

receiving and canning facility (suboption CM) occurs in the years 1998-2001, with 50% of the construction activity for the modular storage facility occurring during the years 2000-2010 and the other 50% occurring during the years 2010-2035. Increases in employment range from 608 (suboptions X and CM) to 1,401 (suboptions Y, P, and CM) and equate to between 0.7 and 1.7 percentage points over baseline projections of regional employment (see **Table 4.3-1).** All operations activity peaks in 2002, with incremental activity tapering off. Increases in employment range from 164 (suboptions X and CM) to 1,220 (suboptions Q, Small Vault, and CM) persons and equate to between 0.2 and 1.4 percentage points over baseline projections. Beyond 2004, operations activity will taper off as processing activities (suboptions P and Q) will occur only through 2005. Operation of the receiving and canning facility will require 190 workers through 2011, falling to 150 workers through 2035. Suboptions Y and Z each require only 50 workers beyond 2005 for operations activity. Because it is anticipated that up to 300 current workers could be reassigned, no incremental socioeconomic impacts are anticipated after 2005. This is also true with suboptions W and X because each would require only 60 workers for operation activities.

5.3.5.1.2 Population.

For construction-related activities, the population is expected to peak in 2000, with increases in population ranging from 1,620 (suboptions X and CM) to 3,818 (suboptions Y, P, and CM) and equating to between 0.9 and 2.2 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity tapering off through 2007. Increases in population range from 450 (suboptions X and CM) to 3,580 (suboptions Q, Small Vault, and CM) persons and equate to between 0.3 and 2.0 percentage points over baseline projections for 2002.

5.3.5.2 Centralization. Minimum Option. Under the minimum option,

Hanford's SNF would be shipped offsite. Some stabilization of fuel would be required prior to shipment of N Reactor and single-pass reactor fuel. Three options were identified for the stabilization: a shear/leach/calcine facility (suboption P); a solvent extraction facility (suboption Q); or a drying and passivation facility (suboption D). Suboptions P and Q are the same processing facilities that were included in the Decentralization Alternative. Table 5.3-6 presents the employment and population impacts of the suboptions under the Centralization minimum option.

5.3.5.2.1 Employment.

All construction activity is assumed to peak **in 1998.** Construction activity for suboptions P and Q occurs in the years 1998-2001. Increases in employment range from 620 (suboption D) to 872 (suboption Q) and equate to between 0.7 and 1.0 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity ending after 2006 for suboptions P and Q, and after 2004 for suboption D. Increases in employment range from 357 (suboption D) to 786 (suboption Q) persons and equate to between 0.4 and 0.9 percentage points over baseline projections.

5.3.5.2.2 Population.

For construction-related activities, the population is expected to peak in 1998, with increases in population ranging from 1,690 (suboption D) to 2,380 (suboption Q) and equating to between 1.0 and 1.4 percentage points over baseline projections (see Table 4.3-1). All operations activity peaks in 2002, with incremental activity ending after 2006. Increases in population range from 1,060 (suboption D) to 2,330 (suboption Q) persons and equate to between 0.6 and 1.3 percentage points over baseline projections for 2002.

5.4 Cultural Resources

The potential impacts of SNF management activities on cultural resources were assessed by 1) identifying project activities that could directly or indirectly affect significant resources; 2) identifying the known or expected significant resources in areas of potential impact; and 3) determining whether a project activity would have no effect, no adverse effect, or an adverse effect on significant resources (36 CFR 800.9). Direct impacts are considered to be those associated with ground disturbance or activities that would destroy or]modify an architectural structure. Indirect impacts are considered to be those resulting from improved visitor access, changes in land status, or other actions that limit scientific investigation of the resources.

Possible measures that would be worked out in consultation with the Washington State Historic Preservation Officer (SHPO), Advisory Council for Historic Preservation, and area tribes may include avoidance or data recovery.

5.4.1 No Action Alternative

The No Action Alternative would not involve upgrade or expansion of existing facilities, other than those that may be required to ensure safety and security. Specific actions considered in the No Action Alternative include continued storage at the following facilities:

- 105-KE and 105-KW Basins

y T Plant

- FFTF
- 308 Building
- 324 Building
- 325 Building
- 327 Building
- Low-Level Burial Grounds.

With the exception of FFTF, these are existing Manhattan Project and/or Cold War facilities currently under evaluation for National Register of Historic Places (NRHP) eligibility.

No new facilities would be required; however, the following facility modifications would be considered:

- Upgrade water supply and distribution system to 100-K Area.
- Upgrade seismic adequacy of K Basins.
- Upgrade fire protection systems for the K Basins.
- Safeguards and security upgrades to the K Basins.

Upgrade of the water supply and distribution system has the potential to adversely affect prehistoric archaeological sites in the vicinity of the 100-K Area. Several archaeological sites (45BN115, 45BN152, 45BN423, 45BN434, 45BN464, 45BN424, and H3-10) have been identified in this area (Chatters et al. 1992). These sites are being evaluated for their National Register eligibility. A careful review of the detailed project plans is necessary prior to initiation of this work. If the upgrade results in ground disturbance, as in the replacement and/or addition of new water lines, then these actions could directly affect the archaeological sites. However, proper design of the upgrade system could allow for avoidance of these prehistoric sites. If avoidance is not possible, some sort of data recovery or other measures may be developed in conjunction with affected Native American Tribes and the SHPO. The remaining facility modifications are not likely to affect the historical or architectural value of the Manhattan Project and/or Cold War facilities.

Some indirect effects might result from the continued operation of SNF storage facilities by Hanford workers in the culturally sensitive 100-K Area, if unauthorized artifact collection would contribute to the degradation of nearby archaeological sites. These effects could be mitigated through a worker education program, which would use posters to inform workers of applicable laws, briefing sessions for all persons expected to work along the corridor, and penalties for disturbing an archaeological site. The briefing sessions would stress the importance of cultural resources and specifics of the laws and regulations that exist for site protection.

Direct or indirect impacts are not anticipated to any known traditional cultural resources that are significant to members of the Yakama Indian Nation, the Confederated Tribes of the Umatilla Indian Reservation, or the Wanapum Band. This conclusion is based on the proposed locations of facilities relative to sacred and culturally important areas identified through ethnohistorical research and interviews with elders of bands that formerly used the Hanford Site (Chatters 1989).

5.4.2 Decentralization Alternative

This alternative would involve additional facility upgrades beyond those described for the No Action Alternative, including the construction of new storage facilities and/or a processing facility. Several suboptions have been proposed that would require construction of new facilities. Table 5.4-1 lists the various suboptions and their facility requirements.

Table 5.4-1. Facility requirements of Decentralization suboptions and estimations of area disturbed, [hectares (acres)].

Sub-options	Process option	New pool	New dry vault	New dry casks	New process facility	New land disturbed
W	None	2.4 (6)	2.4 (6)			4.9 (12)
X	None	2.4 (6)		2 (5)		4.5 (11)
Y	P		4.9 (12)		2.4 (6)	7.3 (18)
	Q		2.4 (6)		4.9 (12)	7.3 (18)
	D		4.9 (12)		2.4 (6)	7.3 (18)
Z	P			4.9 (12)	2.4 (6)	7.3 (18)
	Q			2 (5)	4.9 (12)	6.9 (17)
	D			4.9 (12)	2.4 (6)	7.3 (18)

All suboptions would require the temporary use of 105-KE and 105-KW basins for packaging of fuel prior to relocation to a new wet storage facility, or stabilization for dry storage. These are existing Manhattan Project and/or Cold War facilities (currently under evaluation for National Register eligibility). Modifications to these existing facilities are considered to be comparable to those identified in the No Action Alternative.

Actions during the upgrade of the water supply and distribution system for the 100-K Area that disturb ground have the potential to adversely affect prehistoric archaeological sites in the vicinity of the 100-K Area (45BN115, 45BN152, 45BN423, 45BN434, 45BN464, 45BN424, and H3-10). A review of specific upgrade actions is required to determine these effects prior to initiation of these actions. Design of the upgrade system should incorporate avoidance of these prehistoric sites. If avoidance is not possible, some sort of data recovery or other measures may be developed in conjunction with affected Native American Tribes, the SHPO, and the Advisory Council.

An indirect effect of continued operation and maintenance of these facilities is the potential for Hanford workers to conduct unauthorized artifact collection activities. This effect could be mitigated through a worker education program, which would use posters to inform workers of applicable laws, briefing sessions for all persons expected to work along the corridor, and penalties for disturbing an archaeological site. The briefing sessions would stress the importance of cultural resources and specifics of the laws and regulations that exist for site protection.

All of the suboptions would require the construction of new facilities. Wet storage pool and dry storage vault facilities would be cast-in-place concrete structures. The dry cask storage facility would consist of modular storage casks on a concrete pad. The stabilization facilities would be multilevel steel-reinforced, cast-in-place concrete structures. The total land area disturbed by the construction of these facilities is estimated to range from 11 to 18 acres.

All new facilities would be located on a 160-acre site just west of 200-East Area (Figure 4-1). The construction of these facilities is not expected to directly affect any archaeological resources. The proposed project area has been surveyed for cultural resources (HCRC 94-600-001), and no prehistoric or historic archaeological properties were found. Consultation with the State Historic Preservation Office and affected Native American Tribes is still in progress. No indirect effects would be anticipated either because no archaeological sites are known to occur within approximately 4 kilometers of the location proposed for the SNF storage facilities. The SNF facilities would be constructed in an industrialized area and would not alter the feeling or association of the Manhattan Project and/or Cold War facilities located nearby.

Text describing impacts to areas of known traditional or religious significance to specific Native American Tribes for the No Action Alternative in Subsection 5.4.1 also applies to the Decentralization Alternative.

5.4.3 1992/1993 Planning Basis Alternative

This alternative involves continued SNF onsite transportation, receipt, processing, and storage at the Hanford Site. However, the TRIGA fuel currently stored at Hanford would be shipped to INEL. The impacts to cultural resources caused by storage of this fuel at INEL are covered in Volume 1, Appendix B (INEL Spent Nuclear Fuel Management Program). The storage and stabilization facility options for Hanford under this alternative are assumed to be consistent with those of the Decentralization Alternative. Refer to Subsection 5.4.2 for a discussion of the cultural resource impacts.

5.4.4 Regionalization Alternative

All new facilities would be constructed on the 65 hectare (163-acre) site west of 200-East Area (Figure 4.1). Construction of these facilities is not expected to have a direct effect on any significant archaeologic resources. The proposed project area has been surveyed for cultural resources (HCRC 94-600-017), and no prehistoric or historic archaeological properties were found. Two isolated artifacts, one historic and one prehistoric in origin, were recorded during the inventory. Because of their isolated status, neither of the artifacts is considered significant. No indirect effects are anticipated because no known archaeological sites are present within approximately 4 kilometers (2 1/2 miles) of the location proposed for the SNF storage facilities. Because the site for the new SNF facilities is in an industrialized area, construction of these facilities would not alter the feeling or association of the Manhattan Project and/or Cold War facilities located nearby.

Although no cultural resource impacts are expected, the potential for discovery during construction is proportional to the amount of land that would be disturbed. For the various options of the Regionalization Alternative, those areas would amount to the following amounts of land:

A) From about 2 to 7 hectares (6 to 18 acres) when all SNF, except defense production SNF, would be sent to INEL

B1) From about 14 to 17 hectares (36 to 43 acres) when all SNF west of the Mississippi River, with the exception of Naval SNF, would be sent to Hanford

B2) From about 24 to 27 hectares (61 to 68 acres) when all SNF west of the Mississippi River and Naval SNF would be sent to Hanford

C) About 2 to 5 hectares (6 to 12 acres) when all Hanford SNF would be sent to INEL or NTS.

In any event, the maximum option would require a processing facility (equivalent to Decentralization process options P, Q, or D) with a specialty fuel processing area; an inspection and packaging facility; an SNF storage complex (similar to, but larger than that for the Decentralization options W, X, Y, or Z); and a new Expended Core Facility. The existing 105-KE and 105-KW basins would be used to package fuel for wet transport to the processing facility. These are existing Manhattan Project and/or Cold War facilities that are currently under evaluation for National Register eligibility. Modifications to these facilities are considered to be similar to those depicted for the No Action and Decentralization alternatives (refer to Subsections 5.4.1 and 5.4.2). Ground-disturbing upgrades to the 100-K Area water supply and distribution system are considered to have potentially adverse effects on prehistoric archaeological sites 45BN115, 45BN152, 45BN423, 45BN434, 45BN424, H3-10, and/or 45BN464 located in this vicinity. A review of the specific upgrade plans is required to determine the effects before beginning these activities. Design of the upgraded water supply system should incorporate avoidance of the prehistoric sites. If avoidance is not possible, then some data recovery or other measures would be developed in conjunction with the affected Native American Tribes, the SHPO, and the Advisory Council. Text describing potential unauthorized artifact collection and possible mitigation measures for the Decentralization Alternative in Subsection 5.4.2 also applies to the Regionalization Alternative.

Text describing impacts to areas of known traditional or religious significance to specific Native American Tribes for the No Action Alternative in Subsection 5.4.1 also applies to the Regionalization Alternative.

5.4.5 Centralization Alternative

This alternative consists of two scenarios: shipment of all SNF off of the Hanford Site (minimum option), and storage of all SNF at the Hanford Site (maximum option). For the minimum option, a new fuel stabilization and packaging (canning) facility would be constructed.

The maximum option would require a processing facility (equivalent to Decentralization process options P, Q, or D) with a specialty fuel processing area; an inspection and packaging facility; an SNF storage complex (similar to the decentralization options W, X, Y, or Z); and a new Expended Core Facility. The existing 105-KE and 105-KW Basins would be used to package defense production fuel for wet transport to the processing facility. These are existing Manhattan Project and/or Cold War facilities that are currently under evaluation for National Register eligibility. Modifications to these facilities are considered to be similar to those depicted for the No Action and Decentralization Alternatives (refer to Subsections 5.4.1 and 5.4.2). Ground-disturbing upgrades to the 100-K Area water supply and distribution system are considered to have potentially adverse effects on prehistoric archaeological sites 45BN115, 45BN152, 45BN423, 45BN434, 45BN424, H3-10, and/or 45BN464 located in this vicinity. A review of the specific upgrade plans is required to determine the effects before beginning these activities. Design of the upgraded water supply system should incorporate avoidance of the prehistoric sites. If avoidance is not possible, then some data recovery or other measures would be developed in conjunction with the affected Native American Tribes, the SHPO, and the Advisory Council. Text describing potential unauthorized artifact collection and possible mitigation measures for the Decentralization Alternative in Subsection 5.4.2 also applies to the Centralization Alternative.

All new facilities would be constructed on the 160-acre site west of 200-East Area (Figure 4.1). The construction of these facilities is not expected to have a direct effect on any archaeologic resources. The proposed project area has been surveyed for cultural resources (HCRC 94-600-001), and no prehistoric or historic archaeological properties were found. No indirect effects are anticipated because no known archaeological sites are present within approximately 4 kilometers of the location proposed for the SNF storage facilities. The site for the new SNF facilities is in an industrialized area, thus construction of these facilities would not alter the feeling or association of the Manhattan Project and/or Cold War facilities located nearby.

Text describing impacts to areas of known traditional or religious significance to specific Native American Tribes for the No Action Alternative in Subsection 5.4.1 also applies to the Centralization Alternative.

5.5 Aesthetic and Scenic Resources

Implications of implementing the alternatives for interim storage of SNF on aesthetic and scenic resources at the Hanford Site are discussed in the following subsections.

5.5.1 No Action Alternative

Impacts from this alternative would have no effect on the aesthetic and scenic resources.

5.5.2 Decentralization Alternative

This alternative would require the construction of an SNF facility at Hanford, where most SNF from the Hanford Site would be stored.

Changes caused by construction and operation of an SNF facility would be consistent with the existing overall visual environment of the Hanford Site. Topographic features obstruct the SNF site from view from populated areas. The site could be seen from the farmland bluffs that overlook the Columbia River on the east. However, these lands are on private property not readily accessible to the public. Landowners would likely grant access permission only during the hunting season, if at all. No impacts requiring mitigation would occur to the aesthetics or to the visual environment as a result of construction or operation of an SNF facility at the Hanford Site.

5.5.3 1992/1993 Planning Basis Alternative

Activities in this alternative are sufficiently similar to those of the Decentralization Alternative that they are not repeated here.

5.5.4 Regionalization Alternative

This alternative (see Section 5.1.4 for details) would require the construction of a variety of SNF facilities depending on the option chosen. The facilities would range from a packaging/stabilization facility if all fuel were to be removed from Hanford (option C) to storage facilities for all SNF west of the Mississippi River (option B2). However, changes caused by construction and operation of these facilities would be consistent with the existing overall visual environment of the Hanford Site. Topographic features obstruct the SNF site from view from populated areas. The site could be seen from the farmland bluffs to the east of the site that overlook the Columbia River. However, these lands are on private property that is not readily accessible to the public. Landowners would likely grant access permission only during the hunting season, if at all.

No impacts requiring mitigation would occur to the aesthetics or to the visual environment as a result of construction or operation of an SNF facility at the Hanford Site.

5.5.5 Centralization Alternative

If Hanford is selected as the site for centralization of SNF, then the SNF facility and its support facilities would be constructed here.

Changes caused by construction and operation of an SNF facility would be substantially larger in the Centralization Maximum Alternative. However, they would be consistent with the existing overall visual environment of the Hanford Site. Topographic features obstruct the SNF site from view from populated areas. The site could be seen from the farmland bluffs that overlook the Columbia River on the east. However, these lands are on private property not readily accessible to the public. Landowners would likely grant access permission only during the hunting season, if at all.

No impacts requiring mitigation would occur to the aesthetics or to the visual environment as a result of construction or operation of an SNF facility at the Hanford Site. If Hanford is not selected as the site for centralization of SNF, only an SNF packaging/ processing facility for shipment of fuel would be constructed and there would be even less potential for impact to the aesthetic and scenic resources.

5.6 Geologic Resources

No postulated impacts to the geologic resources of the Hanford Site have been identified under any of the alternatives. Thus, geologic resources would remain as described under Section 4.6.

5.7 Air Quality and Related Consequences

The consequences of the five alternatives on ambient air quality at the Hanford Site are presented in this section. In the case of radiological emissions, the consequences are compared among the alternatives and to current Hanford Site operations. For nonradiological emissions, projected ambient concentration at key receptor locations are compared with current concentrations at the Hanford Site. Development of the specific analysis for each alternative is discussed in subsequent subsections.

The consequences of radiological emissions were evaluated using the GENII computer code package (Napier et al. 1988). The radiological consequences of airborne emissions during normal operation have been estimated for the SNF storage alternatives considered in this document. Three separate analyses were performed for each facility included in a particular alternative using the GENII computer code. The receptors evaluated in these cases were at the location of maximum exposure representing a potential onsite worker outside of the SNF facility, the maximally exposed offsite resident, and the collective population within 80 kilometers. Standard parameters for radiological dose calculations at the Hanford Site were used for these estimates (Schreckhise et al. 1993). The maximum impact of each alternative on offsite receptors and workers was obtained by summing the consequences associated with the individual facilities, although these receptors may be physically at very different locations. The health consequences in terms of cancer fatalities were calculated using recommendations of the International Commission on Radiological Protection in its Publication 60 (ICRP 1991) - 4E-04 fatal cancers/rem for workers and 5E-04 fatal cancers/rem for the general population. Risk conversion factors were applied to both individual and collective doses, although they are based on population averages for individuals with varying degrees of sensitivity. The individual risk estimates therefore represent the risk to a hypothetical individual, which would be somewhat lower than the risk to more sensitive members of the population.

None of the alternatives would result in a dose to the maximally exposed offsite resident that exceeds 1 percent of the current EPA standard of 10 millirem/year. The consequences of the No Action Alternative are caused by emissions from existing facilities where spent fuel is stored. These facilities contribute a relatively small fraction of the total dose from airborne emissions at all Hanford Site operations (less than half and likely much less). The No Action Alternative represents the baseline for SNF operations at Hanford. The consequences of the Decentralization, Regionalization, and Centralization Alternatives vary depending on which storage and processing options are considered. Options including processing of defense reactor fuel result in the highest doses, which are at most an order of magnitude greater than those in the No Action Alternative. The consequences of options involving only containerization of defense reactor fuel followed by wet storage, and dry storage of all other fuel, in a new facility are approximately an order of magnitude lower than those in the No Action Alternative.

The potential nonradiological air quality pollutants of concern for this assessment include all pollutants for which there exist federal, state, or local standards. This includes both the standard set of criteria pollutants (e.g., nitrogen dioxide, oxides of sulfur, respirable particles) and toxic pollutants.

For criteria pollutants, concentration levels are regulated by the provisions of the Clean Air Act; Washington State standards for these criteria pollutants are at least as stringent as the federal standards. In the State of Washington, the Department of Ecology has the responsibility for promulgating and enforcing air quality standards for the protection of public health. The regulation that governs the control of toxic air pollutants (WAC 1990a,b) requires the owners of new or modified air emission sources to apply for approval before construction. Owners of sources emitting toxic air pollutants must demonstrate that they will employ the best available control technology for emissions control with reasonable environmental, energy, and economic impacts.

Construction of new facilities can also negatively impact air quality through the emission of fugitive dusts. To model this aspect, the EPA's Fugitive Dust Model (FDM) was selected. This model is especially designed to compute the air quality impacts from fugitive dust emissions, such as those associated with facility construction sites (Winges 1992). The FDM uses steady-state Gaussian plume algorithms and a gradient-transfer deposition algorithm to compute air quality impacts. Emissions for each source must be apportioned into a series of particle-size classes; each of which is assigned a representative deposition velocity. The model can operate using either joint frequency distributions or hourly meteorological data to represent atmospheric conditions. The model can handle up to 200 sources and 500 receptors per model run. The user may define a variety of point, line, area, and volume sources.

The Industrial Source Complex (ISC2) models were selected to estimate routine nonradiological air quality impacts. There are two ISC2 models: the ISC2 short-term model (ISCST2) and the ISC2 long-term model (ISCLT2). The two ISC2 models use steady-state Gaussian plume algorithms to estimate pollutant concentrations from a wide variety of sources associated with industrial complexes (EPA 1992). The models are appropriate for flat or rolling terrain, modeling domains with a radius of less than 50 kilometers, and urban or rural environments. The ISC2 models have been approved by the EPA for specific regulatory applications and are designed for use on personal computers. Input requirements for the ISC2 model include a variety of information that defines the source configuration and pollutant emission parameters. The user may define a variety of point, line, area, and volume sources. The ISCST2 model uses hourly meteorological data and joint frequency distribution data to compute straightline plume transport. Plume rise, stack-tip downwash, and building wake can be computed. The ISC2 models compute a variety of short- and long-term averaged products at user-specified receptor locations and receptor rings. The ISC2 models also treat deposition processes and allow the exponential decay of pollutants.

5.7.1 No Action Alternative

Facilities included in the No Action Alternative consist of those where SNF is currently stored at the Hanford Site. Minimal repackaging, stabilization, and relocation of fuel would be undertaken to ensure continued safe storage prior to ultimate disposition. The majority of spent fuel at Hanford is located at the 100-K Area wet storage basins. In addition, smaller quantities of fuel are stored at other onsite facilities. These include T Plant and a low-level waste burial ground in the 200-West Area; the Fast Flux Test Facility in the 400 Area; and the 308, 324, 325, and 327 buildings in the 300 Area. Releases for the No Action Alternative are based on operations for these facilities during 1992 (Bergsman 1995). These emissions were assumed to represent operations at existing SNF storage facilities over the EIS evaluation period, although they are subject to change with individual facility missions and operating status. It should also be noted that some existing facilities support a variety of other programs in energy research and waste management in addition to laboratory and hot cell examination of fuel materials. The historical releases from these multi-purpose facilities may reflect other activities in addition to spent fuel storage. The past operating emissions, therefore, represent an upper bound estimate for the fuel storage activities. The No Action Alternative also represents the baseline of maximum expected impacts for future spent fuel storage activities.

5.7.1.1 Radiological. Radiological air emissions for normal operation

of existing fuel storage facilities in the No Action Alternative are listed in Tables 5.7-1 through 5.7-3 (DOE/RL 1993). The sealed fuel canisters temporarily stored at the 200-West Area burial ground are assumed to release negligible quantities of radionuclides in this analysis, although actual emissions from the stored fuel have not been quantified.

The consequences of air emissions from existing facilities utilized in the No Action Alternative are summarized in Table 5.7-4 and include a maximum annual dose of 1E-5 rem to a potential onsite worker with a 5E-9 probability of fatal cancer. The maximum dose to an offsite resident is estimated as 3E-6 rem/year, and the corresponding probability of fatal cancer is 1E-9. The dose estimate for an onsite worker or an offsite individual represents the sum of doses to separate maximally exposed individuals for each of the facilities included in the alternative. Because these facilities are in different areas of the Hanford Site, the respective maximally exposed workers and offsite residents are at different locations. The actual dose to a single worker or

Table 5.7-1. Annual atmospheric releases for normal operation - wet storage basins at 100-KE Area and 100-KW Area.

Radionuclide	100-KE Area Release (Ci/yr)	100-KW Area Release (Ci/yr)
Cobalt-60	1.3E-06	1.4E-06
Strontium-90	1.6E-04	9.9E-07

Cesium-137	2.3E-04	2.7E-05
Europium-154	NA	4.9E-06
Plutonium-238	1.3E-06	3.0E-08
Plutonium-241	3.9E-05	NA
Americium-241	5.1E-06	NA
Plutonium-239	8.5E-06	1.8E-07
Tritium	(b)	(b)

a. NA indicates not available.

b. Although tritium emissions are not routinely monitored at these facilities, the releases from both basins were recently estimated as 1-2 Ci/year. These emissions could account for up to 25% of the total dose from these facilities to the maximally exposed offsite resident. However, the contribution from the 100 area tritium emissions would not change the estimated dose from all Hanford emissions to the site's maximally exposed offsite resident.

Table 5.7-2. Annual atmospheric releases for normal operation - fuel storage at 300 Area 308, 324, 325, and 327 buildings.

Radionuclide	308 Building Release (Ci/yr)	324 Building Release (Ci/yr)	325 Building Release (Ci/yr)	327 Building Release (Ci/yr)

Tritium	NAa	9.6E+00	2.5E+01	NA
Total betab	1.1E-07	6.4E-07	2.4E-06	9.3E-07
Total alphac	3.0E-08	3.9E-07	8.5E-07	1.1E-07

a. NA indicates not available.
b. Total beta emissions were assumed to be strontium-90 for modeling purposes.
c. Total alpha emissions were assumed to be plutonium-239 for modeling purposes.

Table 5.7-3. Annual atmospheric releases for normal operation - fuel storage at 200 West Area T Plant and 400 Area FFTF.

Radionuclide	200-West Area T Plant Release (Ci/yr)	400 Area FFTF Release (Ci/yr)
Argon-41	NAa	8.5E+00b
Total beta/strontium-90	1.2E-05	6.7E-06c
Cesium-137	1.3E-05	NA
Americium-241	2.0E-06	NA
Total alpha/plutonium-239	2.2E-05	1.1E-06d

a. NA indicates not available.
b. Releases of Ar-41 occurred during reactor operation in 1992. The reactor was subsequently shut down, and releases of short-lived activation products are not anticipated from future fuel storage activities.
c. Total beta emissions were assumed to be strontium-90 for modeling purposes.
d. Total alpha emissions were assumed to be plutonium-239 for modeling purposes.

offsite resident from all facilities combined would therefore be less than the sum of the individual facility receptor doses reported in Table 5.7-4. The peak collective dose to the population within 80 kilometers (50 miles) is 3E-2 person-rem per year, which is predicted to result in less than one fatal cancer (6 x 10-4) over 40 years of storage.

5.7.1.2 Nonradiological Consequences. The No Action Alternative

involves no new construction so there would not be an increase in particulate emissions. The facilities currently used in storing the SNF do not have any nonradiological releases, so there would be no increase in concentrations of these pollutants.

5.7.2 Decentralization Alternative

The Decentralization Alternative permits construction of new facilities where these represent an improvement over current storage practices. Relocation of fuel could be undertaken as part of this alternative to meet programmatic needs; however, no fuel would be shipped to, or received from, offsite locations. It is assumed for purposes of this analysis that new facilities would be constructed under this alternative, and that they would be located in a dedicated SNF management complex adjacent to the 200-East Area.

Table 5.7-4. Radiological consequences of airborne emissions during normal operation in the No-Action Alternative for spent nuclear fuel storage at Hanford.

		Onsite worker		Offsite resident		80 kilometer population	
Area	Facility	Peak annual dose (EDE) (rem/yr)	Probability of fatal cancer	Peak annual dose (EDE) (rem/yr)	Probability of fatal cancer	Peak annual dose (EDE) (person-rem/yr)	Number of fatal cancers
100 KE	Wet Basin	9.3E-06		2.0E-07		5.7E-03

Total from All Facilities		1.2E-05	4.6E-09	2.6E-06	1.3E-09	2.7E-02	1.3E-05

The Decentralization Alternative at Hanford includes two basic options, each with several suboptions depending on the types of storage and processing facilities included. The first major option includes a combination of wet storage of defense production fuel and dry storage of all other fuel in either a small vault facility (suboption W) or in casks (suboption X). The second major option provides for dry storage of all fuel, which would require processing of defense fuel prior to dry storage. If a shear/leach/calcine process is used (suboption P), the calcine product and all other fuel would be consolidated in a single large vault facility (suboption Y) or in casks (suboption Z). If a solvent extraction process is chosen for the defense fuel (suboption Q), the oxide products could be stored in either new or existing facilities that would have lower space and shielding requirements than for the calcine product. A high-level liquid waste stream would also be produced and transferred to underground storage tanks. All fuel other than the processed defense fuel would be stored in a small vault facility or in casks as in suboptions W and X.

5.7.2.1 Radiological. Estimated radiological air emissions for normal operations of new facilities in the Decentralization Alternative are listed in Tables 5.7-5 through 5.7-7. The dry storage facilities are assumed to have no radiological emissions under normal operating conditions because all fuel is contained in sealed decontaminated canisters and storage casks. Therefore, there is no mechanism for routine release of radionuclides from dry storage facilities over the time period covered in this document.

The consequences of air emissions from individual facilities in the Decentralization Alternative are summarized in Table 5.7-8 and include a maximum annual dose of 2E-9 rem to a

potential onsite worker (8E-13) probability of fatal cancer) for the option including a combination of wet and dry spent fuel storage facilities. The dose to an offsite resident at the highest exposure location is estimated as 6E-10 rem/year, and the corresponding probability of fatal cancer is 3E-13. The peak collective dose to the population within 80 kilometers is 2E-5 person-rem per year, which is predicted to result in less than one (4 x 10-7) fatal cancer over 40 years of storage.

Table 5.7-7. Estimated annual atmospheric releases for normal operation - spent nuclear fuel solvent extraction fuel process at 200-East Area.

Table 5.7-8. Radiological consequences of airborne emissions during normal operation in the Decentralization Alternative for spent nuclear fuel storage at Hanford.

		Onsite worker		Offsite resident		80 km population	
Area	Facility	Peak annual dose (EDE) (rem/yr)	Probability of fatal cancer	Peak annual dose (EDE) (rem/yr)	Probability of fatal cancer	Peak annual dose (EDE) (person-rem/yr)	Number of fatal cancers
Combination Wet + Dry Storage Option							
200 E	New Wet Storage	2.0E-09	8.0E-13	5.7E-10	2.8E-13	2.3E-05	1.2E-08
200 E	New Dry Storage	0.0E+00	0.0E+00	0.0E+00	0.0E+00	0.0E+00	0.0E+00
Dry Storage Only Option with Defense Fuel Processing							
200 E	New Dry Storage	0.0E+00	0.0E+00	0.0E+00	0.0E+00	0.0E+00	0.0E+00
200 E	New Fuel Calcine	4.1E-06	1.7E-09	7.0E-06	3.5E-09	3.4E-01	1.7E-04
200E	New Solvent Extraction	2.7E-05	1.1E-08	2.1E-05	1.1E-08	1.3E+00	6.3E-04

For the all dry storage option, processing defense fuel is required in the Decentralization Alternative (suboptions P and Q), and additional emissions would result from these activities if they were conducted. The dose to the onsite worker from air emissions would be 4E-6 rem per year for a shear/leach/calcine process or 3E-5 rem per year for a solvent extraction process (2E-9 or 1E-8 probability of fatal cancer, respectively) in addition to those from the dry storage facility. The corresponding consequences for the offsite resident would be 7E-6 rem per year (4E-9 probability of fatal cancer) for the shear/leach/calcine facility and 2E-5 rem per year (1E-8 probability of fatal cancer) for the solvent extraction facility. The collective dose to the offsite population from the respective fuel processing facilities is estimated at 0.3 to 1 person-rem per year, resulting in less than one expected fatal cancer (<0.02) over 40 years of storage.

5.7.2.2 Nonradiological Consequences. Fugitive dust emissions from new

construction activities, toxic chemical emissions, and nitrogen oxide emissions from fuel processing would contribute to the non-radiological emissions in the Decentralization Alternative.

5.7.2.2.1 Fugitive Dust.

Three different construction options are under consideration in this alternative: 1) construction of wet and dry storage facilities, 2) construction of dry storage and the shear/leach/calcine facility, and 3) construction of a dry storage and a solvent extraction facility. In options 1 and 2, approximately 12 acres would be disturbed for the construction of the storage facilities; in option 3, 6 acres would be disturbed for the dry storage facility. An additional 6 acres would be disturbed for the shear/leach/calcine facility or 12 acres for the solvent extraction facility. In total up to 12 acres would be disturbed in the first option and 18 acres in the second and third options (Bergsman 1995).

Details of the construction process are not available for the alternatives, but a standard default value of 1.2 tons/acre/month of particles can be assumed to be generated during new construction (EPA 1977). Most of the particles produced by construction activities are large and settle a short distance from the source (Seinfeld 1986). A conservative estimate is that approximately 30 percent of the mass released would be particles small enough to be transported away from the construction site (EPA 1988).

Experience with construction activities at Hanford indicates that fugitive dust concentrations at the nearest point of public access and at the site boundaries would be less than Washington State PM10 limits for both annual and 24-hour averages. Standard control techniques (such as applying water to the disturbed ground) could be used to limit the PM10 emissions at the construction site and resulting airborne concentrations. Although extensive construction activities have the potential to contribute to short-term airborne particulate concentrations if they coincide with high wind events, such effects would generally be obvious only in the immediate area and could be mitigated by dust control measures over both the short and long term. In any case, such activities would be temporary and would not adversely affect regional air quality on a continuing basis. Construction activities would also result in increased emissions of pollutants from diesel- and gasoline-powered construction equipment. However, the increase in ambient levels of pollutants would be minimal because of the relatively low levels of emission and large distances to the nearest points of public access and the site boundary.

5.7.2.2.2 Nitrogen Oxides.

Nitrogen oxide emissions during facility operation are approximately the same for both the shear/leach/calcine facility and the solvent extraction facility. It is assumed that all nitrogen oxide emissions are in the form of nitrogen dioxide. Annual concentrations at the nearest point of public access, 7.5 kilometers (6.4 miles) southwest of the release site, are estimated to be 0.1 micrograms per cubic meter. This concentration is 0.1 percent of the allowed Washington State standard and 0.4 percent of the Prevention of Significant Deterioration (PSD) standard.

Nitrogen oxide concentrations were also calculated for onsite locations. The maximum annual concentration estimated by the model is 1.2 micrograms per cubic meter, which occurs 500 meters (0.3 miles) south of the processing facility. The maximum ground level concentration is some distance from the processing facility because the emissions are from an elevated stack rather than at ground level. For example, at a distance of 100 meters (0.06 miles) from the base of the facility, the greatest estimated nitrogen oxide annual concentration is only 1.8 x 10-5 micrograms per cubic meter.

5.7.2.2.3 Toxic Chemical Emissions.

Information about routine toxic chemical emissions from either the shear/leach/calcine facility or the solvent extraction facility is unavailable. However control techniques would be used to ensure that concentrations of toxics in the atmosphere comply with the DOE abatement policy and local permitting requirements.

5.7.3 1992/1993 Planning Basis Alternative

The 1992/1993 Planning Basis Alternative is assumed to be similar to the Decentralization Alternative discussed in the previous section, including construction of wet or dry storage facilities adjacent to the 200-East Area and process facilities for defense production fuel if it is to be stored dry. The only change to the Hanford Site fuel inventory would involve shipment of a relatively small quantity of TRIGA fuel to an offsite location. This would not substantially alter the scope of planned spent fuel storage activities, and the 1992/1993 Planning Basis Alternative assumes emissions for new facilities are the same as those in the Decentralization Alternative.

5.7.3.1 Radiological Consequences. The consequences for this

alternative are assumed to be the same as those for the Decentralization Alternative. Refer to Table 5.7-8 for the list of facilities included in this option and their consequences.

5.7.3.2 Nonradiological Consequences. The consequences for this

alternative are considered to be the same as those for the Decentralization Alternative.

5.7.4 Regionalization Alternative

The Regionalization Alternative at Hanford includes three options, depending on the quantity of SNF shipped to, or from, the site. Option A provides for regional storage of SNF by type, and would entail shipping all fuel at Hanford except defense production fuel to another location. In this case, defense fuel would either be stored wet at a new pool facility, or it would be processed for dry storage using suboptions similar to those described in the Decentralization Alternative.

An additional option in the Regionalization Alternative describes importing SNF to Hanford from other sites based on their geographic distribution. In the first option, designated Option B1, all fuel at locations west of the Mississippi River except Naval SNF would be stored at Hanford. In the second option, designated Option B2, all SNF at locations west of the Mississippi River and Naval SNF would be stored at Hanford. All imported fuel would ultimately be placed into a new dry storage facility, the size of which would be determined by the quantity of imported fuel to be stored. In addition, a receiving and canning facility would be built to repackage any fuel as needed, and to provide temporary wet storage for fuels that could not be immediately placed into dry storage. This option would also include a technology development facility for fuel characterization and research related to SNF management. SNF currently at Hanford would be stored according to the options described in the Decentralization Alternative. Option B2 would include a separate facility to examine and characterize Naval SNF, as described in Appendix D to Volume 1 of this EIS.

The third Regionalization option (designated Option C) would relocate all SNF at the Hanford Site to another western U.S. location. The only new facility that would be required for this option is a processing and packaging facility to stabilize and repackage defense fuel and to place other fuel into canisters as needed for shipping offsite. Prior to preparation for offsite shipment, SNF would continue to be managed at existing facilities, as for the No Action Alternative. All new facilities considered in the Regionalization Alternative options would be constructed in a dedicated SNF management complex adjacent to the 200-East Area, as for the Decentralization Alternative.

5.7.4.1 Radiological Consequences. Emissions from new facilities in

Regionalization Alternative A would be the same as those described for the Decentralization Alternative in Table 5.7-8. Although this option does not include the dry storage capacity for fuel other than defense production fuel, dry storage facilities add nothing to the normal operating emissions; therefore, the emissions and consequences from this alternative would be quantitatively the same as those previously described for the Decentralization Alternative.

Emissions from the new facilities in the Regionalization Alternative B and C options are expected to be bounded by those in the Centralization maximum and minimum options, respectively, as described in Section 5.7.5.

5.7.4.2 Nonradiological Consequences. Because of the similarity of

operations, consequences for the Regionalization Alternative are considered to be the same as those for the Decentralization Alternative.

5.7.5 Centralization Alternative

The Centralization Alternative at Hanford includes two options: a maximum option in which all SNF for which DOE is responsible would be stored at Hanford, and a minimum option in which all SNF currently at Hanford would be shipped to another site. The maximum option is similar to that described in the Regionalization Option B2, except that the size of the receiving and canning and dry storage facilities would be increased as necessary to accommodate the larger quantity of imported fuel. The minimum option is identical to that described for the Regionalization Alternative, Option C. All new facilities considered in the Centralization Alternative options would be constructed in a dedicated SNF management complex adjacent to the 200-East Area.

5.7.5.1 Radiological. For the Centralization maximum option at

Hanford, emissions from the wet storage and processing facilities would be identical to those described in the Decentralization Alternative (refer to Tables 5.7-5 through 5.7-7). Minimal emissions from the large dry storage facility are assumed in this case (see Table 5.7-9) because some of the imported fuel could be stored without canning, and the assumption of zero emissions could not be justified as in the Decentralization Alternative. The consequences of emissions from a relocated Expended Core Facility (ECF) are described in Appendix D to Volume 1 of this EIS and are not included here. It should be noted that the assumptions used in Appendix D calculations for the ECF at Hanford may differ from those used to estimate the consequences of emissions from other Hanford facilities.

The consequences of air emissions from individual facilities in the Centralization Alternative maximum option are summarized in Table 5.7-10 and include a maximum annual dose of 9E-9 rem to a potential worker (4E-12 probability of fatal cancer) for a combination of wet and dry spent fuel storage facilities. The dose to an offsite resident at the highest exposure location is estimated as 2E-9 rem/year, and the corresponding probability of fatal cancer is 8E-13. The peak collective dose to the population within 80 kilometers is 7E-5 person-rem per year, which is predicted to result in less than one (4 x 10-8) fatal cancer.

Table 5.7-9. Estimated annual atmospheric releases for normal operation - new dry storage at 200-East Area (maximum option).

Radionuclide	200-East Area Release (Ci/yr)
Cobalt-60	2.8E-08
Strontium-90	9.1E-07
Yttrium-90	9.1E-07
Cesium-137	1.2E-07
Plutonium-239	2.8E-07

Table 5.7-10. Radiological consequences of airborne emissions during normal operation in the

Centralization Alternative for spent nuclear fuel storage at Hanford.

Area	Facility	Onsite worker		Offsite resident		80 km population	
		Peak annual dose (EDE) (rem/yr)	Probability of fatal cancer	Peak annual dose (EDE) (rem/yr)	Probability of fatal cancer	Peak Annual Dose (EDE) (Person-rem/yr)	Number of Fatal Cancers
Combination Wet + Dry Storage Option							
200 E	New Wet Storage	2.0E-09	8.0E-13	5.7E-10	2.9E-13	2.3E-05	1.2E-08
200 E	New Dry Storage	7.0E-09	3.0E-12	1.0E-09	5.0E-13	4.8E-05	2.4E-08
Dry Storage Only Option with Defense Fuel Processing							
200 E	New Dry Storage	7.0E-09	3.0E-12	1.0E-09	5.0E-13	4.8E-05	2.4E-08
200 E	New Fuel Calcine	4.1E-06	1.7E-09	7.0E-06	3.5E-09	3.4E-01	1.7E-04
200E	New Solvent Extraction	2.7E-05	1.1E-08	2.1E-05	1.1E-08	1.3E+00	6.3E-04
Relocation of Expended Core Facility[a]							

[a] Data for the expended core facility (ECF) are presented in Appendix D to Volume 1 of this EIS. Assumptions used in Appendix D calculations for the ECF at Hanford may differ from those used to estimate the doses consequences of emission from other Hanford facilities.

Processing of defense fuel is required prior to dry storage in the maximum option, and additional air emissions would result from those activities if defense fuel is stored dry rather than wet. The dose to the worker would increase by 4E-6 rem/year for a shear/ leach/ calcine process or 3E-5 rem/year for a solvent extraction process (2E-9 or 1E-8 probability of fatal cancer, respectively). The corresponding added consequences for the offsite resident would be 7E-6 rem/year (4E-9 probability of fatal cancer) for the shear/leach/calcine facility and 2E-5 rem/year (1E-8 probability of fatal cancer) for the solvent extraction facility. The collective dose to the offsite population from the respective fuel processing facilities is estimated at 0.3 to 1 person-rem per year, resulting in less than one (5 x 10-4) fatal cancer.

In the Centralization Alternative minimum option, the consequences of existing facilities utilized for interim fuel storage prior to shipment offsite are the same as in the No Action Alternative. Consequences for defense fuel processing prior to shipment are described under the centralization maximum alternative and are equivalent to those from the shear/leach/calcine facility. Refer to Tables 5.7-4 and 5.7-10 for the consequences of facilities included in this option.

5.7.5.2 Nonradiological. Because of the similarity of operations

leading to nonradiological impacts on air quality, consequences for the Centralization Alternative are considered to be the same as those for the Decentralization Alternative with the addition of emissions from the naval fuels Expended Core Facility. Analysis of nonradiological releases from the Expended Core Facility can be found in Volume 1, Appendix D.

5.8 Water Quality and Related Consequences

This section evaluates the potential impacts to groundwater and surface water resources from the construction and operation of SNF storage and associated support facilities at the Hanford Site. Potential impacts to groundwater and surface water, water use, and water quality from the potential release of contaminants into, and migration through, hydrologic water-based environments are evaluated. The potential significance of these impacts is evaluated with respect to environmental contaminant levels from potential releases of contaminants into the environment and the health impacts of these contaminant levels. Contaminant waste streams include radionuclide and chemical carcinogens and noncarcinogenic chemicals.

The Multimedia Environmental Pollutant Assessment System (MEPAS), a computer model, was utilized to simulate the release, migration, fate, exposure, and risk to surrounding receptors of wastes that are discharged into the environment from the operation of SNF facilities. The MEPAS model is a fully integrated, physics-based, PC-platform, intermedia transport- and risk computation code that is used to assess health impacts from actual and potential releases of both hazardous chemicals and radioactive materials. The MEPAS model is designed for site-specific assessments using readily available information. It follows EPA risk-assessment guidance in evaluating 1) the release of contaminants into the environment; 2) their movement through and transfer between various environmental media [i.e., subsurface (vadose and saturated zones), surface water, overland (surface soil), and atmospheric]; 3) exposure to surrounding receptors via inhalation, ingestion, dermal contact, and external dose; and 4) risk to carcinogens and hazard to noncarcinogens. The MEPAS model follows ICRP/NCRP and EPA guidelines, where the user is allowed to choose the appropriate guidelines.

5.8.1 No Action Alternative

The only release directly to the surface water in the No Action Alternative was associated with the 105-KE and 105-KW basins. The 105-KE and 105-KW basins were combined as one release and represented by a "single liquid release point to the Columbia River" (Bergsman 1995). The annual liquid discharge is assumed to be 1.4E+06 cubic meters per year (3.7E+08 gallons per year), with a total activity of approximately 0.4 Ci: 0.26 Ci tritium, 0.066 Ci cobalt-60, 0.01 Ci cesium-137, 0.0010 Ci strontium-90, and 9.2E-06 Ci plutonium-239 (Bergsman 1995). All of the constituents in this assessment are radionuclides. The release is assumed to continue at this level over the period of 18 years from 1997 through 2015. Operational liquid effluents from the K Basins are discharged to the Columbia River via the monitored and regulated National Pollutant Discharge Elimination System (NPDES) permitted 1908-KE outfall. Contaminant migration is from the point-source discharge point to the Columbia River, and in the Columbia River to receptors downstream. The flow discharge in the Columbia River is assumed to be under low-flow conditions of 1,000 cubic meters per second (36,000 cubic feet per second) (Whelan et al. 1987), which represents the most conservative case for maximizing surface water concentrations. As a conservative assumption, the removal of water from the Columbia River is assumed to be 100 meters (328 feet) downstream of the point of entry of the contaminant into the river. The assessment addressed recreational activities (e.g., boating, swimming, and fishing) in the Columbia River and use of the water as a drinking water supply and for bathing, irrigation, etc. The risk of fatal cancer in this scenario considering all pathways was found to be less than one chance in a billion. For more information, refer to Whelan et al. (1994).

Intermittent leakage of water from the K Basins is monitored via onsite groundwater sampling. Although radionuclide concentrations in some of the 100-K area monitoring wells exceed EPA drinking water standards, this condition does not constitute a risk to the public because the groundwater is not used directly for human consumption or food production. Analyses of water from the K area springs, where groundwater enters the Columbia River, indicate that radionuclide levels are below the EPA drinking water standards. Dilution of this seepage in the river flow would further reduce the risk to the downstream population, as indicated by the fact that radionuclide concentrations in the Columbia River at the Richland pump house are orders of magnitude below the drinking water standard (Dirkes et al 1994).

5.8.2 Decentralization Alternative

The Spent Nuclear Fuel Wet Transfer and Storage scenario was documented. The source term represents the maximum potential water releases that would be expected if a secondary containment failure and/or piping leak occurred and went undetected for one month at a state-of-the-art wet storage fuel/transfer facility utilizing water treatment technology now available. Releases resulting from such a failure should not be thought of as operational or planned releases. However, for the purposes of a nonzero release source-term, this scenario addresses those situations where an unexpected release may occur. The source-term information was derived from data related to the operation of the Flourinel and Storage Facility (FAST) at INEL's Chemical Processing Plant (ICPP 666) and is considered to be extremely conservative, given the state-of-the-art engineering practices, monitoring, leak-detection equipment, and surveillance procedures likely to be used at any new SNF facility, such as FAST.

Any new facility would be built using state-of-the-art technologies, including leak detection and water-balance monitoring equipment. This equipment, along with the uncertainties associated with evaporation monitoring, will have a minimum detection sensitivity. It is possible that the new SNF facility could experience a failure that would result in a leak that is below the sensitivity of the detection system. Based on the size of the facility and the current monitoring programs at similar facilities, 5 gallons per day has been established as a conservative value to account for potential undetected leakage from the facility. The nonzero release source term would then exceed what could be expected for a new SNF wet storage or transfer facility. Factors contributing to the conservatism in volume estimates are the design criteria, which state that the new facility will contain leak-detection systems (Hale 1994) and will have a lower surface area [i.e., 2000 square meters (6600 square feet)] available for leakage as compared to FAST [i.e., 3830 square meters (12,560 square feet)] (Hale 1994). For the purposes of this assessment, the entire release is assumed as a point source, which is the most conservative assumption. The concentration data associated with the release were contained in or derived from January 6, 1986 to February 14, 1994 weekly water quality reports for FAST and are considered to be reasonable nonzero release source terms at the 95% confidence level. Although surveillance at the FAST facility occurs daily with radiological surveys occurring weekly, the aqueous release assumes that the liner and/or piping leaks and secondary containment failure go undetected for one month.

The specific radionuclide activities in the release solution are assumed as follows: 280 pCi/L strontium-90, 3360 pCi/L cobalt-60, 160 pCi/L cobalt-57(a), 93 pCi/L cesium-137, and 100 pCi/L antimony-125. All of the constituents in this assessment are radionuclides. Contaminant migration is through the vadose zone through the saturated zone to the Columbia River, and in the Columbia River to receptors downstream. The flow discharge in the Columbia River is assumed to be under low-flow conditions 1000 m3 per second (36,000 cubic feet per second) (Whelan et al. 1987), which represents the most conservative case for maximizing surface water concentrations. As a conservative assumption, the removal of water from the Columbia River is assumed to be 100 meters (328 feet) downstream of the contaminant influent point to the river. The assessment addresses recreational activities (e.g., boating, swimming and fishing) in the Columbia River and use of the water as a drinking-water supply and for bathing, irrigation etc. The risk of fatal cancers considering all pathways was found to be significantly less than one chance in a trillion. For more information, refer to Whelan et al. (1994).

The Decentralization Alternative also includes an operational release scenario to the Hanford 200 Area Treated Effluent Disposal Facility (TEDF). Liquid effluents would be added to the TEDF, which receives liquid effluent from many facilities in the 200 Area. The "Discharge Target" allowable concentrations in the TEDF are presented in Bergsman (1995). Only 380 liters (100 gallons) per day will be discharged to the TEDF basin from this operation, although other facilities unrelated to SNF storage will also be discharging to the basin. For a ponded situation, the maximum outflow from the basin is equal to the transmission rate (i.e., saturated hydraulic conductivity under a unit hydraulic gradient) of the soil immediately below the basin, which is 24 cubic meters per day (6260 gallons per day). To maximize the flow velocity through the vadose zone and the mass flux of contaminant leaving the basin (i.e., concentration x area x flow velocity), the assessment assumes that this facility leaks into the vadose zone over a 4-year period with the infiltration rate limited by the transmission rate of the soil. The discharge from the pond is assumed to last for 4 years from 2002 through 2006.

Based on the movement of the second tritium plume from the Plutonium and Uranium Recovery through Extraction cribs in the 200 Area to Well 699-24-33, a distance of 6 kilometers (4 miles) in a 5-year period (1983 to 1988), the average pore-water velocity (i.e., specific discharge divided by the effective porosity) in the saturated zone was 3.3 meters per day (10.8 feet per day) (Schramke et al. 1994). Davis et al. (1993) performed a more recent analysis and determined the pore-water velocity as 0.02 meters per day (0.08 feet per day) just below the TEDF site, although this is not necessarily indicative of the velocity as the water moves toward the river. Both velocities were initially used in assessing the migration of contamination from the basin to determine the most conservative result with respect to risk. In the final analysis, the highest pore-water velocity of 3.3 meters per day (10.8 feet per day) was used because 1) it is consistent with other assessments at the installation, 2) the contaminants reached the river and receptors earlier, and 3) the resulting exposure analysis provided the more conservative estimate of risk over the 7000-year assessment time frame.

Radionuclides, chemical carcinogens, and noncarcinogens are contained in the waste stream. The concentrations in the TEDF were represented by the discharge target allowable concentrations. Contaminant migration is from the

---

a. Cobalt-57 is substituted in the analysis for cobalt-58 because the MEPAS database contains only cobalt-57.

ponded water, through the vadose zone, through the saturated zone to the Columbia River, and in the Columbia River to receptors downstream. The flow discharge in the Columbia River is assumed to be under low-flow conditions of 1000 cubic meters per second (36,000 cubic feet per second) (Whelan et al. 1987), which represents the most conservative case for maximizing surface water concentrations. As a conservative assumption, the removal of water from the Columbia River is assumed to be 100 meters (328 feet) downstream of the point of entry of the contaminant into the river. The assessment addressed recreational activities (e.g., boating, swimming, and fishing) in the Columbia River and use of the water as a drinking-water supply and for bathing, irrigation, etc.

The maximum radionuclide and chemical carcinogenic risks were found to be less than 50 chances in a billion for all of the constituents through all of the exposure routes. Likewise, noncarcinogenic chemical individual doses were found to be below their respective reference doses, except chromium VI, which had a dose about 50 percent higher than the reference dose. Chromium VI had an assigned distribution coefficient (i.e., Kd) of zero (Serne and Wood 1990), which represents the most mobile condition in the vadose zone. For more information, refer to Whelan et al. (1994).

5.8.3 1992/1993 Planning Basis Alternative

Scenarios and consequences relating to water quality would be the same as for the Decentralization Alternative. For more information, refer to Whelan et al. (1994).

5.8.4 Regionalization Alternative

Scenarios and consequences relating to water quality in the Regionalization options would be the same as for water quality aspects in the Decentralization Alternative. For more information, refer to Whelan et al. (1994).

5.8.5 Centralization Alternative

Scenarios and consequences relating to water quality would be the same as for the Decentralization Alternative. For more information, refer to Whelan et al. (1994).

5.9 Ecological Resources

Implications of implementing the alternatives for interim storage of SNF on terrestrial resources, wetlands, aquatic ecosystems, and threatened and endangered species at the Hanford Site are discussed in the following subsections.

5.9.1 No Action Alternative

Implications of implementing the No Action Alternative for interim storage of SNF on terrestrial resources, wetlands, aquatic resources, and threatened and endangered species at the Hanford Site are discussed in the following subsections.

5.9.1.1 Terrestrial Resources. No new SNF facilities would be

constructed at Hanford and there would be no impacts to the terrestrial resources of the Hanford Site beyond those resulting from natural processes of succession and the impacts of ongoing Hanford operations. They would remain as described under Section 4.9.1.

5.9.1.2 Wetlands. No new SNF facility would be constructed; therefore,

no changes to wetlands on the Hanford Site would be expected beyond those changes resulting from natural processes and the impacts of ongoing Hanford operations (see Section 4.9.3).

5.9.1.3 Aquatic Resources. No new SNF facility would be constructed

and the fact that there are no surface water facilities on the SNF facility site indicates that there would be no impacts on the aquatic resources of the Hanford Site other than those changes resulting from natural processes and the impacts of ongoing Hanford operations and they would remain as described in Section 4.9.3.

5.9.1.4 Threatened and Endangered Species. No new SNF facilities would

be constructed and operated at Hanford. Thus, populations of species listed as endangered or threatened, or candidates for such listing by the federal and Washington State governments, or species listed as monitor species by the Washington State government would not be impacted (either directly by displacement or indirectly by habitat alteration) beyond effects resulting from ongoing Hanford operations and natural processes.

5.9.1.5 Radioecology. Releases of radionuclides to the environment are

expected to be on the order of those released in the recent past by site operations (Woodruff and Hanf 1993), and thus will not be accumulated into terrestrial or aquatic ecosystems in concentrations that could cause measurable impacts.

5.9.2 Decentralization Alternative

Implications of implementing the Decentralization Alternative for interim storage of SNF on terrestrial resources, wetlands, aquatic resources, and threatened and endangered species at the Hanford Site are discussed in the following subsections.

5.9.2.1 Terrestrial Resources. This alternative would require the

construction of an SNF facility for fuel management and storage. Most spent fuel from the Hanford Site would be stored here.

Construction of an SNF facility at Hanford would disturb up to 9 hectares (24 acres) on the 65 hectare (160 acres) site, representing about 0.01 percent of the total area of the Hanford Site. Approximately 9 hectares (24 acres) would be occupied by facilities, access roads, or rights-of-way and therefore, would remain developed for the life of the project. The remaining land would be revegetated with native grasses and shrubs upon completion of construction.

Vegetation within construction areas would be destroyed during land-clearing activities. Plant species that are dominant on the Hanford SNF site, and thus would be most affected, include big sagebrush, cheatgrass, and Sandberg's bluegrass. Total area destroyed would amount to about less than 1 percent of this community on the Hanford Site. Although the plant communities to be disturbed are well-represented on the Hanford Site, they are relatively uncommon regionally because of the widespread conversion of shrub-steppe habitats to agriculture. Disturbed areas are generally recolonized by cheatgrass, a nonnative species, at the expense of native plants. Mitigation of these impacts could include minimizing the area of disturbance and revegetating with native species, including shrubs, and establishing a 2:1 acreage replacement habitat in concert with a habitat enhancement plan presently being developed for the Hanford Site in general. Adverse impacts to vegetation on Hanford are expected to be limited to the project area and vicinity and are not expected to affect the viability of any plant populations on the Hanford Site.

Construction of an SNF facility and support facilities would have some adverse affect on animal populations. Less mobile animals such as invertebrates, reptiles, and small mammals within the project area would be destroyed during land-clearing activities. Larger mammals and birds in construction and adjacent areas would be disturbed by construction activities and would move to adjacent suitable habitat, and these individual animals might not survive and reproduce. Project facilities would displace about 9 hectares (up to 24 acres) of animal habitat for the life of an SNF facility. Revegetated areas (e.g., construction laydown areas and buried pipeline routes) would be reinvaded by animal species from surrounding, undisturbed habitats. The adverse impacts of construction are expected to be limited to the project area and vicinity and should not affect the viability of any animal populations on the Hanford Site because similar suitable habitat would remain abundant on the site.

Very small quantities of radionuclides would be released to the atmosphere during SNF facility operations. No organisms studied to date are reported to be more sensitive than man to radiation (NRC-8). Therefore, as concluded for humans, the effects of these releases on terrestrial organisms are expected to be minor.

These impacts to the vegetation and animal communities could be mitigated by minimizing the amount of land disturbed during construction, employing soil erosion control measures during construction activities, and revegetating disturbed areas with native species. These measures would limit the amount of direct and indirect disturbance to the construction area and surrounding habitats and would speed the recovery process for disturbed lands.

Operational impacts to terrestrial biotic resources would include exposure of plants and animals to small amounts of radionuclides released during operation of the SNF facility. The levels of radionuclide exposure would be below those levels that produce adverse effects.

5.9.2.2 Wetlands. No wetlands occur on or near the SNF facility site,

so no impacts from the construction and operation of the facility to wetlands would occur. Wetlands resources on the Hanford Site would remain as described in Section 4.9.2. No mitigation efforts would be required because no wetlands would be affected.

5.9.2.3 Aquatic Resources. No aquatic habitats occur on the SNF site;

thus, no impacts to aquatic resources are expected from the construction and operation of the SNF facility. No mitigation efforts would be required because no impacts are anticipated to aquatic resources.

5.9.2.4 Threatened and Endangered Species. Construction and operation

of the SNF facility would remove approximately 9 hectares (24 acres) of relatively pristine big sagebrush/ cheatgrass-Sandberg's bluegrass habitat. This sagebrush habitat is considered priority habitat by the State of Washington because of its relative scarcity in the state and its use as nesting/ breeding habitat by loggerhead shrikes, sage sparrows, sage thrashers, burrowing owls, pygmy rabbits, and sagebrush voles. Bald Eagles, peregrine falcons, and Oregon silverspot butterflies do not inhabit the potential proposed site.

Loggerhead shrikes, listed as a federal candidate (Category 2) and state candidate species, forage on the proposed SNF site and are relatively common on Hanford. This species is sagebrush-dependent, as it is known to select primarily tall big sagebrush as nest sites. Construction of the SNF facility would remove big sagebrush habitat which would preclude loggerhead shrikes from nesting there. SNF site development would also be expected to reduce the value of the site as foraging habitat for shrikes known to nest in adjacent areas.

Sage sparrows and sage thrashers, both state candidate species, occur in mature sagebrush/ bunchgrass habitat at Hanford. Sage thrashers were not observed on the SNF site, and are extremely rare on the Hanford Site. These species are known to nest primarily in sagebrush. Construction of the SNF facility would preclude both of these species nesting there and reduce the site's suitability as foraging habitat for these species.

SNF construction is not expected to substantially decrease the Hanford population of loggerhead shrike, sage sparrow, or sage thrashers because similar sagebrush habitat is still relatively common on the Hanford Site. However, the cumulative effects of constructing the SNF facility, in addition to future developments that further reduce sagebrush habitat (causing further fragmentation of nesting habitat), could negatively affect the long-term viability of populations of these species on the Hanford Site.

Burrowing owls, a state candidate species, are relatively common on the Hanford Site and nest in abandoned ground squirrel burrows on the proposed SNF site. SNF construction would remove sagebrush and disturb soil, displacing ground squirrels and thus reducing the suitability of the area for nesting by burrowing owls. Construction would also displace small mammals, which constitute a portion of the prey base for this species. Construction for an SNF facility would, however, not be expected to negatively impact the viability of the population of burrowing owls on Hanford, as their use of ground squirrel burrows as nests is not limited to burrows in big sagebrush habitat.

Pygmy rabbits, a federal candidate (Category 2) and state threatened species, are known to utilize tall clumps of big sagebrush habitat throughout most of their range. However, this species has not recently been observed on the Hanford Site. Construction of the SNF facility would therefore reduce the potential for recolonization by this species by removing habitat suitable for its use.

Sagebrush voles, a state monitor species, are common on the Hanford Site and select burrow sites near sagebrush; however, this species is common only at higher elevations around the Hanford Site. Construction of the SNF facility would remove sagebrush habitat, precluding sagebrush voles from utilizing the site. However, construction would not affect the overall viability of sagebrush vole populations on the Hanford Site because the majority of the population is found on the Fitzner/Eberhardt Arid Lands Ecology Preserve.

The closest known nests of ferruginous hawks, a federal candidate (Category 2) and state threatened species, and Swainson's hawk, a state candidate, are 8.5 km (5 mi) and 6.2 km (3.7 mi), respectively, from the proposed SNF site. The SNF site comprises a portion of the foraging range of these hawks. Construction of the SNF facility is not expected to disrupt the nesting activities of these species. However, construction would displace small mammal populations and thus reduce the prey for these birds. The cumulative effects of constructing the SNF facility, in addition to future reductions in sagebrush habitat (causing further fragmentation of foraging habitat), could negatively affect the long-term viability of populations of these two species on Hanford.

5.9.2.5 Radioecology. Releases of radionuclides to the environment are

expected to be below those currently released by site operations (Woodruff and Hanf 1993), and thus will not be accumulated into terrestrial or aquatic ecosystems in concentrations that could cause measurable impacts.

5.9.3 1992/1993 Planning Basis Alternative

The 1992/1993 Planning Basis Alternative differs from the Decentralization Alternative only in that TRIGA fuel currently stored at the Hanford Site would be shipped to INEL for storage. (It is possible that the TRIGA fuel may be transferred to third parties for beneficial use prior to the planned time of shipment to INEL.) Thus, impacts on terrestrial resources, wetlands, aquatic resources, threatened and endangered species, and radioecology at the Hanford Site would be essentially the same as described for the Decentralization Alternative.

5.9.4 Regionalization Alternative

All new facilities would be constructed on the 65 hectare (163-acre) site west of 200-East Area (Figure 4.1). Although impacts on terrestrial resources are expected to be minimal, the impacts that would occur would be roughly proportional to the amount of land that would be disturbed during construction. For the various options of the Regionalization Alternative, those areas would amount to the following amounts of land:

A) From about 2 to 7 hectares (5 to 18 acres) when all SNF except defense production SNF would be sent to INEL.

B1) From about 15 to 17 hectares (38 to 43 acres) when all SNF west of the Mississippi River except Naval SNF would be sent to Hanford.

B2) From about 25 to 28 hectares (63 to 70 acres) when all SNF west of the Mississippi River and Naval SNF would be sent to Hanford.

C) From about 2 to 5 hectares (5 to 12 acres) when all Hanford SNF would be sent to INEL or NTS.

While the largest area cited above (28 hectares) is about three times the size of the area to be disturbed in the Decentralization Alternative, it is still a very small fraction of similar habitat on the Hanford Site. By and large the discussion on flora and fauna presented in Section 5.9.2 applies to the Regionalization Alternative, bearing in mind that the area involved would be more or less depending on the option chosen.

5.9.5 Centralization Alternative

If Hanford is selected as the site for the Centralization Alternative, an SNF facility, as substantially described in the Decentralization Alternative, would be constructed at Hanford. Although the facility would store about 25 weight percent more SNF than would be stored under the Decentralization Alternative and the number of casks would increase the required space, the ecological impacts would be essentially the same as those described in Section 5.9.2.

If Hanford is not selected as the site for the Centralization Alternative, an SNF packaging facility would be built to prepare the fuel for shipment offsite. While that facility would not be as extensive as the SNF facility, the ecological impacts would not likely be importantly different from those described in Section 5.9.3 for the Decentralization Alternative.

5.10 Noise

Implications of implementing the alternatives for interim storage of SNF on noise levels at the Hanford are discussed in the following subsections.

5.10.1 No Action Alternative

Under this alternative, new SNF facilities would not be constructed, and the noise associated with SNF facility construction and operation activities would not occur. Because no major changes in existing noise-emitting sources are expected at Hanford during the projected SNF facility construction period, the ambient noise levels at Hanford would be expected to remain essentially the same for the no-action alternative as during the baseline period.

5.10.2 Decentralization Alternative

This alternative would require the construction and operation of an SNF facility for fuel management and storage. Most spent fuel from the Hanford Site would be stored here. The results of a detailed analysis of the potential noise impacts from constructing and operating a new production reactor (project since cancelled) and its support facilities at Hanford have been published. The analysis indicates that noise from constructing a facility the size of a production reactor, and from operational facilities, equipment, and machines, would not cause ambient noise levels to exceed the limits set by the Washington State noise control regulations or EPA guidelines. The latter are set to protect the public from the effect of broadband environmental noise and to protect the public against hearing loss. The results also indicate that increases in noise levels from constructing and operating a facility the size of a production reactor and its support facilities, including increased traffic along the major roadways, would result in little or no increase in the annoyance level experienced by communities or individuals.

No significant noise impacts from activities associated with SNF facility construction and operation are expected at sensitive receptor locations outside the Hanford boundary or at residences along the major highways leading to the proposed SNF site at Hanford.

5.10.3 1992/1993 Planning Basis Alternative

The 1992/1993 Planning Basis Alternative differs from the Decentralization Alternative only in that TRIGA fuel currently stored at the Hanford Site would be shipped to INEL for storage. (It is possible that the TRIGA fuel may be transferred to third parties for beneficial use prior to the planned time of shipment to INEL.) Thus, impacts would be essentially the same as described for the Decentralization Alternative.

5.10.4 Regionalization Alternative

All new facilities would be constructed on the 65 hectare (163-acre) site west of 200-East Area (Figure 4.1). Although noise is not expected to be a factor in evaluating the alternatives, the amount and duration of noise associated with construction would be roughly proportional to the amount of land that would be disturbed during construction. For the various options of the Regionalization Alternative, those areas would amount to the following amounts of land:

A) From about 2 to 7 hectares (5 to 18 acres) when all SNF except defense production SNF would be sent to INEL.

B1) From about 15 to 17 hectares (38 to 43 acres) when all SNF west of the Mississippi River except Naval SNF would be sent to Hanford.

B2) From about 25 to 28 hectares (63 to 70 acres) when all SNF west of the Mississippi River and Naval SNF would be sent to Hanford.

C) From About 2 to 5 hectares (5 to 13 acres) when all Hanford SNF would be sent to INEL or NTS.

Although not likely to be heard offsite, the duration of noise that is generated would range from about a quarter to three times that described for the Decentralization Alternative depending on the Regionalization option chosen.

5.10.5 Centralization Alternative

If Hanford is selected as the site for centralization of SNF, new SNF facilities would be constructed at Hanford. Although somewhat larger than for the Decentralization Alternative, the impacts from noise would be the same as those described in Subsection 5.10.2.

5.11 Traffic and Transportation

The implications of implementing the alternatives for interim storage of SNF on traffic and incident-free onsite transportation of SNF and materials supporting SNF storage at the Hanford are discussed in the following subsections. The impacts of offsite transportation of SNF are discussed in

Appendix I.

5.11.1 No Action Alternative

Implications of implementing the No Action Alternative for interim storage of SNF on traffic and incident-free onsite transportation of SNF and materials supporting SNF storage are discussed in the following subsections.

5.11.1.1 Traffic. Under the No Action Alternative, the number of

workers would stay the same as under present conditions; therefore, there would be no change in traffic patterns. At present, there are periods of moderate traffic congestion, some of which is expected to be alleviated by a new road to the 200 areas.

5.11.1.2 Transportation. The RISKIND (Yuan et al. 1993) and RADTRAN 4

(Neuhauser and Kanipe 1992) computer codes were applied to calculate the radiation doses to transport workers and the public that are estimated to result from incident-free onsite transportation of SNF. RISKIND was also used to calculate the consequences of bounding transportation accidents. All of the onsite SNF shipments were assumed to emit radiation that would result in a dose rate at the regulatory limit (i.e., 0.01 rem per hour at 2 meters (6 feet) from the external surface of the shipments). This assumption contributes to the conservatism of the analysis because the shipment dose rates cannot be larger than this value but frequently will be substantially smaller. All shipments were assumed to be made by truck. A detailed description of the approach and other important shipment-related parameters are discussed in Volume 2, Chapter 5, and Appendix I. Hanford-specific information and input parameters are presented in this section.

The doses per incident-free shipment of each type of SNF were calculated using RISKIND and RADTRAN 4. The potential receptors considered are the transportation crew of two, on-link (on the road) and off-link (persons near the roadway) populations. Guards and/or inspectors may also be exposed to the shipments. Guards and inspectors may be exposed when they prepare a shipment to leave its origin facility or prepare to receive a shipment that has arrived at a destination facility. Guards and inspectors may also be exposed while the shipment is enroute between facilities. Guard and inspector doses at origin and destination facilities are included in the doses calculated in Section 5.13. Most onsite shipments originate in the 200 and 100 Areas and will not travel through a guarded checkpoint. The guard/inspector doses for these shipments are zero. Only the miscellaneous fuel shipments originating in the 300 Area and the FFTF shipments originating in the 400 Area will travel past a guarded checkpoint (see Wye Barricade in Section 4.11). Doses to the guards at the Wye Barricade were calculated assuming they were exposed briefly at a distance of 5 meters, (16 feet) from the shipment, as described in Volume 2, Chapter 5. The computer code RISKIND was used to calculate maximum and individual doses; RADTRAN 4 was used to calculate collective population doses.

Five general classes of SNF were considered in this analysis. These include N Reactor fuel, FFTF fuel, single-pass reactor (SPR) fuel, PWR Core-II fuel, and miscellaneous fuel. A sixth type of fuel, fuel wastes in EBR-II metal casks, was assumed to have similar shipping characteristics to miscellaneous fuels. Some of the key shipment characteristics for these fuels are presented in Table 5.11-1, including the SNF material forms, quantities, shipment capacities, and numbers of shipments. Radionuclide inventories for the various types of fuel shipments are provided in Table 5.11-2. The radionuclide inventories were derived from the irradiated fuel inventories and characteristics provided by Bergsman (1994, 1995) and the shipment characteristics listed in Table 5.11-2.

The population densities of the different areas of the Hanford Site across which shipments must travel will influence the transportation impacts. Doses to persons along the highways (i.e., off-link doses) will be received only by Hanford Site workers for onsite shipments.

Table 5.11-1. Spent nuclear fuel shipment characteristics.

Fuel Type	Material Form	Quantity, Assemblies	Shipment Capacity, Assemblies/shipment	Number of Shipmentsa

N Reactor	Uranium metal clad with Zircalloy-2	Short: 66,300 Long: 63,700	Short: 128 Long: 96	Short: 518 Long: 664 Total: 1,182
FFTF	Mixed uranium-plutonium oxide in stainless steel tubes	317	4	80
Single-pass reactor	Uranium metal enclosed in aluminum jackets	1,100	900	2
PWR Core-II	Natural uranium oxide clad in zirconium alloy	72	1	71
Fuel wastes in EBR-II metal casks	Plutonium-uranium compounds sealed in stainless steel canisters	24 casks	1 cask per shipment	24
Miscellaneous	Various uranium compounds from research and development programs	77	4	20

a. This column provides the number of onsite shipments projected to occur in the Decentralization, 1992/1993 Planning Basis, Regionalization, and Centralization Alternatives. For the No-Action Alternative, one shipment of N Reactor fuel currently at PUREX and all of the miscellaneous fuels were assumed to be transported onsite.

a. Radionuclide inventory data were derived from information in Bergsman (1994) and WHC (1993c).

b. For radionuclides that are indicated to have 0.0 Ci per shipment, the quantities of fission and activation are less than 5 Ci/assembly and less than 10 g/assembly for actinides. Radionuclides not listed on the table are also less than these quantities.

c. Fuel inventories for EBR-II casks are assumed to be applicable to miscellaneous fuels. The SNF in EBR-II casks and miscellaneous SNF consist primarily of irradiated light-water reactor fuels.

The population densities for each work area on the site, used for occupational dose calculations, are listed in Table 5.11-3. The off-link doses are included in the occupational dose results.

For the calculation of doses to persons traveling on the highways (i.e., on-link doses), two-lane highways were assumed and the number of persons per vehicle was assumed to be 2.0. No vehicle stops were included in the calculations because the shipments are not long enough to warrant intermediate stops for food and rest. One-way traffic densities were based on traffic counts provided in DOE (1989). Because average traffic densities were not available in that document and there are no administrative restrictions on time of day when SNF transport could occur, the peak count on a given route segment (vehicles per day) was used to calculate the traffic density for that route. The traffic densities used for the five types of SNF and shipping distances for the various fuel types are provided below.

- FFTF Fuel - 640 vehicles per hour; 28 kilometers one-way shipping distance
- N Reactor Fuel - 170 vehicles per hour; 16 kilometers one-way shipping distance
- PWR Core II Fuel - 180 vehicles per hour; 5 kilometers one-way shipping distance
- Single-pass Reactor Fuel - 100 vehicles per hour; 16 kilometers one-way shipping distance
- EBR-II/300 Area Miscellaneous Fuel - 640 vehicles per hour; 37 kilometers one-way shipping distance.

Table 5.11-3. Population densities for work areas at Hanford.

Work Area	Worker Population	Land Area, km2	Worker Density, per km2
100 B and C	4	1.7	3
100 D and DR	4	1.5	3
100 H	4	0.7	6
100 K	124	0.9	140
100 N	360	1.0	360
200 West	1968	9.5	210
200 East	2923	9.0	330
300	2487	1.5	1700
400	638	2.1	300
600	514	1450	0.35
WPPSS	1125	4.4	260

The computer code RISKIND was used to calculate the doses to Maximally-Exposed Individual (MEI) members of the public as discussed in Volume 2, Chapter 5. Two exposure scenarios were modeled, including a "tailgater" and a "bystander." The dose received by a tailgater was calculated by assuming that an individual precedes or follows an SNF shipment for the entire duration of a shipment. The exposure distance was assumed to be 48.8 meters (160 feet). The dose calculated in Volume 2, Chapter 5, was based on a 37 kilometers (23 miles) shipping distance, which is also the same as the longest shipping distance anticipated for SNF shipments at Hanford (300 Area to the 200 Area). Therefore, the public MEI dose amounts to 0.015 millirem per tailgating incident.

The dose to a "bystander" was calculated in Volume 2, Chapter 5, to be 0.0014 millirem. This dose was calculated assuming a shipment passes by an individual at an average speed of 56 kilometers per hour (35 miles per hour) at a distance of 1 meter (3 feet) from the shipment. This individual was postulated to be standing on the side of the road as an SNF shipment passes by and was assumed to be exposed only one time.

The dose to the maximally-exposed worker from incident-free transportation will be received by the truck crew. The dose to the truck crew was calculated using the maximum allowable dose rate in the truck cab (2 millirem per hour) for all shipments. It was assumed that the maximum-exposed worker will accompany all of the spent fuel shipments, even though the dose will most likely be apportioned over a larger number of workers. The total dose received by this individual was calculated by multiplying the maximum dose rate by the total shipping time. The total shipping time for the various alternatives was determined by dividing their total shipping distances by the average speed, 56 kilometers per hour (35 miles/hour).

The results of the analysis of the No Action Alternative are presented in Table 5.11-4. As shown, two shipment campaigns occur in this alternative; 1) shipment of N Reactor fuels at PUREX to the 105-K basins for storage and 2) shipment of miscellaneous SNF in the 300 Area to the 200 Area to be placed in dry storage. The total radiological impacts from incident-free transportation in this alternative are dominated by the shipments of miscellaneous fuels from the 300 Area to the 200 Area. This is primarily because there are approximately 24 shipments of miscellaneous fuels, and the N Reactor fuel at PUREX will make up only a fraction of a shipment.

Table 5.11-4. Impacts of incident-free transportation for the No Action Alternative.

Impacts[b]	General Population[c]	Occupational
Total Dose (person-rem)	7.8E-02	1.2E-01
Cancer Fatalities	3.9E-05	4.7E-05

a. The N Reactor fuel currently at PUREX is the only N Reactor fuel transported in this alternative. The impacts of transporting this fuel were calculated by adjusting the impacts of transporting all N Reactor fuel (0.3 MTHM at PUREX/2096 MTHM total N Reactor fuel).

b. Total detriment, which includes latent cancer fatalities, nonfatal cancers, and genetic effects in subsequent generations, can be calculated by multiplying the total dose to the general population by 7.3E-04 effects per person-rem and the total occupational dose by 5.6E-04 effects per person-rem.

c. Rural population density.

The doses to the maximally-exposed workers and members of the public are summarized below:

- The dose to a tailgater was calculated to be 0.015 millirem.
- The dose to a bystander was calculated to be 0.0014 millirem.
- The dose to a truck crewman that accompanies all of the spent fuel shipments in the No Action Alternative was calculated to be about 46 millirem.

The RISKIND computer code was used to calculate the radiological consequences of accidental releases of radioactive material during transportation. Consequences of severe, reasonably foreseeable accidents were calculated to workers and the offsite population. Workers were placed at a distance that maximizes the dose from a potential release. Hanford-specific population density data (see Beck et al. 1991) were used to assess the integrated doses to the offsite public, as described in Volume 2, Chapter 5.

As discussed in Appendix I, maximum radiological impacts were calculated for a severe, reasonably foreseeable accident. For this assessment, the consequences were assessed to populations and individuals assuming the most severe accident scenario with a probability greater than 1E-07. The methods and data described in Appendix I were used to calculate the accident probabilities of the various shipments in the No Action Alternative. Hanford-specific numbers of shipments and shipping distances were used in the calculations. Accident rate information from Saricks and Kvitek (1991) for urban areas in the State of Washington were used in the calculations. The results of these calculations indicate that the probabilities of the severe accident defined in Appendix I for the irradiated fuels transported in the No Action Alternative are less than the 1E-07 criteria. The most likely severe accident scenario was determined to be one involving shipments of miscellaneous fuels from the 300 Area. The probability of such an accident was calculated to be about 1E-09. As shown in Table 5.11-5, this is also the highest-consequence accident scenario for the No Action Alternative.

The impacts of potential severe transportation accidents for the No Action Alternative are shown in Table 5.11-5. The maximum exposed individual and public collective doses are shown in Table 5.11-5 for shipments of miscellaneous SNF in the 300 Area to dry storage in the 200 Area. This was determined to be the most severe reasonably foreseeable onsite transportation accident scenario for the No Action Alternative, even though its probability is significantly smaller than 1E-07, as discussed above. As shown, consequence estimates are presented for two atmospheric dispersion conditions; 1) neutral (Pasquill stability class D, wind speed = 4 meters per second) and 2) stable (Pasquill stability class F , wind speed = 1 meters per second).16

Table 5.11-5. Impacts of accidents during transportation for the No Action Alternative.

Dose Consequence

Cancer Fatalities

Point Estimate of Risk

Exposure Group

Stability Category

Stability Category

Stability Category

	D	F	D	F	D	F
Offsite Population[b]	1.4E+01 person-rem	1.1E+02 person-rem	6.8E-03	5.5E-02	6.8E-12	5.5E-11
Maximum Exposed Individual	5.0E-01 rem	1.7E+00 rem	2.0E-04	6.7E-04	2.0E-13	6.7E-13

a. The maximum-consequence onsite transportation accident for the No Action Alternative is one involving a shipment of miscellaneous fuels currently located in the 300 Area. This is also the most likely accident scenario, but its probability is below the 1E-07 criteria for a maximum reasonably foreseeable accident.

b. Rural population density.

Nonradiological impacts consist of fatalities that may result from traffic accidents as well as health effects from pollutants emitted from vehicles involved in onsite shipments of spent nuclear fuel. These risks are unrelated to the radioactive nature of the materials being transported. Nonradiological impacts from accidents were calculated using unit risk factors derived by Saricks and Kvitek (1991) that convey the estimated number of fatalities per unit distance traveled. The total nonradiological impacts are calculated by multiplying the total shipping distance traveled by onsite shipments by the appropriate unit risk factors.

The total nonradiological transportation impacts for the No Action Alternative were calculated to be less than one (1.9E-05) fatality.

5.11.2 Decentralization Alternative

Implications of implementing the Decentralization Alternative for interim storage of SNF on traffic and incident-free onsite transportation of SNF and materials supporting SNF storage are discussed in the following subsections.

5.11.2.1 Traffic. Under the Decentralization Alternative, the number of construction workers would range from about 220 to 870. During operations, the number of workers would range from about 1100 to 1300, depending on the option selected. This would add from 1 to 6 percent to the present workforce and to additional commuting traffic on the Hanford Site, assuming that the proportion of workers that take the bus to work or drive their own vehicles remains essentially constant.

5.11.2.2 Transportation. The same approaches and basic assumptions and data described in Section 5.11.1.2 for the No Action Alternative were used to assess the impacts of onsite transportation for the Decentralization Alternative. The key differences between the alternatives are the numbers of shipments and destinations. More SNF is transported in this alternative than in the No Action Alternative. In this alternative, all N Reactor SNF in the 105-K Basins is to be transported to the 200 Area for processing and/or storage, depending upon the particular suboption selected. The FFTF fuel is to be transported from the 400 Area to the 200 Area for storage. The PWR Core-II, single- pass reactor fuels, and 300 Area miscellaneous fuels are also to be transported to a new facility in the 200 Area for storage.

Table 5.11-6 presents the incident-free transportation impacts for the Decentralization Alternative. As shown in Table 5.11-6, the truck crews are the largest exposure group. The total doses were found to be dominated by the exposures received during transportation of N Reactor fuel. This is because there are significantly more truck shipments of N Reactor fuel in this alternative than shipments of other types of fuel.

The doses to the maximally-exposed workers and members of the public are summarized below:

- The dose to a tailgater was calculated to be 0.015 millirem.

- The dose to a bystander was calculated to be 0.0014 millirem.

- The dose to a truck crewman that accompanies all of the spent fuel shipments in the Decentralization Alternative was calculated to be about 800 millirem.

The worker MEI dose is higher than that calculated for the No Action Alternative because there are many more onsite spent fuel shipments in the Decentralization Alternative.

Table 5.11-7 presents the impacts of potential severe transportation accidents for the Decentralization Alternative. The maximum exposed individual and public collective doses are shown in Table 5.11-7 for two accident scenarios: the highest probability and highest consquence. As explained in the table footnotes, the probabilities of both scenarios are less than MEI 1E-07 criteria discussed in Appendix I. As shown, consequence estimates are presented for two atmospheric dispersion conditions; 1) neutral (Pasquill stability class D, wind speed = 4 meters per second) and 2) stable (Pasquill stability class F , wind speed = 1 meters per second). This table is different from Table 5.11-5 (No Action Alternative) because of the additional fuel types transported in the Decentralization Alternative.

Table 5.11-6. Impacts of incident-free transportation for the Decentralization Alternative.

Impacts[a]	General Population[b]	Occupational
Total Dose (person-rem)	4.3E-01	1.7E+00
Cancer Fatalities	2.2E-04	6.8E-04

a. Total detriment, which includes latent cancer fatalities, non-fatal cancers, and genetic effects in subsequent generations, can be calculated by multiplying the total dose to the general population by 7.3E-04 effects per person-rem and the total occupational dose by 5.6E-04 effects per person-rem.
b. Rural population density.

Table 5.11-7. Impacts of accidents during transportation for the Decentralization Alternative.

Accident Scenario	Exposure Group	Dose Consequence		Cancer Fatalities		Point Estimate of Risk	
		Stability Category		Stability Category		Stability Category	
		D	F	D	F	D	F
Highest Probability[a]	Offsite Population[b]	1.7E+01 Person-rem	1.4E+02 Person-rem	8.6E-03	6.8E-02	4.3E-10	3.4E-09
	Maximum Exposed Individual	7.2E-01 Rem	2.4E+00 Rem	2.9E-04	9.6E-04	1.4E-11	4.8E-11
Highest Consequence[c]	Offsite Population	1.7E+02 Person-rem	1.3E+03 Person-rem	8.4E-02	6.7E-01	5.0E-10	4.0E-09
	Maximum Exposed Individual	5.4E+00 Rem	1.8E+01 Rem	2.2E-03	7.2E-03	1.3E-11	4.3E-11

a. The highest-probability accident is one involving a shipment of N Reactor fuel. The probability of this accident scenario was calculated to be approximately 5E-8 over the entire N-Reactor fuel shipping campaign.
b. Rural population density.
c. The highest-consequence accident scenario was determined to be one involving shipments of FFTF fuel. However, the probability of the accident scenario analyzed here is approximately 6E-09, which is below the 1E-07 probability criteria for a reasonably foreseeable accident.

The total nonradiological transportation impacts for the Decentralization Alternative were calculated to be 6.6E-04 fatalities. The nonradiological transportation impacts of this alternative are significantly higher than the impacts of the No Action Alternative because the numbers of shipments, and thus total shipment mileage, is significantly higher.

5.11.3 1992/1993 Planning Basis Alternative

Implications of implementing the 1992/1993 Planning Basis Alternative for interim storage of SNF on traffic and incident-free onsite transportation of SNF and materials supporting SNF storage are discussed in the following subsections.

5.11.3.1 Traffic. Because the only difference between the

Decentralization Alternative and the 1992/1993 Planning Basis Alternative is the shipment of the small amount of TRIGA fuel offsite, traffic patterns would not be significantly different from those described for the Decentralization Alternative.

5.11.3.2 Transportation. The impacts of onsite transportation for the

1992/1993 Planning Basis Alternative are substantially the same as the impacts of the Decentralization Alternative (see Section 5.11.2). The only difference between these two alternatives is the disposition of the TRIGA fuel in the 308 Building. The quantity and number of TRIGA fuel shipments is small relative to the other fuel types so the disposition of the TRIGA fuels will have a negligible impact on the results presented in Tables 5.11-3 and 5.11-4.

5.11.4 Regionalization Alternative

Implications of implementing the Regionalization Alternative for interim storage of SNF on traffic and incident-free onsite transportation of SNF and materials supporting SNF storage are presented in this section. The onsite transportation requirements for the four Regionalization Alternative options are as follows:

- Option A - Defense production fuel will be shipped from the 105-K basins and Plutonium and Uranium Recovery through Extraction to a new facility in the 200 Area for storage. All other fuel will be shipped offsite; the transportation impacts of offsite shipments are addressed in Appendix I.

- Option B1 - All SNF located or to be generated west of the Mississippi River will be sent to Hanford for storage, except for Naval SNF. Shipments of SNF from offsite locations are addressed in Appendix I. The onsite SNF will be transported from its current locations to the 200 Area for storage. In terms of onsite transportation impacts, this option is essentially the same as the Decentralization Alternative (see Section 5.11.2).
    - Option B2 - The same as Option B1 except that Naval SNF will also be transported to Hanford. This alternative would result in the same onsite transportation impacts as Option B1.

- Option C - All Hanford SNF will be transported offsite to a facility at INEL or NTS. Offsite transportation impacts are addressed in Appendix I.

5.11.4.1 Traffic. Under the Regionalization Option A, the number of

construction workers would range from about 180 to 1200, depending on the option selected. During operations, the number of workers would range from about 280 to 320, depending on the suboption selected. This would add from less than 1 to about 5 percent to the present workforce and to additional commuting traffic on the Hanford Site, assuming that the proportion of workers that take the bus to work or drive their own vehicles remains essentially constant. Assuming that all of the N Reactor fuel shipments travel 16 kilometers (10 miles) one way (approximate distance from the 100 Areas to the 200 Area), a total of about 40,000 vehicle-kilometers are needed for the N Reactor fuel shipments in this option. It was stated in Section 4.11 that in 1988 DOE vehicles logged over 19,000,000 vehicle-kilometers (12,000,000 vehicle-miles) at Hanford. The increase in vehicle mileage resulting from the Regionalization Option A, assuming that all the Hanford SNF shipments will be made in one year, is less than 1 percent above the 1988 base DOE-vehicle mileage.

For the Regionalization options B1 and B2, the impacts on traffic would be essentially the same as those described for the Decentralization Alternative (see Section 5.11.2.1).

The Regionalization Option C involves offsite shipments of Hanford fuel. The number of Hanford workers would stay approximately the same as the No Action Alternative. The impacts on traffic are predominantly related to the additional vehicles on the highways that are carrying Hanford fuels to INEL or NTS. Assuming that all of the onsite Hanford fuel shipments travel 48 kilometers (30 miles) one way (approximate distance from the 100 Areas to the 300 Area), a total of about 130,000 vehicle-miles are needed for the onsite segments of these shipments. It was stated in Section 4.11 that in 1988 DOE vehicles logged over 12,000,000 miles at Hanford. The increase in vehicle mileage resulting from Regionalization Option C, assuming that all the Hanford fuel shipments will be made in one year, is about 1 percent above the 1988 base DOE-vehicle mileage.

5.11.4.2 Transportation. In Regionalization Option A, all N Reactor

SNF in the 105-K basins and at PUREX would be transported to the 200 Area for processing and/or storage, depending on the particular suboption selected. The FFTF, PWR Core-II, single-pass reactor fuels, and 300 Area miscellaneous fuels are to be transported to INEL. Offsite transportation impacts are addressed in Appendix I. Onsite transportation impacts for this option, therefore, would consist of the impacts of transporting N Reactor fuel from the 105-K basins and PUREX to the 200 Area.

The transportation impacts of this option were calculated by determining the impacts of transporting N Reactor fuel on a per-shipment basis and then multiplying the total number of shipments. The methods and input data described in Section 5.11.1 were used to calculate the per-shipment impacts. The results of the transportation impact calculations for the Regionalization Option A are as follows:

- Incident-free transportation impacts: Public exposures - 2.4E-01 person-rem (9.6E-05 LCFs); Worker exposures - 1.4E+00 person-rem (5.6E-04 LCFs).

- Impacts of transportation accidents: Public, Pasquill Stability Class D - 1.7E+01 person-rem (8.6E-03 LCFs); Public - Pasquill Stability Class F - 1.4E+02 person-rem (6.8E-02 LCFs). Maximum exposed individual, Pasquill Stability Class D - 7.2E-01 rem (2.9E-04 LCFs); Maximum exposed individual Pasquill Stability Class F - 2.9E+00 rem (9.6E-04 LCFs). See the "highest probability" accident in Table 5.11-7.

- Nonradiological impacts: 5.6E-04 fatalities.

The incident-free doses to the maximally-exposed workers and members of the public are summarized below:

- The dose to a tailgater was calculated to be 0.015 millirem.

- The dose to a bystander was calculated to be 0.0014 millirem.

- The dose to a truck crewman who accompanies all of the SNF shipments in Regionalization Option A was calculated to be about 680 millirem.

The worker MEI dose is higher than that calculated for the No Action Alternative because there are many more onsite spent fuel shipments in the Regionalization Option A. The worker MEI dose is lower than that calculated for the Decentralization Alternative because only N Reactor fuel is shipped onsite in Regionalization Option A, and all fuel types are shipped onsite in the Decentralization Alternative.

In Regionalization options B1 and B2, all Hanford SNF would be shipped onsite from its current locations to the 200 Area. Traffic and transportation impacts for both Regionalization options B1 and B2 would be essentially the same as those calculated for the Decentralization Alternative.

In Regionalization Option C, all of the Hanford Site SNF would be shipped to and stored at either INEL or NTS. Because all of the shipments of Hanford SNF would be considered to be offsite shipments, the impacts are addressed in Appendix I. For Hanford, this option is identical to the Centralization Alternative, minimum option.

5.11.5 Centralization Alternative

Implications of implementing the Centralization Alternative for interim storage of SNF on traffic and incident-free onsite transportation of SNF and materials supporting SNF storage are discussed in the following subsections.

5.11.5.1 Traffic. Traffic patterns would be essentially the same as

for the Decentralization Alternative if Hanford were selected to receive all DOE SNF. The patterns would last for up to twice as long because of the additional fuel to be brought to the reprocessing/ stabilization and storage facility (although there is only 25 weight percent more fuel to be shipped, it would likely require smaller quantities per shipment because of its higher heat load). If all Hanford fuel were to be shipped offsite, traffic patterns would not be significantly different from those of the No Action Alternative.

5.11.5.2 Transportation. The Centralization Alternative results in the

same onsite transportation impacts as the Decentralization Alternative. In the Decentralization Alternative, all Hanford Site SNF will be transported to the 200 Areas for further processing and/or storage, depending on the specific option. In the Centralization Alternative, all Hanford Site SNF is transported to either a stabilization/packaging facility in the 200 Area for preparation for offsite shipment or to the Central Storage Facility to be located in the 200 Area. All of these cases requires onsite shipment of Hanford SNF from their current locations to a 200 Area facility. Therefore, the onsite transportation impacts for the Centralization Alternative are the same as those for the Decentralization Alternative (see Section 5.11.2).

5.12 Occupational and Public Health and Safety

Implications of implementing the alternatives for interim storage of SNF on worker and public health and safety at the Hanford Site are discussed in the following subsections. By and large this material consists of summary material extracted from Section 5.7, "Air Quality and Related Consequences;" 5.8, "Water Quality and Related Consequences;" 5.11, "Traffic and Transportation;" and 5.15, "Accidents."

5.12.1 No Action Alternative

Radiological and nonradiological consequences relating to occupational and public health and safety for the No Action Alternative are presented in the following subsections.

5.12.1.1 Radiological Consequences. The consequences of air emissions

from routine operations of existing facilities utilized in the No Action Alternative include a maximum annual dose of 1E-5 rem to a potential onsite worker with a 5E-9 probability of fatal cancer. The collective annual dose to workers in spent fuel storage facilities is 24 person-rem per year (Bergsman 1995), which would require about 60 years of such operation to accumulate a collective worker dose from which one fatal cancer might be inferred.

The dose to an offsite resident at the highest exposure location is estimated as 3E-6 rem/year, and the corresponding probability of fatal cancer is 1E-9.

The peak collective dose to the population within 80 kilometers (50 miles) is 3E-2 person-rem per year, which is predicted to result in less than one fatal cancer (about 36,000 years of such operation would be required to reach a dose from which one fatal cancer might be inferred).

5.12.2 Decentralization Alternative

Radiological and nonradiological consequences relating to occupational and public health and safety for the Decentralization Alternative are presented in the following subsections.

**5.12.2.1 Radiological Consequences. The consequences of air emissions from individual facilities in the Decentralization Alternative are summarized in Table 5.7-8 and include a maximum annual dose of 2E-9 rem to a potential onsite worker (8E-13 probability of fatal cancer) for any combination of wet or dry spent fuel storage facilities. The dose to an offsite resident at the highest exposure location is estimated as 6E-10 rem per year, and the corresponding probability of fatal cancer is 3E-13. The peak collective dose to the population within 80 km is 2E-5 person-rem per year, which is predicted to result in less than one fatal cancer. The collective annual dose to workers at SNF facilities for a combination of wet and dry storage facilities is 2 person-rem per year for maintenance and operations. Loading the new facilities would require an additional 17-18 person-rem depending on the form of dry storage. For dry storage only, the dose from initial loading would be 7-12 person-rem, and there would be no dose from normal operations (Bergsman 1995).

For dry storage of defense fuel, stabilization prior to dry storage is included in the routine operations of the Decentralization Alternative, and additional emissions would result from these activities. The dose to the onsite worker from air emissions would increase by 4E-6 rem/year for a shear/leach/calcine process or 3E-5 rem/year for a solvent extraction process (2E-9 or 1E-8 probability of fatal cancer, respectively). Collective worker dose at fuel stabilization facilities would range from 44 person-rem per year at a shear/ leach/ calcine facility to 78 person-rem per year at a solvent extraction facility over the 4 years in which these facilities are expected to operate (Bergsman 1995). The dose to an individual worker in the facility is assumed to be limited by administrative controls to no more than 0.5 rem per year.

The consequences from stabilization for the offsite resident would be 7E-6 rem per year (4E-9 prob- ability of fatal cancer) for the shear/leach/ calcine facility and 2E-5 rem per year (1E-8 probability of fatal cancer) for the solvent extraction facility. The collective dose to the offsite population from the respective fuel stabilization facilities is estimated at 0.3 to 1 person-rem per year, resulting in less than one fatal cancer (would require from about 1000 to 3700 years of such exposure to reach a dose from which one fatal cancer might be inferred).

5.12.3 1992/1993 Planning Basis Alternative

Because the activities are similar, radiological consequences of routine operations for the 1992/1993 Planning Basis Alternative are considered to be the same as those for the Decentralization Alternative.

5.12.4 Regionalization Alternative

Radiological and nonradiological consequences relating to occupational and public health and safety for the Regionalization Alternative are presented in the following subsections.

5.12.4.1 Radiological Consequences. Because of the similarity of

activities, the radiological consequences of routine operations for the Regionalization Alternative Option A are considered to be the same as those for the Decentralization Alternative. The consequences to the public of options B and C are the same as described in the following section for the Centralization Maximum and Minimum options, respectively. Consequences to onsite workers would differ based on the processing and storage options for onsite fuel as in the decentralization alternative, as well as on the quantity of imported fuel to be received and placed into dry storage under each option. The consequences over the 40-year storage period range from 98 to 320 person-rem for option A, 700-920 person-rem for options B1 and B2, and 190-320 person-rem for option C. No fatal cancers would be expected as a result of implementing any of these options.

5.12.5 Centralization Alternative

Radiological and nonradiological consequences relating to occupational and public health and safety for the Centralization Alternative are presented in the following subsections.

5.12.5.1. Radiological consequences of air emissions from routine

operations in the Centralization Alternative include a maximum annual dose of 9E-9 rem to a potential onsite worker (4E-12 probability of fatal cancer) for any combination of wet or dry spent fuel storage facilities.

The collective

annual dose to SNF facility workers for a combination of wet and dry storage facilities is 2 person-rem per year for maintenance and operations. Loading the new facilities would require an additional 19-22 person-rem depending on the form of dry storage. For dry storage only, the dose from initial loading would be 9-12 person-rem, and there would be no dose from normal operations (Bergsman 1995). Shear/leach/calcine and solvent extraction activities would add 44 or 78 person-rem per year, respectively, and the receiving, canning, and technology development facilities would entail an additional 20 person-rem per year.

The dose from air emissions to an offsite resident at the highest exposure location is estimated as 2E-9 rem per year, and the corresponding probability of fatal cancer is 8E-13. The peak collective dose to the population within 80 kilometers (50 miles) is 7E-5 person-rem per year, which is predicted to result in less than one fatal cancer. These estimates do not include relocation of the expended core facility to Hanford, which is discussed in Appendix D to Volume 1 of this EIS. Assumptions used in the Appendix D calculations for consequences of locating an expended core facility at Hanford may differ from those used for other Hanford facilities.

5.13 Site Services

Implications of implementing the alternatives for interim storage of SNF on site services at the Hanford Site are discussed in the following subsections.

5.13.1 No Action Alternative

Implementing the No Action Alternative would require no significant additional consumption of material or energy; however, about 12,000 megawatt-hours per year are currently used for SNF management activities.

5.13.2 Decentralization Alternative

Incremental requirements for materials and energy in construction associated with the Decentralization Alternative are shown in Table 5.13-1. Annual consumption of energy during operations is similar to that used during construction for the water storage options (W and X), the total would be a small fraction of the present consumption rate. Annual consumption of energy during operations in the options where defense production fuel is stabilized is significantly greater; however it is still within the capacity of existing facilities.

Table 5-13-1. Materials and energy required for Decentralization suboptions.

Item	Option					
	W	X	Y	Z	P	Q
Concrete, thousand cubic meters/(cubic yards)	13 (17)	15 (20)	17 (23)	24 (32)	22 (29)	29 (38)
Carbon steel, thousand tonnes (tons)	2.4 (2.7)	2.8 (3.1)	3.3 (3.6)	4.5 (5.0)	3.9 (4.2)	5.1 (5.6)
Stainless steel, thousand tonnes (tons)	0.1 (0.1)	0.1 (0.1)	0	0	0.5 (0.6)	0.7 (0.8)
Copper, thousand tonnes (tons)	0	0	0	0	0.06 (0.07)	0.08 (0.09)
Lumber, thousand cubic meters (board feet)	1.2 (500)	1.4 (570)	1.6 (650)	2.2 (930)	2.0 (850)	2.6 (1100)
Asphalt, sand, and crushed rock, thousand cubic meters (thousand cubic yards)	0.6 (0.8)	0.7 (0.9)	0.8 (1.1)	1.2 (1.5)	1.1 (1.4)	1.4 (1.8)
Electricity						
Construction (MW-hrs)	2500	2900	3500	4800	4370	5700
Operations (MW-hrs/yr)	1600	1600	100	100	40,000a	127,000a
Diesel fuel, thousand cubic meters (thousand gallons)	0.5 (130)	0.6 (150)	0.7 (175)	0.9 (240)	0.8 (220)	1.1 (290)
Gasoline, thousand cubic meters (thousand gallons)	0.5 (130)	0.6 (150)	0.7 (175)	0.9 (240)	0.8 (220)	1.1 (290)
Construction Cost ($ Million)	265	280	350	310	580	835

a. Assumes operation of the process facility (28,000 or 115,000 MW-hrs/yr) concurrently with those facilities where SNF is currently stored (12,000 MW-hrs/yr, as in the No Action Alternative) for an interim period less than 4 years.

In the Decentralization Alternative, an extension of existing utilities to the project site area would likely be necessary. This would include water mains, electrical power lines, sewage facilities, telephone lines, etc. All of these utilities are available in the adjacent 200-East Area. In addition, an existing rail line might need to be upgraded for increased traffic, and construction of new spurs going to various proposed new facilities would likely be required. The project would be served by an 8-inch water main capable of delivering 7600 liters per minute (2000 gallons per minute). Facilities would be designed to preclude discharge of water except for sanitary waste.

5.13.3 1992/1993 Planning Basis Alternative

Energy requirements in the 1992/1993 Planning Basis Alternative would be essentially the same as those cited above for the Decentralization Alternative.

5.13.4 Regionalization Alternative

Material and energy requirements in the Regionalization Option A would be slightly less than those cited above for the Decentralization Alternative. Material and energy requirements in the Regionalization options would be similar to those cited above for the Decentralization Alternative, although the construction requirements would occur over most of the interim storage period. Incremental requirements for materials and energy in construction associated with the Regionalization options are shown in Tables 5.13-2 and

5.13-3. For the Regionalization options that involve fuel from other

locations being stored at the Hanford Site, the requirements shown are for fuel received from other locations and are in addition to those shown in **Table 5.13-1 for fuel already at the Hanford Site.** For the Regionalization option that has no fuel stored at the Hanford Site, the requirements shown are the total incremental requirements.

5.13.5 Centralization Alternative

Similar to the Decentralization Alternative, annual consumption of energy during operations is similar to that used during construction for the water storage options (W and X), and the total would be a small fraction of the present consumption rate. Annual consumption of energy during operations in the options where defense production fuel is stabilized is significantly greater; however it is still within the capacity of existing facilities. Materials and energy requirements for construction in the Centralization Alternatives are shown in Table 5.13-4. Similar to the Regionalization options, the Centralization Alternative that involves fuel from other locations being stored at the Hanford Site shows the requirements associated with storing the fuel received from other locations and are in addition to those shown for fuel already at the Hanford Site in Table 5.13-1. For the Centralization option that has no fuel stored at the Hanford Site, the requirements shown are the total incremental requirements.

In the Centralization Alternative where all SNF is brought to the Hanford Site, an extension of existing utilities to the project site area would be necessary. This would include water mains, electrical power lines, sewage facilities, telephone lines, etc. All of these utilities

Table 5-13-2. Materials and energy required for Regionalization A suboptions.

Construction Cost ($ Million)	765	1465	560

a. Minimum value represents requirements during the period after all fuel has been placed into dry storage, or has been shipped offsite. Maximum value represents requirements during the interim period (less than 4 years) while SNF is being processed and prepared for storage or shipment offsite, assuming concurrent operation of the process facility and the existing facilities where SNF is currently stored (as in the No Action Alternative). are available in the adjacent 200-East Area. In addition, an existing rail line might need to be upgraded for increased traffic and the construction of new spurs to various proposed new facilities would likely be required.

The following section describes the material requirements for operation of facilities in each SNF alternative and the corresponding quantities of waste generated by these activities. Table 5.14-1 lists the breakdown by alternative and suboption of the various types of waste generated by SNF management facilities.

Table 5-13-4. Materials and energy requirements for construction of Centralization options.

Item	No Fuel Stored at the Hanford Site	All Offsite Fuel Stored at the Hanford Site
Concrete, thousand cubic meters (cubic yards)	18 (23)	150 (200)
Carbon Steel, thousand tonnes (tons)	3.1 (3.4)	25 (27.5)
Stainless Steel, thousand tonnes (tons)	0.4 (0.5)	0.1 (0.1)
Copper, thousand tonnes (tons)	0.045 (0.05)	0
Lumber, thousand cubic meters (board feet)	1.6 (660)	13 (5600)
Asphalt, Sand, and Crushed Rock (thousand cubic meters (thousand cubic yards)	0.8 (1.1)	7.2 (9.5)
Electricity		
Construction (MW-hrs)	3400	40,000
Operations (MW-hrs/yr)a	0-20,000	100-127,000
Diesel fuel, thousand cubic meters (thousand gallons)	0.6 (170)	5.7 (1500)
Gasoline, thousand cubic meters (thousand gallons)	0.6 (170)	5.7 (1500)
Construction Cost ($ Million)	560	1950

a. Minimum value represents requirements during the period after all fuel has been placed into dry storage, or has been shipped offsite. Maximum value represents requirements during the interim period (less than 4 years) while SNF is being processed and prepared for storage or shipment offsite, assuming concurrent operation of the process facility and the existing facilities where SNF is currently stored (as in the No Action Alternative).

5.14 Materials and Waste Management

5.14.1 No Action Alternative

The No Action Alternative involves only fuel storage at existing facilities, and material requirements for the current configuration are minimal. The exception is make-up water for the 105-K fuel storage basins, which amounts to 2.8 million cubic meters per year.

The quantity of waste generated in the No Action Alternative is also relatively small because the only planned modifications to existing facilities are safety and security upgrades to the 105-K basins. About 530 cubic meters of low-level waste would result from containerization of SNF in 105-KE Basin, and small quantities of radioactive and mixed waste are generated at the 325 Building.

Table 5.14-1. Waste generation for spent nuclear fuel management alternatives.

Waste Type	No Action	Decentralization						Centralization	
		W	X	Y	Z	P	Q	Offsite	at Hanford a,b
Construction Waste (m3, total)	0	1500	1700	1700	2800	2600	3400	2000	15000
High-Level	0	0	0	0	0	0	57	14	0

Radioactive Waste (m3/y)									
Transuranic Waste (m3/y)	0	0	0	0	0	28	50	0	0
Low-Level Radioactive Waste (m3/y)[c]	95	41	50	0	0	280	420	140	68
Mixed Waste (Low-Level Radioactive and Hazardous, (m3/y)	0.96	0.23	0.23	0	0	2.0	2.0	1.0	0.28
Non-radioactive Hazardous Waste (m3/y)	2.3	1.1	1.1	0	0	2.8	2.8	1.4	1.1

a. These quantities are associated with new facilities that would be required for management of SNF shipped to Hanford from other sites. They represent incremental increases over those for facilities that are required to manage SNF currently at Hanford, which are discussed in the No-Action and Decentralization Alternatives.

b. A new ECF is not included in these totals; requirements for this facility are discussed in Volume 1, Appendix D.

c. Annual totals do not include containerization of defense production reactor SNF currently stored at the 105-K basins. This activity is expected to generate 530 cubic meters of low-level radioactive waste over a period of approximately 2 years.

Table 5.14-1. (contd)

Waste Type	Regionalization							
	AX	AY	AZ	AP	AQ	B1[a]	B2[a,b]	C
Construction Waste (m3, total)	900	1600	2100	2600	3400	5400	11,500	2000
High-Level Radioactive Waste (m3/y)	0	0	0	0	57	0	0	14
Transuranic Waste (m3/y)	0	0	0	28	50	0	0	0
Low-Level Radioactive Waste (m3/y)[c]	61	0	0	280	420	1.7	1.7	140
Mixed Waste (Low-Level Radioactive and Hazardous, (m3/y)	0.23	0	0	2.0	2.0	0.028	0.028	1.0
Non-radioactive Hazardous Waste (m3/y)	1.1	0	0	2.8	2.8	0.057	0.057	1.4

a. These quantities are associated with new facilities that would be required for management of SNF shipped to Hanford from other sites. They represent incremental increases over those for facilities that are required to manage SNF currently at Hanford, which are discussed in the No-Action and Decentralization Alternatives.

b. A new ECF is not included in these totals; requirements for this facility are discussed in Volume 1, Appendix D of this document.

c. Annual totals do not include containerization of defense production reactor SNF currently stored at the 105-K basins. This activity is expected to generate 530 cubic meters of low-level radioactive waste over a period of approximately 2 years.

5.14.2 Decentralization Alternative

Material requirements for the Decentralization Alternative depend on the suboption chosen. The suboptions involving wet storage of production reactor fuel (suboptions W and X) require make-up water for the storage basin at approximately 2300 cubic meters per year. Material requirements for dry storage of fuel (suboptions Y and Z) are minimal, and consist of decontamination chemicals in small quantities. Those suboptions including processing of production reactor fuel (suboptions P and Q, which would be combined with either Y or Z) require relatively large quantities of nitric acid (2000 - 4000 cubic meters per year) and other process chemicals in smaller quantities.

Construction waste generated for each of the suboptions depends on the size and number of facilities required. Dry storage of all fuel, including processing of production reactor fuel, would result in the largest quantity of construction waste, which is assumed to be nonradioactive, nonhazardous solids. Radioactive and hazardous waste from operations is also greater for the dry storage suboption with processing. Wet storage of production reactor fuel and dry storage of other onsite fuel results in the smallest quantity of both construction and operational hazardous waste.

5.14.3 1992/1993 Planning Basis Alternative

This alternative would be essentially the same as the Decentralization Alternative at Hanford.

5.14.4 Regionalization Alternative

Regionalization Alternative Option A would be essentially the same as the Decentralization Alternative at Hanford in terms of operational material requirements and waste generation because these originate largely from the storage pool or process facilities, depending on the suboption selected. The quantity of construction waste would be smaller because the dry storage capacity for nondefense production fuel would not be needed.

The Regionalization Alternative B options would require materials in similar quantities to the Decentralization Alternative, but would generate construction and operational wastes in greater quantities because of additional facilities that would be necessary to receive, package, and store imported SNF. Note that the waste quantities reported in Table 5.14-1 represent incremental increases for SNF facilities above those listed for the Decentralization Alternative.

The Regionalization Alternative Option C involves only stabilization of defense production fuel and packaging of all Hanford SNF for shipment offsite. It is identical to the Centralization Alternative minimum option as described in Section 5.14.5.

5.14.5 Centralization Alternative

The Centralization Alternative minimum option for offsite shipment of Hanford fuel requires construction of a stabilization and canning facility, which would produce annual quantities of construction and operational wastes similar to those for onsite combined wet and dry storage (suboptions W and X) in the Decentralization Alternative. However, these wastes would only be generated for the time required to stabilize and package fuel for offsite shipment (approximately 4 years).

Centralization at Hanford (maximum option) would include the same suboptions as Decentralization for SNF currently at Hanford, and the material requirements and waste generation would be identical. For SNF imported from other sites, additional dry storage capacity would be needed, and new additional facilities to package and examine the fuel would be constructed.

The estimates in Table 5.14-1 for Centralization at Hanford represent incremental increases for these additional facilities above those in the Decentralization Alternative. They do not incorporate the additional requirements of the Expended Core Facility, which are discussed in Volume 1, Appendix D of this document. Operational material requirements for the incremental dry storage capacity would be minimal, as would be the quantities of waste generated. Construction of the new facilities would generate nonhazardous solid waste in quantities greater than any of the other options, but operation of the additional facilities would produce relatively small quantities of radioactive and hazardous waste.

5.15 Facility Accidents

Implications of facility accidents associated with implementing the alternatives for SNF storage at Hanford are discussed in the following section. The method used to screen and select accidents for analysis is described, as are the procedures for evaluating the consequences of selected accidents, and the results of the analysis. Additional detail concerning specific accidents and parameters used in the analysis is provided in Attachment A, Facility Accidents.

5.15.1 Historical Accidents Involving SNF at Hanford

There are no known instances at Hanford where storage, handling, or processing of SNF has resulted in an accident that involved a significant release of radioactive or other hazardous materials to the environment or that resulted in detrimental exposure of workers or members of the public to hazardous materials.

5.15.2 Emergency Preparedness Planning at Hanford

Although the safety record for operations at Hanford and other DOE facilities is generally good, DOE-RL and all Hanford Site contractors have established Emergency Response Plans to prepare for and mitigate the consequences of potential emergencies on the Hanford Site (DOE 1992c). These plans were prepared in accordance with DOE Orders and other federal, state, and local regulations. The plans describe actions that will be taken to evaluate the severity of a potential emergency and the steps necessary to notify and coordinate the activities of other agencies having emergency response functions in the surrounding communities. They also specify levels at which the hazard to workers and the public are of sufficient concern that protective action should be taken. The Site holds regularly scheduled exercises to ensure that individuals with responsibilities in emergency planning are properly trained in the procedures that have been implemented to mitigate the consequences of potential accidents and other events.

5.15.3 Accident Screening and Selection for the EIS Analysis

The alternatives for SNF storage considered in this EIS necessitate evaluation of accidents at a variety of different types of facilities. In the No Action Alternative, the facilities consist of those where SNF is currently stored on the Hanford Site, or those where SNF will be stored at the time of the record of decision. All facilities considered in the No Action Alternative currently exist at the Hanford Site, and no construction of new facilities is assumed. For many of these facilities, storage of SNF is incidental to other activities that take place in the buildings. For the other alternatives (Decentralization, Regionalization, 1992/1993 Planning Basis, and Centralization), construction of new facilities dedicated solely to SNF management is assumed.

Accidents evaluated for existing facilities at Hanford consisted of maximum reasonably foreseeable accidents described in such previously published analyses as safety or NEPA documentation. The source documents for specific accidents evaluated in this section are referenced in the detailed accident descriptions in Attachment A. In the case of new facilities, hypothetical accidents were based on operation of similar facilities at

Hanford or other sites. Depending on the time at which the source document was prepared, the number and types of accidents considered for each facility would be somewhat variable. However, the screening process used in the relatively recent analyses considers a wide scope of accident initiators and scenarios, including industrial accidents (fires, explosions, overpressurization, loss of containment or confinement), criticality, operator error or injury, external hazards (surface vehicle or aircraft impact), waste management, natural phenomena (seismic events, wind, floods, volcanic activity), interactions with activities at adjacent facilities (construction, maintenance, operations), and common cause events (power failure). Older safety documents generally address these issues as well, although perhaps not with the same rigor as newer analyses. Transportation accidents are considered in a separate section of this appendix and are not discussed here.

Acts of terrorism are accounted for indirectly in the present analysis because the potential consequences of terrorist activities are used to determine security requirements for a given facility. Security measures are implemented to mitigate the impact, or reduce the probability, of high consequence events. Therefore, reasonably foreseeable scenarios for terrorist activities would entail risks that are similar to those for the types of accident initiators generally considered in the source documents that provide the basis for this analysis.

For the purposes of this EIS, accidents are ideally grouped into three categories based on their estimated frequencies as follows: abnormal events (frequency >10-3 per year), design basis accidents (frequencies <10-3 to 10-6 per year), and beyond design basis accidents (frequency <10-6 to 10-7 per year). Because the accident categories commonly used for development of safety documents encompass different probability ranges, the estimated frequencies (or frequency ranges) for Hanford facility accidents are reported as indicated in the source document without regard to the accident frequency categories established for use in the EIS. For accidents where only a range rather than a point estimate of frequency is available, the frequency of the accident is reported as being less than the highest frequency that defines the range. In alternatives that consider SNF imported from other sites (such as other DOE facilities or U.S. and foreign research reactors), frequencies for specific accidents have been adjusted to account for increased fuel handling at receiving, canning, and storage facilities.

Accident frequencies as reported in safety documents (Safety Analysis Reports and related analyses) typically represent the overall probability of the accident, including the probability of the initiating event combined with the frequency of any contributing events required for an environmental release to occur. The contributing events may include equipment or barrier failures, or failures of other mitigating systems designed to prevent accidental releases. In general, the safety documents do not evaluate the consequences of events with expected frequencies of <10-6 per year because such accidents are not considered reasonably foreseeable; therefore, accidents in the beyond design basis category are generally not evaluated for this analysis. Evaluation of aircraft traffic at the Richland and Pasco, Washington airports determined that impacts of commercial or military aircraft were less than 1x10-7 for a facility in the Hanford 300 Area, which is at highest risk because of its location (PNL 1992a). Therefore, aircraft accidents are not considered further in this analysis as initiators for accidents at Hanford SNF management facilities.

As noted previously, the safety documents for SNF facilities generally considered a broad range of accidents; however, only the consequences of the maximum reasonably foreseeable accidents for each facility in a given alternative were evaluated for this document. Of the existing facilities assessed in the No Action Alternative, most are multipurpose facilities with diverse missions such as research or process development. These facilities typically contain relatively small quantities of SNF relative to the 105-K basins, where the bulk of Hanford's existing SNF is stored. The accidents evaluated in the source documents for multipurpose facilities may therefore reflect activities other than SNF storage or handling. The risks for such accidents are reported in this EIS for completeness, although in some cases, neither the frequency nor the consequences associated with the accident depend on the presence of SNF in the facility.

5.15.4 Method for Accident Consequence Analysis

In the No Action Alternative, accident consequence analyses utilized release estimates as presented in the source document for a given existing facility. For new facilities, release estimates were based on historical operation of similar facilities at Hanford. These estimates were also assumed to represent typical accidental releases in alternatives that consider storage of fuel from offsite locations, such as other DOE facilities or U.S. and foreign research reactors. Accidents evaluated for the research reactor fuels indicate that releases for such specialized fuels would be comparable to those included in this analysis (DOE 1993b; Hale and Reutzel 1993). The assumptions used to determine radionuclide releases are included in Attachment A.

Because most source documents (other than the more recent Safety Analysis Reports) do not evaluate hazardous materials other than radionuclides, a different approach was used for accidents involving nonradioactive materials. The hazardous material inventories for each facility were used to estimate releases based on the physical state of each compound as described in Attachment A. Specific initiators and accident scenarios were generally not postulated for nonradioactive materials; therefore, frequencies were not estimated for hazardous chemical accidents.

The downwind concentrations for materials released in accidents were then calculated at receptor locations as defined for the EIS. The receptors included a worker who is onsite but outside the facility where the accident takes place, a member of the public who is temporarily at the nearest access location (such as a road that crosses the site or at the site boundary), and the maximally exposed offsite resident. Collective dose to the population within 80 kilometers (50 miles) was also calculated for radionuclide releases. Individual dispersion calculations were performed using 95 percent atmospheric conditions (those resulting in air concentrations that would not be exceeded more than 5 percent of the time). Dose to the population was calculated using both 50 percent and 95 percent atmospheric dispersion parameters. Dispersion calculations were performed using the GENII computer code (Napier et al. 1988) for radionuclide releases and the EPIcode (Homann 1988) for nonradioactive compounds.

The radiation dose to each receptor evaluated for the EIS was recalculated for the specific conditions and release location as appropriate to each alternative using the GENII computer code. Doses were calculated as the effective dose equivalent using standard assumptions for the Hanford Site as summarized in Schreckhise et al. (1993). Health effects were also estimated as probability of fatal cancer based on recommendations of the International Commission on Radiological Protection in its Publication 60 (ICRP 1991). The accident doses were recalculated for this analysis using a consistent, reasonably conservative set of methods and assumptions and to include the complete set of receptors that are to be evaluated in the EIS. This was necessary because the methods used in the source documents were not necessarily consistent and in some cases were outdated. For this reason, the doses developed for this analysis may differ from those reported in the source documents that describe the accidents; however, they should be viewed as a screening analysis for the purposes of the EIS and are not intended to replace or invalidate the previous results.

Individual doses were based on exposure of the receptor during the entire release, except where the release time was sufficiently long that such an assumption is unrealistic. For releases that were expected to last more than a few hours, the exposure duration for onsite workers and members of the public at accessible onsite locations was limited to 2 hours, corresponding to the maximum time required to evacuate the Hanford Site in the event of an accident. Offsite residents were assumed to be exposed during the entire release, regardless of the accident duration. Exposure via inhalation and external pathways (groundshine and submersion in the plume) were considered for workers and the nearest public access receptors; ingestion of contaminated food was evaluated only for offsite residents. Because protective action guidelines specify mitigative actions to prevent consumption of contaminated food, the ingestion dose to offsite individuals and populations is reported separately from the other exposure routes. Reduced exposure to the plume or to contaminated ground surface as a result of early evacuation of offsite populations is not assumed for the purposes of this analysis, although such actions would also be mandated if the projected dose from an accident exceeded the protective action guidelines. Because the circumstances and consequences postulated for workers at the scene of an accident are so speculative, they serve no useful purpose in the decision-making process. As a consequence, discussion of impacts on "close-in" workers are not brought forward into the text of this Appendix. Consequences in terms of the "close-in" workers for one scenario in each accident may be found in Attachment A.

5.15.5 Radiological Accident Analysis

5.15.5.1 No Action Alternative. The No Action Alternative consists of

fuel storage at existing Hanford facilities, including the 100-K wet storage basins; T Plant, and a low-level burial ground in the 200-West Area; the 308, 324, 325, and 327 buildings in the 300 Area; and the Fast Flux Test Facility (FFTF) in the 400 Area. Of these facilities, only the 100-K storage basins and the FFTF fuel storage facility are primarily devoted to SNF storage; the others are all multipurpose facilities that house a variety of activities in addition to storing relatively small quantities of SNF. The consequences and risks of accidents associated with these facilities are described in Tables 5.15-1 through 5.15-5.

The maximum reasonably foreseeable accident for multipurpose facilities is an earthquake scenario at the 324 Building, which releases non-SNF related radioactive material that has accumulated in a hot cell (Table 5.15-1 through **Table 5.15-5).** The contributions of other activities at the facility, including SNF storage, are estimated to be relatively minor. The maximum reasonably foreseeable accident directly involving SNF management is a fire at a fuel storage facility adjacent to FFTF. Several of the accident scenarios evaluated for this alternative involve initiators that could affect more than one facility (e.g., earthquakes); however, the combined consequences of releases from potentially affected facilities have not been evaluated for a common receptor.

5.15.5.2 Decentralization Alternative. The Decentralization

Alternative involves several options for construction of new facilities at Hanford. One option includes a combination of new wet storage for defense production reactor fuel currently stored at the 105-K basins and new dry storage for fuel that is currently at other locations. Alternative options are included for processing of production reactor fuel prior to dry storage. The consequences of accidents at the new facilities are based on previously evaluated accidents for similar installations, adapted for the conditions and location of these facilities as assumed in this EIS.

The maximum reasonably foreseeable accident for the new facilities is a severe cask impact followed by a fire at a dry storage facility (Tables 5.15-1 through 5.15-5). The risk from a cask drop while loading fuel at a wet storage facility is similar for most receptors, although this scenario is conservative for a new facility as discussed in Attachment A.

5.15.5.3 1992/1993 Planning Basis Alternative. Accidents and

consequences would be essentially the same as for the Decentralization Alternative.

5.15.5.4 Regionalization Alternative. The consequences of the

regionalization alternatives are similar to those of other action alternatives because they only differ in the quantity of imported fuel placed into dry storage at the site. The types of facilities and activities involved are generally the same as those considered for the decentralization and centralization alternatives. Point estimates of risk for some accidents differ from those of corresponding

Table 5.15-1. Radiological accidents, individual worker probability of latent cancer fatality.

a. NA = Not applicable.

b. The dose from this scenario (1.1E + 03) rem is sufficiently high that application of a fatal cancer risk factor is inappropriate.
c. See Appendix D for consequences of accidents at this facility.
d. Dash indicates that the information was not available.
e. The consequences associated with this accident are a result of existing contamination in the 324 Building hot cells, and neither its likelihood nor its severity depend on the presence of spent nuclear fuel at the facility. The actual contribution of spent nuclear fuel to releases from the accident is assumed to be negligible compared with that of other sources.

a. The offsite dose from this accident is assumed to be limited to 0.5 rem by application of protective action guidelines. Potential dose without protective action is 1.4 rem for 105-K Basin Cask drop, 5400 rem for 324 Building seismic event, 16 rem for 325 Building seismic event, and 5 rem for FFTF liquid metal fire.
b. NA = Not applicable.
c. See Appendix D for consequences of accidents at this facility.
d. The consequences associated with this accident are a result of existing contamination in the 324 Building hot cells, and neither its likelihood nor its severity depend on the presence of SNF at the facility. The actual contribution of SNF to releases from the accident is assumed to be negligible compared with that of other sources.

accidents in the other alternatives because the frequencies were adjusted to account for the quantity of fuel handled in each option (See Tables 5.15-1 through 5.15-5). Under subalternatives A and B, the types of accidents and their consequences would be the same as those for the decentralization alternative. However, the frequencies (and therefore the risks), would differ in some cases because of the volume of imported fuel that would be placed into dry storage. For subalternative C, all fuel currently at Hanford would be transported to another site, and the risks would be identical to those in the centralization minimum alternative.

5.15.5.5 Centralization Alternative. The Centralization Alternative

consists of two options at Hanford: a minimum option in which all DOE spent fuel at Hanford is transported offsite to another location for interim storage, and a maximum option that would result in storage of all DOE spent fuel at Hanford. Accident scenarios for the minimum option would include those discussed under the No Action Alternative prior to shipment of the fuel offsite. In addition, defense reactor fuel would be processed and repackaged in a new facility prior to shipment. The risks associated with this new facility are expected to be similar to the processing facility discussed under the Decentralization Alternative. The cask impact accident at a dry storage facility has been included in this option to account for handling of fuel prior to shipment from Hanford.

The maximum option contains suboptions for wet or dry fuel storage with processing similar to those for the Decentralization Alternative, and the consequences are expected to be essentially the same as those described previously. The frequency of the cask impact at a dry storage facility has been increased to account for additional fuel that would be handled at Hanford under this option. The only other installation that would be included in this option is the Expended Core Facility (ECF), which would be relocated from INEL. The consequences of accidents at this facility are discussed in Volume 1, Appendix D of this EIS, and are not described here. Note that the accident analysis for the ECF in Appendix D incorporates different assumptions than those used for other Hanford facilities in this section, and the two sets of results are not directly comparable. The consequences of ECF accidents at Hanford using assumptions consistent with those in this section would be higher than those reported in Appendix D.

5.15.6 Secondary Impacts of Radiological Accidents

Secondary impacts of radiological accidents have been evaluated qualitatively for this analysis. Accidents that resulted in doses to the maximally exposed offsite resident of less than 100 millirem were considered to have little or no secondary impact because the levels of environmental contamination in these cases would be relatively small. Accidents that exceed this level may have secondary impacts with severity depending on the expected levels of environmental contamination. Although the levels of environmental contamination were not assessed quantitatively for this analysis, the offsite individual dose provides a measure of the air concentration and radionuclide deposition at the receptor location and can be used as a semi-quantitative estimate of the level of environmental contamination from a given accident. The estimated secondary consequences of maximum reasonably foreseeable SNF facility accidents are presented in Table 5.15-6.

5.15.7 Nonradiological Accident Analysis

For purposes of the EIS, a worst case accident scenario was developed for each existing and planned facility. The details of the nonradiological accident scenario are presented in Attachment A, and the information is summarized in this section. The accident assumes that a chemical spill occurs within a building and is followed by an environmental release from the normal exhaust system. It is assumed that the building remains intact but containment measures fail, allowing releases occur through the ventilation system. It is assumed that all, or a portion of, the entire inventory of toxic chemicals stored in each building is spilled. The environmental releases are modeled, and the hypothetical concentrations at three receptor locations are compared to toxicological limits.

Several chemical inventory and chemical emissions lists are provided by alternative and facility (Bergsman 1995). Effects to onsite workers, the nearest point of public access, and the public at the nearest offsite residence were estimated using the computer model EPIcode (DOE 1993b). Results from the EPIcode model were compared to available Emergency Response Planning Guideline (ERPG) values, Immediately Dangerous to Life and Health (IDLH) values, and Threshold Limit Values/Time Weighted Averages (TLV/TWA). In the absence of these values, toxicological data for similar health endpoints, from the Registry of Toxic Effects for Chemical Substances (RTEC) are used.

The results of the accident scenario for each alternative are presented in **Table 5.15-8.** As a general statement, in the event of an accident, the existing 105-KE and 105-KW facilities and the proposed new wet storage facility present the predominant risk for chemical exposure.

Under the No Action Alternative there is a potential for irreversible health effects to occur in the 308, 324, 325 A and B buildings, while nitric acid is a potential odor and irritation problem from both of the proposed fuel stabilization alternatives.

5.15.7.1 No Action Alternative. A baseline of chemicals kept in spent

nuclear storage facilities was developed from chemical inventories for these facilities compiled to comply with the Emergency Planning and Community Right-To-Know Act (EPCRA). The existing storage facilities include 105-KE, 105-KW, PUREX (202A), T-Plant (221T), 2736-ZB Building, 200-West low-level burial grounds, FFTF 403 Building, 308 Building, 324 Building, 325 A&B Building, and 327 Building. The Emergency Planning and Community Right-To-Know Act (EPCRA) lists used are from 1992.

Because most facilities have various missions, the need to have a supply of chemicals at these facilities may not be related to the storage of SNFs. However for purposes of the EIS, the assumption is made that the existing inventories represents the anticipated amounts and types of chemicals which may be needed in the future.

The results of the accident scenario under conditions of the No Action Alternative are presented in Table 5.15-7.

5.15.7.2 Decentralization Alternative. The Decentralization Alternative

involves construction of several new facilities at Hanford, including new dry storage for spent fuel, or a combination of new wet and dry storage. Options are also included for several types of fuel processing prior to storage. The consequences of new facilities are based on previously evaluated accidents for similar installations, adapted for the conditions and locations of these facilities as assumed in this EIS.

The baseline chemical inventory for the proposed facilities is primarily derived from the facility costs section in the engineering design data (Bergsman 1995). However, the wet storage facility uses the 105-KE Basin as a surrogate for a baseline chemical inventory because the facility cost section lists only two chemicals, sodium hydroxide and sulfuric acid.

Table 5.15-6. Assessment of secondary impacts of accidents for the No-Action Alternative.

	Environmental or Social Factor							
Accident Description	Biotic Resources	Water Resources	Economic Impacts	National Defense	Environmental Contamination	Endangered Species	Land Use	Treaty Rights, Cultural

Resources,

Native Cultures

Accidents with frequencies y10-3 per year								
308 Building (fuel handling accident)	a	a	a	a	a	a	a	a
Accidents with frequencies <10-3 per year								
324 Building (seismic event)	Potential local effects on individ- uals of some species	Potential temporary closure of Hanford Reach of Columbia River to boat traffic, restriction of water use locally (Richland, Pasco)	Possible loss of crops, cost incurred for clean-up	None antici- pated	May be extensive in vicinity of facility and adjacent offsite areas	None anticipated	Restriction on use of adjacent land for agriculture, and of Columbia River islands, pending radiological survey	Possible temporary restrictions on access to traditional fishing sites
325 Building (seismic event)	b	b	b	b	b	b	b	b
FFTF fuel storage (liquid metal fire)	b	b	b	b	b	b	b	b
105-K wet storage (cask drop)	b	b	b	b	b	b	b	b
200-W burial ground (cask impact & fire)	b	b	b	b	b	b	b	b
327 Building (hot cell fire)	b	b	b	b	b	b	b	b
T-plant (fuel damage)	a	a	a	a	a	a	a	a

a. Consequences of this accident would be limited to very local onsite impact only, if any.
b. Consequences of this accident would be similar in nature to those of the 324 building or new dry storage facility (worst case) accidents; however they would be less severe because offsite concentrations would be lower by at least two orders of magnitude.

The results of the accident scenario under conditions of the Decentralization Alternative are presented in Table 5.15-8.

5.15.7.3 1992/93 Planning Basis Alternative. Accidents and consequences

would be essentially the same as for the Decentralization Alternative.

5.15.7.4 Regionalization Alternative. Except for Regionalization Option

C, which would be essentially the same as the Centralization Alternative minimum case, accidents and consequences for options A, B1, and B2 would be essentially the same as for the Decentralization Alternative. The quantity of nondefense fuels placed into dry storage would not affect the potential for releases of hazardous chemicals because no such materials are present in the dry storage facilities.

5.15.7.5 Centralization Onsite Alternative. The Centralization Onsite

Alternative consists of consolidating all spent fuel at the Hanford site. Options are available for wet or dry fuel storage with processing similar to those for the Decentralization Alternative. The consequences are expected to be essentially the same as those described for the first 5 years of the No Action Alternative, and then they are the same as those described for the Decentralization Alternative.

The results of the accident scenario under conditions of the No Action and Decentralization Alternatives are presented in Table 5.15-8.

5.15.7.6 Centralization Offsite Alternative. The Centralization Offsite

Alternative consists of transporting all DOE SNF at Hanford offsite to another location for interim storage. Fuel would be stabilized prior to shipment in a fuel drying and passivation facility. Therefore the impacts from this alternative are the same as those for the No Action Alternative for the first 5 years, and then they are the same as those described for the fuel drying and passivation facility.

The results of the accident scenario under conditions of the No Action Alternative and the fuel drying and passivation facility are presented in Table 5.15-8.

Table 5.15-7. Assessment of secondary impacts of accidents for the Decentralization, 1992/1993 Planning Basis, Regionalization, and Centralization Alternatives.

Accident Description	Environmental or Social Factor							
	Biotic Resources	Water Resources	Economic Impacts	National Defense	Environmental Contamination	Endangered Species	Land Use	Treaty Rights/ Cultural Resources/ Native Cultures
New dry storage (cask impact with fire)	Minimal local effects	Possible temporary restriction of use of Columbia River for recreation	Clean-up costs locally, potential loss of crops	None anticipated	Moderate in immediate environs & offsite	None anticipated	Temporary restriction on agriculture pending radiological survey	Possible temporary restriction on access to traditional fishing sites

storage
(cask drop)

a. Consequences of this accident would be limited to very local onsite impact only, if any.
b. Consequences of this accident would be similar in nature to those of the 324 building or new dry storage facility (worst case) accidents; however they would be less severe because offsite concentrations would be lower by at least two orders of magnitude.

5.15.8 Construction and Occupational Accidents

Table 5.15-9 shows the predicted number of injuries, illnesses, and fatalities among workers from construction activities and operations activities for each alternative. Injury, illness, and fatality counts for construction workers are presented separately because of the relatively more hazardous nature of construction work.

Decentralization suboptions P and Q represent the highest predicted construction and occupational accident count of any of the alternatives. The higher number of accidents is attributable to increased construction and fuel processing required by these alternatives. The Centralization Onsite Alternative has accident counts similar to those for suboptions P and Q. The lowest accident counts are for the No Action Alternative and the Centralization Offsite Alternative. All other alternative are similar in their predicted accident counts.

5.16 Cumulative Impacts Including Past and Reasonably Foreseeable Actions

Cumulative impacts associated with implementing the alternatives for interim storage of SNF at the Hanford Site together with impacts from past and reasonably foreseeable future actions are described in the following subsections.

5.16.1 No Action Alternative

Cumulative impacts associated with implementation of the No Action Alternative are described in the following subsections.

5.16.1.1 Land Use. The Hanford Site consists of about 1450 square

kilometers (360,000 acres), of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of the No Action Alternative would not change that land use. Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1 square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

a. Facility construction and operation estimates are based on DOE and DOE contractor accident rates (See Volume 2, Part B, Table F-4-7 of this EIS).
b. Worker year estimates from Bergsman (1995).
c. Dry storage suboptions (Y or Z) would be paired with either of two processing options (P or Q).
d. These estimates represent incremental increases for fuel imported from offsite locations only; estimates for storage (and stabilization where required) of onsite fuel woule be the same as in the Decentralization Alternative.

5.16.1.2 Air Quality. Air quality limits (WAC 173-470-030,-100) at the

Hanford Site boundary are not expected to be approached as a result of implementing the No Action Alternative or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or from decommissioning of unused facilities or site restoration activities.

5.16.1.3 Waste Management. Under the No Action Alternative, there

would be a continuing generation of about 100 cubic meters of low-level wastes per year from incidental activities and about 530 cubic meters during containerization of SNF and sludge in the 100-K Area basins. All presently anticipated activities on the Hanford Site would result in approximately 20,000 cubic meters of low-level waste per year. Thus, at a maximum, the total quantity of low-level waste from SNF activities would account for about 5 percent of the annual quantity of low-level waste generated at the Hanford Site.

5.16.1.4 Socioeconomics. Under the No Action Alternative, the SNF

workforce would remain the same, about 60 workers. The Hanford Site workforce is expected to drop from about 18,700 in 1995 to 14,700 in 1997 and to remain approximately at 14,700 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period.

5.16.1.5 Occupational and Public Health. The cumulative population

dose since plant startup was estimated to be about 100,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 50 (essentially all of which would be attributed to dose received in the 1945-52 time frame). In the 50 years since plant startup, the population of interest (assuming a constant population of 380,000 and an individual dose of about 0.3 rem/year) would have received about 5,000,000 person-rem from naturally occurring radiation sources (natural background) which would relate to about 2,500 latent cancer fatalities. In the same 50 years about 27,000 cancer fatalities from all causes would have been expected in that population.

If the Hanford sitewide contribution to public dose from all exposure pathways is considered (0.8 person-rem per year from DOE facilities and 0.7 person-rem per year from Washington Public Power Supply System reactor operation for 40 years), it is estimated that the cumulative collective dose would be approximately 60 person-rem. No latent fatal cancers would be expected from such a dose. Over 40 years of interim storage of SNF, the population of interest would have received 4,000,000 person-rem from natural background radiation. That dose would relate to 2,000 latent cancer fatalities. In the same 40 years, about 21,000 cancer fatalities from all causes would be expected among the population in the region of interest (380,000 population).

Air quality limits [(40 CFR 61 Subpart H), 10 millirem per year at the Hanford Site boundary] are not expected to be approached as a result of implementing the No Action Alternative or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or from decommissioning of unused facilities or site restoration activities.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one fatal cancer might be inferred. In the near term the annual increments to cumulative worker dose would be expected to be about 24 person-rem. No latent fatal cancers would be expected from 40 years of the No Action Alternative (960 person-rem).

The cumulative worker dose since start up of activities at the Hanford Site is about 90,000 person-rem, to which would be added about 210 person-rem/yr for a total cumulative worker dose of about 100,000 person-rem through the next 40 years. Thus for 90 years of Hanford operations, about 50 latent cancer fatalities (LCFs) might be inferred (4 LCFs inferred from 1995 onward). In those 90 years about 4,500 LCFs would be inferred from natural background radiation and 48,000 LCFs from all causes would be expected.

Although the worker dose assocated with all future site restoration activities is expected to be small in comparison with cumulative worker dose to date, it is too speculative to quantify at this time.

5.16.2 Decentralization Alternative

Cumulative impacts associated with implementation of the Decentralization Alternative are described in the following subsections.

5.16.2.1 Land Use. The Hanford Site consists of about 1450 square

kilometers (360,000 acres), of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of the Decentralization Alternative would disturb an additional area of up to 0.6 square kilometers (160 acres) for a total of about 88 square kilometers (22,000 acres). The amount of land actually occupied by new facilities would range from about 4 ha (11 acres) to about 7 hectares (18 acres). Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1 square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

5.16.2.2 Air Quality. Air quality limits (WAC 173-470-030,-100) at the

Hanford Site boundary are not expected to be approached as a result of implementing any of the options in the Decentralization Alternative or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or from decommissioning of unused facilities or restoration activities.

5.16.2.3 Waste Management. In the near term under the Decentralization

Alternative, there would be about 530 cubic meters of low-level waste generated during 2 years of repackaging and containerization of SNF and sludge in the 100-K Basins. Thereafter low-level waste generation would range from 41 to 420 cubic meters per year for about 4 years depending on suboption selected. All presently anticipated activities on the Hanford Site would result in approximately 20,000 cubic meters of low-level waste per year. Thus, at a maximum, the total low-level waste from SNF activities would account for about 8 percent of the annual quantity of low-level waste generated at the Hanford Site.

High-level waste that might be generated in the Decentralization Alternative would not add significantly to the more than 250,000 cubic meters of waste at Hanford currently handled as high-level waste.

5.16.2.4 Socioeconomics. Under the Decentralization Alternative, the

SNF workforce would increase from 80 to about 740. The Hanford Site workforce is expected to drop from 18,700 in 1995 to 14,700 in 1997 and remain at approximately 14,700 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period. The maximum change with respect to the regional workforce would be an increase of about 0.9 percent.

5.16.2.5 Occupational and Public Health. The cumulative population

dose since plant startup was estimated to be about 100,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 50 (essentially all of which would be attributed to dose received in the 1945-52 time frame). In the 50 years since plant startup, the population of interest (assuming a constant population of 380,000 and an individual dose of about 0.3 rem/year) would have received about 5,000,000 person-rem from naturally occurring radiation sources (natural background), which would relate to 2,500 latent cancer fatalities. In the same 50 years about 27,000 cancer fatalities from all causes would have been expected in the region of interest.

If the Hanford sitewide contribution to public dose from all exposure pathways is considered (0.8 person-rem per year from DOE facilities and 0.7 person-rem per year from Washington Public Power Supply System reactor operation for 40 years), it is estimated that the cumulative collective dose would be approximately 60 person-rem. Additional collective population dose from implementation of the Decentralization Alternative would range from 1 to 4 person-rem over 40 years (dose from 4 years of processing would dominate). Thus, in total, the collective population dose from man-made sources would remain approximately 60 person-rem. No latent fatal cancers would be expected from such a dose. Over 40 years of interim storage of SNF, the population of interest would have received 4,000,000 person-rem from naturally occurring radiation sources (natural background). That dose would relate to 2,000 latent cancer fatalities. In the same 40 years, about 21,000 cancer fatalities from all causes would be expected among the population in the region of interest (380,000 population).

Air quality limits [(40 CFR 61 Subpart H), 10 millirem per year at the Hanford Site boundary] are not expected to be approached as a result of implementing the Decentralization Alternative or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or decommissioning of unused facilities, or site restoration activities.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one latent fatal cancer might be inferred. Collective worker dose from SNF activities would amount to about 80 person-rem for maintenance and operations, 18 person-rem for loading storage facilities, and 180 to 320 person-rem depending on processing option selected. Thus, the total collective 40-year worker dose from SNF activities would be from about 300 to 420 person-rem. Within the accuracy of the estimates, cumulative worker dose in the Decentralization Alternative would not add significantly to the cumulative Hanford Site worker dose over 90 years as described for the No Action Alternative.

5.16.3 1992/1993 Planning Basis Alternative

Because of the similarity of activities, cumulative impacts of the 1992/1993 Planning Basis Alternative would be essentially the same as those described for the Decentralization Alternative.

5.16.4 Regionalization Alternative (Options A, B1, B2, and C)

Cumulative impacts for implementation of the four Regionalization Subalternatives are described in the following subsections.

5.16.4.1 Regionalization Option A . Cumulative impacts associated with

implementation of the Regionalization Option A where Hanford's defense SNF is stored at the Hanford Site and other SNF is shipped offsite for storage are described in the following subsections.

5.16.4.1.1 Land Use.

The Hanford Site consists of about 1450 square kilometers (360,000 acres) of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of Regionalization Option A would disturb an additional area of up to 0.6 square kilometers (160 acres), for a total of about 88 square kilometers (22,000 acres). The amount of land actually occupied by new facilities would range from about 2 hectares (6 acres) to about 7 hectares (18 acres). Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1 square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

5.16.4.1.2 Air Quality.

Air quality limits (WAC 173-470-030,-100) at the Hanford Site boundary are not expected to be approached as a result of implementing any of the options in the Regionalization A Alternative or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or from decommissioning of unused facilities or restoration activities.

5.16.4.1.3 Waste Management.

In the near term under Regionalization Option A, there would be about 530 cubic meters of low-level waste generated during containerization of SNF and sludge in the 100-K basins. Thereafter, low-level waste generation would range from 61 to 420 cubic meters per year for about 4 years depending on option selected.. All presently anticipated activities on the Hanford Site would result in approximately 20,000 cubic meters of low-level waste per year. Thus, at a maximum, the total low-level waste from SNF activities would account for about 8 percent of the annual Hanford generation of low-level waste.

High-level waste that might be generated in Regionalization A would not add significantly to the more than 250,000 cubic meters of waste at Hanford currently handled as high-level waste.

5.16.4.1.4 Socioeconomics.

Under Regionalization Option A, the SNF workforce would increase by 60 to about 470. The Hanford Site workforce is expected to drop from about 18,700 in 1995 to about 14,700 in 1997 and to remain at approximately 14,700 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period. The maximum change with respect to the regional workforce would be an increase of about 0.6 percent.

5.16.4.1.5 Occupational and Public Health.

The cumulative population dose since plant startup was estimated to be about 100,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 50 (essentially all of which would be attributed to exposures in the 1945-52 time frame). In the 50 years since plant startup the population of interest (assuming a constant population of 380,000 and an individual dose of about 0.3 rem/year) would have received about 5,000,000 person-rem from naturally occurring radiation sources (natural background), which would relate to 2,500 latent cancer fatalities. In the same 50 years about 27,000 cancer fatalities from all causes would have been expected in the region of interest.

If the Hanford sitewide contribution to public dose from all exposure pathways is considered (0.8 person-rem per year from DOE facilities and 0.7 person-rem per year from Washington Public Power Supply System reactor operation for 40 years), it is estimated that the cumulative collective dose would be approximately 60 person-rem. Additional collective population dose from implementation of Regionalization Option A would range from 1 to 4 person-rem over 40 years (dose from 4 years of processing would dominate). Thus, in total, the collective population dose from man-made sources would be about 60 person-rem. No latent fatal cancers would be expected from such a dose. Over 40 years of interim storage of SNF, the population of interest would have received 4,000,000 person-rem from naturally occurring radiation sources (natural background). That dose would relate to 2,000 latent cancer fatalities. In the same 40 years, about 21,000 cancer fatalities from all causes would be expected among the population in the region of interest (380,000 population).

Air quality limits ([40 CFR 61 Subpart H], 10 millirem per year at the Site boundary) are not expected to be approached as a result of implementing the Regionalization Alternative or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory, or decommissioning of unused facilities, or site restoration activities.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one latent fatal cancer might be inferred. Collective worker dose from SNF activities would amount to about 80 person-rem for maintenance and operations, 18 person-rem for loading storage facilities, and 180 to 320 person-rem depending on processing option selected. Thus the total collective 40-year worker dose would be from about 300 to 420 person-rem. Within the accuracy of the estimates, cumulative worker dose in Regionalization A would not add significantly to the cumulative Hanford Site work dose over 90 years as described for the No Action Alternative.

5.16.4.2 Regionalization Option B1. Cumulative impacts associated with

the implementation of Regionalization Option B1, where all SNF west of the Mississippi River, except for Naval SNF, is transported to Hanford are described in the following subsections.

5.16.4.2.1 Land Use.

The Hanford Site consists of about 1450 square kilometers (360,000 acres), of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of Regionalization Option B1 would disturb an additional area of upto 0.6 square kilometers (160 acres), for a total of about 88 square kilometers (22,000 acres). The amount of land actually occupied by new facilities would range from about 15 hectares (36 acres) to about 28 hectares (68 acres). Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1

square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

5.16.4.2.2 Air Quality.

Air quality limits (WAC 173-470-030,-100) at the Hanford Site boundary are not expected to be approached as a result of implementing any of the options in Regionalization Option B1 or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or from decommissioning of unused facilities or restoration activities.

5.16.4.2.3 Waste Management.

In the near term under Regionalization Option B1, there would be about 530 cubic meters of low-level waste generated during repackaging and containerization of SNF and sludge in 100-K Basins. Thereafter low-level waste generation would range from 61 to 420 cubic meters per year for about 4 years depending on the suboption selected. All presently anticipated processing activities on the Hanford Site would result in approximately 20,000 cubic meters of low-level waste per year. Thus, the total quantity of low-level waste from SNF activities would account for about 8 percent of the annual quantity of low-level waste generated at the Hanford Site.

High-level waste that might be generated in Regionalization B1 would not add significantly to the more than 250,000 cubic meters of waste at Hanford currently handled as high-level waste.

5.16.4.2.4 Socioeconomics.

Under Regionalization Option B1, the SNF workforce would increase by about 170 to about 800. The Hanford Site workforce is expected to drop from 18,700 in 1995 to 14,700 in 1997 and remain around 14,700 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period. The maximum change with respect to the regional workforce would be an increase of about 1 percent.

5.16.4.2.5 Occupational and Public Health.

The cumulative population dose since plant startup was estimated to be about 100,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 50 (essentially all of which would be attributed to exposures in the 1945-52 time frame). In the 50 years since plant startup, the population of interest (assuming a constant population of 380,000) would have received about 5,000,000 person-rem from naturally occurring radiation sources (natural background), which would relate to 2,500 latent cancer fatalities. In the same time, about 27,000 cancer fatalities from all causes would have been expected in the region of interest.

If the Hanford sitewide contribution to public dose from all exposure pathways is considered (0.8 person-rem per year from DOE facilities and 0.7 person-rem per year from Washington Public Power Supply System reactor operation for 40 years), it is estimated that the cumulative collective dose would be approximately 60 person-rem. Additional collective population dose from implementation of Regionalization Option B1 would range from 1 to 4 person-rem over 40 years (dose from 4 years of processing would dominate). Thus, in total, the collective population dose from man-made sources would remain approximately 60 person-rem. No latent fatal cancers would be expected from such a dose. Over 40 years of interim storage of SNF, the population of interest would have received 4,000,000 person-rem from naturally occurring radiation sources (natural background). That dose would relate to 2,000 latent cancer fatalities. In the same 40 years, about 21,000 cancer fatalities from all causes would be expected among the population in the region of interest (380,000 population).

Air quality limits [(40 CFR 61 Subpart H), 10 millirem per year at the Hanford Site boundary] are not expected to be approached as a result of implementing Regionalization Option B1 or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory or from decommissioning of unused facilities or site restoration activities.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one latent fatal cancer might be inferred. Collective worker dose from SNF activities would amount to about 80 person-rem for maintenance and operations, 18 person-rem for loading storage facilities, and 180 to 320 person-rem depending on processing option selected. Thus the total collective 40-year worker dose would be from about 300 to 420 person-rem. Within the accuracy of the estimates, cumulative worker dose in Regionalization B1 would not add significantly to the cumulative Hanford Site worker dose over 90 years as described for the No Action Alternative.

5.16.4.3 Regionalization Option B2. Cumulative impacts associated

with the implementation of Regionalization Option B2, where all SNF west of the Mississippi River and Naval SNF, are transported to Hanford are described in the following subsections.

5.16.4.3.1 Land Use.

The Hanford Site consists of about 1450 square kilometers (360,000 acres) of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of Regionalization Option B2 would disturb an additional area of up to 0.6 square kilometers (160 acres), for a total of about 88 square kilometers (22,000 acres). The amount of land actually occupied by new facilities would range from about 21 hectares (52 acres) to about 30 hectares (74 acres). Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1 square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

5.16.4.3.2 Air Quality.

Air quality limits (WAC 173-470-030,-100) at the Hanford Site boundary are not expected to be approached as a result of implementing any of the suboptions in Regionalization Option B1 or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory, or from decommissioning of unused facilities or restoration activities.

5.16.4.3.3 Waste Management.

In the near term under Regionalization Option B2, there would be about 530 cubic meters of low-level waste generated during repackaging and containerization of SNF and sludge in the 100-K Basins. Thereafter, low-level waste generation would range from 61 to 420 cubic meters per year. All presently anticipated activities on the Hanford Site would result in approximately 20,000 cubic meters of low-level waste per year. Thus, at a maximum, the total quantity of low-level waste from SNF activities would account for about 4 percent of the annual quantity of low-level waste generated at the Hanford Site.

High-level waste that might be generated in Regionalization B2 would not add significantly to the more than 250,000 cubic meters of waste at Hanford currently handled as high-level waste.

5.16.4.3.4 Socioeconomics.

Under Regionalization Option B2, the SNF workforce would increase by about 170 to about 800. The Hanford Site workforce is expected to drop from 18,700 in 1995 to 14,700 in 1997 and remain around 14,700 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period. The maximum change with respect to the regional workforce would be an increase of about 1 percent.

5.16.4.3.5 Occupational and Public Health.

The cumulative population dose since plant startup was estimated to be about 100,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 100 (essentially all of which would be attributed to exposures in the 1945-52 time frame). In the 50 years since plant startup, the population of interest (assuming a constant population of 380,000) would have received about 5,000,000 person-rem from naturally occurring radiation sources (natural background) which would relate to 2,500 latent cancer fatalities. In the same time about 27,000 cancer fatalities from all causes would have been expected in the region of interest.

If the Hanford Site contribution from all exposure pathways to public dose is added (0.8 person-rem per year from DOE facilities and 0.7 person-rem per year from Washington Public Power Supply System reactor operation for 40 years), it is estimated that the cumulative collective dose would be approximately 60 person-rem. Additional collective population dose from implementation of Regionalization Option B2 would range from 1 to 4 person-rem over 40 years (dose from 4 years of processing would dominate). Thus, in total, the collective population dose from man-made sources would remain approximately 60 person-rem. No latent fatal cancers would be expected from such a dose. Over 40 years of interim storage of SNF, the population of interest would have received 4,000,000 person-rem from naturally occurring radiation sources (natural background). That dose would relate to 2,000 latent cancer fatalities. In the same 40 years, about 21,000 cancer fatalities from all causes would be expected among the population in the region of interest (380,000 population).

Air quality limits [(40 CFR 61 Subpart H), 10 millirem per year at the Site boundary] are not expected to be approached as a result of implementing Regionalization Option B2 or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory, or decommissioning of unused facilities or site restoration activities.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one latent fatal cancer might be inferred. Collective worker dose from SNF activities would amount to about 80 person-rem for maintenance and operations, 18 person-rem for loading storage facilities, and 180 to 320 person-rem depending on the processing suboption selected. Thus the total collective 40-year worker dose would be from about 300 to 420 person-rem. Within the accuracy of the estimates, cumulative worker dose in Regionalization B2 would not add significantly to the cumulative Hanford Site worker dose over 90 years as described for the No Action Alternative.

5.16.4.4 Regionalization C Option. Cumulative impacts in this option,

where all Hanford SNF is sent to INEL or NTS, would be essentially the same as those described for the Centralization Alternative, minimum option.

5.16.5 Centralization Alternative

Cumulative impacts associated with implementation of one or the other of two options under the Centralization Alternative are described in the following subsections.

5.16.5.1 Centralization Alternative Maximum Option. Cumulative impacts

associated with implementation of the Centralization Alternative maximum option, where all SNF is sent to the Hanford Site, are described in the following subsections.

5.16.5.1.1 Land Use.

The Hanford Site consists of about 1450 square kilometers (360,000 acres), of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of the Centralization Alternative maximum option would disturb up to an additional area of about 0.6 square kilometers (160 acres) for a total of about 88 square kilometers (22,000 acres). The amount of land actually occupied by new facilities would range from about 35 hectares (86 acres) to about 38 hectares (93 acres). Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1 square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

5.16.5.1.2 Air Quality.

Air quality limits (WAC 173-470-030,-100) at the Hanford Site boundary are not expected to be approached as a result of implementing any of the suboptions in the Centralization Alternative maximum option or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory, or from decommissioning unused facilities or restoration activities.

5.16.5.1.3 Waste Management.

In the near term under the Centralization Alternative maximum option, there would be about 532 cubic meters of low-level waste generated during repackaging and containerization of SNF and sludge in the 100-K Basins. Thereafter, low-level waste generation would amount to about 140 cubic meters per year. All presently anticipated activities on the Hanford Site would result in approximately 20,000 cubic meters of low-level waste per year. Thus, at a maximum, SNF activities would account for about 1 percent of the total.

High-level waste that might be generated in the Centralization maximum option would not add significantly to the more than 250,000 cubic meters of waste at Hanford currently handled as high-level waste.

5.16.5.1.4 Socioeconomics.

Under the Centralization Alternative maximum option, the SNF workforce would increase by about 290 to about 900. The Hanford Site workforce is expected to drop from 18,700 in 1995 to 14,700 in 1997 and remain around 14,700 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period. The maximum change with respect to the regional workforce would be an increase of about 1 percent.

5.16.5.1.5 Occupational and Public Health.

The cumulative population dose since plant startup was estimated to be about 100,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 50 (essentially all of which would be attributed to exposures in the 1945-52 time frame). In the 50 years since plant startup, the population of interest (assuming a constant population of 380,000) would have received 5,000,000 person-rem from naturally occurring radiation sources (natural background), which would relate to 2,500 latent cancer fatalities. In the same time about 27,000 cancer fatalities from all causes would have been expected in the region of interest .

If the Hanford sitewide contribution to public dose from all exposure pathways is considered (0.8 person-rem per year from DOE facilities and 0.7 person-rem per year from Washington Public Power Supply System reactor operation for 40 years), it is estimated that the cumulative collective dose would be approximately 60 person-rem. Additional collective population dose from implementation of the Centralization Alternative maximum option would range from 1 to 4 person-rem over 40 years (dose from 4 years of processing would dominate). Thus, in total, the collective population dose from man-made sources would remain approximately 60 person-rem. No latent fatal cancers would be expected from such a dose. Over 40 years of interim storage of SNF, the population of interest would have received 4,000,000 person-rem from naturally occurring radiation sources (natural background). That dose would relate to 2,000 latent cancer fatalities. In the same 40 years, about 21,000 cancer fatalities from all causes would be expected among the population in the region of interest (380,000 population).

Air quality limits [(40 CFR 61 Subpart H), 10 millirem per year at the Hanford Site boundary] are not expected to be approached as a result of implementing the Centralization Alternative maximum option or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory, or decommissioning of unused facilities or site restoration activities.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one latent fatal cancer might be inferred. Collective worker dose from SNF activities in the Centralization Alternative maximum option would amount to about 80 person-rem for maintenance and operations, 18 person-rem for loading storage facilities, and 180 to 320 person-rem depending on processing suboption selected.

Within the accuracy of the estimates, cumulative worker dose in the Centralization maximum option would not add significantly to the cumulative Hanford Site worker dose over 90 years as described for the No Action Alternative.

5.16.5.2 Centralization Alternative Minimum Option. Cumulative impacts

associated with implementation of the Centralization Alternative minimum option, where all SNF on the Hanford Site is shipped offsite for storage, are described in the following subsections.

5.16.5.2.1 Land Use.

The Hanford Site consists of about 1450 square kilometers (360,000 acres) of which about 87 square kilometers (22,000 acres) have been disturbed. Implementation of the Centralization Alternative minimum option would disturb up to an additional area of about 0.6 square kilometers (160 acres) for a total of about 88 square kilometers (22,000 acres). The amount of land actually occupied by new facilities would range from about 2 hectares (6 acres) to about 15 hectares (12 acres). Construction of the Environmental Restoration Disposal Facility will require disturbance of approximately 4.1 square kilometers (1.020 acres) of land. However, restoration of existing disturbed sites will compensate for this loss.

5.16.5.2.2 Air Quality.

Air quality limits (WAC 173-470-030,-100) at the Hanford Site boundary are not expected to be approached as a result of implementing the any of the suboptions in the Centralization Alternative minimum option or from reasonably foreseeable additions to the Hanford Site, e.g., construction and operation of a Laser Interferometer Gravitational-Wave Observatory, or from decommissioning unused facilities or restoration activities.

5.16.5.2.3 Waste Management.

In the near term under the Centralization Alternative minimum option, there would be about 532 cubic meters of low-level waste generated during repackaging and containerization of SNF and sludge in the 100-K Basins. Thereafter, low-level waste generation would range from 110 to 490 cubic meters per year. All presently anticipated activities on the Hanford Site would result in approximately 21,000 cubic meters of solid waste per year. Thus, at a maximum, SNF activities would account for about 2 percent of the annual generation of low-level waste at the Hanford Site.

High-level waste that might be generated in the Centralization mininim option would not add significantly to the more than 250,000 cubic meters of waste at Hanford currently handled as high-level waste.

5.16.5.2.4 Socioeconomics.

Under the Centralization Alternative minimum option, the SNF workforce would increase by about 390 to about 590. The Hanford Site workforce is expected to remain at about 18,000 from 1995 through 2004. The regional workforce is expected to range from 81,000, to 86,000 in that same period. The maximum change with respect to the regional workforce would be an increase of about 0.7 percent.

5.16.5.2.5 Occupational and Public Health.

The cumulative population dose since plant startup was estimated to be about 200,000 person-rem (estimated to one significant figure; Section 4.12.2.4.2). The number of inferred fatal cancers since plant startup would amount to about 50 (essentially all of which would be attributed to exposures in the 1945-52 time frame). In the 50 years since plant startup, the population of interest (assuming a constant population of 380,000) would have received 5,000,000 person-rem from naturally occurring radiation sources (natural background), which would relate to 2,500 latent cancer fatalities. In the same time about 24,000 cancer fatalities from all causes would have been expected in the region of interest.

Cumulative spent fuel worker dose from plant startup to date was estimated at about 2,000 person-rem (Section 4.12.1.2), from which one latent fatal cancer might be inferred. Collective worker dose from SNF activities in the Centralization Alternative minimum option would amount to about 80 person-rem for maintenance and operations, 18 person-rem for loading storage facilities, and 180 to 320 person-rem depending on processing suboption selected. Thus the total collective 40-year worker dose would be from about 300 to 420 person-rem.

Within the accuracy of the estimates, cumulative worker dose in the Centralization minimum option would not add significantly to the cumulative Hanford Site worker dose over 90 years as described for the No Action Alternative.

5.17 Adverse Environmental Impacts that Cannot be Avoided

Unavoidable adverse impacts that might arise as a result of implementing the alternatives for interim storage of SNF at the Hanford Site are discussed in the following subsections.

5.17.1 No Action Alternative

Adverse impacts associated with the No Action Alternative would derive from the expense and radiation exposure associated with maintaining facilities that are near or at the end of their design life and the possible future degradation of fuel and facilities, thus increasing the potential for releases of materials to the environment.

5.17.2 Decentralization Alternative

Adverse impacts associated with the Decentralization Alternative would derive principally from construction activities needed for new facilities. There would be displacement of some animals from the construction site and the destruction of plant life within the site up to 9 hectares (24 acres). Criteria pollutants, radionuclides, and hazardous chemicals would also be released in up to permitted quantities during processing preparations. Traffic congestion and noise are expected to increase by a few percent during the construction of major facilities. Competition for adequate housing would increase in the already tight market, and capacities at some of the local school would be moderately strained with approximately 0.5 to 1.5 percent additional students, depending on which processing and/or storage option were chosen.

5.17.3 1992/1993 Planning Basis Alternative

Adverse impacts associated with the 1992/1993 Planning Basis Alternative would be essentially the same as those for the Decentralization Alternative. If transport of any amount of SNF were considered an adverse impact, that impact would occur in this alternative if the small amount of TRIGA fuel at Hanford were transported to INEL.

5.17.4 Regionalization Alternative

Unavoidable adverse environmental impacts for the Regionalization Alternative range from those of the Centralization (Minimum) Alternative for Regionalization C where all Hanford SNF is shipped offsite to essentially those of the Centralization (Maximum) Alternative for Regionalization B2 where all SNF west of the Mississippi River including Naval SNF is shipped to Hanford.

5.17.5 Centralization Alternative

In the option where Hanford receives all DOE SNF, adverse impacts would be somewhat larger than those associated with implementing the Decentralization Alternative because about 25 weight percent more fuel than already exists on the Hanford Site would need to be stored; however, higher heat loads on that fuel might nearly triple the capacity needed for storage. Transport of that 25 weight percent of SNF to the Hanford Site also likely would be viewed as an adverse impact.

In the option where Hanford ships all of its fuel to another site, adverse impacts would be associated with construction and operation of a fuel packaging facility. The impacts, however, would be expected to be substantially less than those noted for the Decentralization Alternative. Transporting a relatively large amount of SNF offsite to another DOE facility also likely would be considered an adverse impact.

5.18 Relationship Between Short-Term Uses of the Environment and the Maintenance and Enhancement of Long-Term Productivity

SNF storage is contemplated for up to 40 years pending decisions on ultimate disposition. SNF is essentially uranium-238 with varying amounts of uranium-235 and small amounts of plutonium contaminated by small masses of fission products (but high activity). Because of this composition, a decision could be made at the end of the planned storage period to either continue storage until the energy resource value of the SNF warrants processing for power-reactor fuel or to determine that the fuel will never have any resource value and will be disposed of. If the decision is to continue to store the SNF, that option could be seen as the best use of land at the Hanford Site in terms of long-term productivity. This conclusion would apply to all of the alternatives except for the Regionalization C Alternative and the Centralization Alternative with storage at other than Hanford.

If the decision is to dispose of the SNF or if the non-Hanford centralization option for storage is selected, the land on the Hanford Site would become available for other uses. Because of the potential for, or perception of, contamination, use of the land for agriculture might not be appropriate. Moreover, the land occupied (or that would be occupied) by SNF facilities was of marginal utility for farming before it was obtained for the Hanford Site, and it remains so. However, other uses, such as for wildlife refuges, might be appropriate long-term uses of land vacated by SNF facilities after decommissioning is completed.

5.19 Irreversible and Irretrievable Commitment of Resources

This section addresses the irretrievable commitment of resources that would likely be used to implement the proposed project or its alternatives. An irretrievable resource is a natural or physical resource that is irreplaceably lost and cannot be replenished.

Implementation of the proposed project would result in the irretrievable use of fossil fuels in construction activities and in the transport of raw materials to the project site. In addition, there would be an irretrievable use of electricity and fossil fuel in the SNF operations. Briefly summarized below are discussions of irretrievable and irreversible resource impacts for each alternative.

5.19.1 No Action Alternative

The irreversible and irretrievable commitment of resources for the No Action Alternative would include an additional increment of energy, materials, and manpower to maintain safe and secure facilities. A new SNF facility would not be built, and Hanford SNF would continue to be managed in the current mode.

If the No Action Alternative were implemented, the following facilities would likely be used at the Hanford Site to maintain continued safe and secure storage of SNF: the 105-KE and KW Basins, FFTF, T-Plant, and the 308, 324, 325, and 327 buildings. Excluding energy and materials expended during construction of minor facilities to maintain safety and security, the operational staff is estimated at 215 personnel, and electrical power consumption is estimated to be 12,000 megawatt hours per year. This alternative represents less than a 2 percent increase in existing personnel at the Hanford Site and a negligible increase in the total amount of electrical energy currently used at the Hanford Site.

5.19.2 Decentralization Alternative

The irreversible and irretrievable commitment of resources for the Decentralization Alternative would include an additional increment of energy, materials, and personnel. Existing Hanford Site SNF would be safely stored for a 40-year period, with some limited SNF shipments. To accommodate this mission, existing facilities would require upgrading and new storage systems would need to be constructed. Various options have been proposed on which facilities to build and how to upgrade existing ones, but it has not been determined exactly which kind of facilities would need to be built. A representative set of values is presented in Table 5.19-1, which roughly indicates the material, personnel, and energy commitments. Depending on the option chosen, the alternative could require less than a 1.5 percent increase or up to a 33 percent increase (but only for 4 years) in the total amount of electrical energy currently used at the Hanford Site.

In addition to energy increases, additional water resources would be required for this alternative, but are not expected to be an excessive amount, compared to the more than 15 million cubic meters (4 billion gallons) of water used each year on the Hanford Site for all processes.

Table 5.19-1. Irretrievable commitment of materials in the Decentralization Alternative suboptions.

Item	Suboption					
	W	X	Y	Z	P	Q
Concrete,	13 (17)	15 (20)	17	24 (32)	22 (29)	29 (38)

thousand cubic meters/(cubic yards)			(23)			
Lumber, thousand cubic meters (board feet)	1.2 (500)	1.4 (570)	1.6 (650)	2.2 (930)	2.0 (850)	2.6 (1100)
Electricity						
Construction (MW--hrs)	2500	2900	3500	4800	4370	5700
Operations (MW-hrs/yr)	1600	1600	100	100	40,000	127,000
Diesel fuel, cubic meters (thousand gallons)	500 (130)	570 (150)	660 (175)	900 (240)	830 (220)	1100 (290)
Gasoline, cubic meters (thousand gallons)	500 (130)	570 (150)	660 (175)	900 (240)	830 (220)	1100 (290)

a. Assumes operation of the process facility (28,000 or 115,000 MW-Hrs/yr) concurrently with those facilities where SNF is currently stored (12,000 MW-Hrs/yr, as in the No Action Alternative) for an interim period less than 4 years.

5.19.3 1992/1993 Planning Basis Alternative

The irreversible and irretrievable commitment of resources for the 1992/1993 Planning Basis Alternative would be very similar to those for the Decentralization Alternative. The materials, personnel, and energy estimates are assumed to approximate those stated in the Decentralization Alternative.

5.19.4 Regionalization Alternative

The Regionalization Alternative as it applies to the Hanford Site contains the following options:

- Option A - All SNF except defense production SNF would be sent to INEL.
- Option B1 - All SNF west of the Mississippi River except Naval SNF would be sent to Hanford.
- Option B2 - All SNF west of the Mississippi River and Naval SNF would be sent to Hanford.
- Option C - All Hanford SNF would be sent to INEL or NTS.

With the exception of Option C, which for Hanford is equivalent to the Centralization Alternative minimum option, the irretrievable and irreversible commitment of material resources are provided in Tables 5.19-2 through 5.19-4.

5.19.5 Centralization Alternative

The Centralization Alternative has two major options: either all Hanford SNF would be shipped offsite to another DOE facility where all SNF would be centralized (minimum option), or the Hanford Site would become the centralized location for all DOE SNF to be temporarily

Table 5.19-2. Irretrievable commitment of material resources in the Regionalization A suboptions.

Item	Suboption W	X	Y	Z	P	Q
Concrete, thousand cubic meters/(cubic yards)	9 (12)	9 (12)	16 (21)	19 (25)	22 (29)	29 (38)

Lumber, thousand cubic meters (board feet)	0.8 (350)	0.8 (350)	1.4 (600)	1.7 (700)	2.0 (850)	2.6 (1100)
Electricity						
Construction (MW-hrs)	1800	1800	3200	3800	4370	5700
Operations (MW-hrs/yr)	1600	1600	100	100	40,000a	127,000a
Diesel fuel, cubic meters (thousand gallons)	380 (100)	380 (100)	610 (160)	720 (190)	830 (220)	1100 (290)
Gasoline, cubic meters (thousand gallons)	380 (100)	380 (100)	610 (160)	720 (190)	830 (220)	1100 (290)

a. Assumes operation of the process facility (28,000 or 115,000 MW-Hrs/yr) concurrently with those facilities where SNF is currently stored (12,000 MW-Hrs/yr, as in the No Action Alternative) for an interim period less than 4 years.

Table 5.19-3. Irretrievable commitment of material resources in the Regionalization B1 option.
(In addition to those listed for the Decentralization Alternative)

Concrete, thousand cubic meters/(cubic yards)	54 (70)
Lumber, thousand cubic meters (board feet)	5 (2,000)
Electricity, megawatt hours per year	3.000
Diesel fuel, cubic meters (thousand gallons)	1,900 (500)
Gasoline, cubic meters (thousand gallons)	1,900 (500)

Table 5.19-4. Irretrievable commitment of material resources in the Regionalization B2 option.
(In addition to those listed for the Decentralization Alternative)

Concrete, thousand cubic meters/(cubic yards)	120 (150)
Lumber, thousand cubic meters (board feet)	10 (4,200)
Electricity, megawatt hours per year	3,000
Diesel fuel, cubic meters (thousand gallons)	4,400 (1,200)
Gasoline, cubic meters (thousand gallons)	4,400 (1,200)

stored (maximum option). The increases in energy, materials, and personnel for both options are shown in Table 5.19-5. If all the SNF were shipped to the Hanford Site, then the impacts would be similar, although somewhat larger, than those of the Regionalization B options. If all the SNF were shipped offsite, then the impacts would be identical to the similar Regionalization B options. If all SNF were shipped offsite, construction and operation of a fuel packaging facility would be necessary before shipments could be made to an offsite facility.

5.20 Potential Mitigation Measures

This section summarizes possible mitigation measures that might be considered to avoid or reduce impacts to the environment as a result of Hanford Site operations in support of SNF management. These measures would be reviewed and revised as appropriate, depending on the specific actions to be taken at a facility, the level of impact, and other pertinent factors.

Table 5.19-5. Irretrievable commitment of materials in the Centralization options.

Item	No Fuel Stored at the Hanford Site	All Offsite Fuel Stored at the Hanford Site
Concrete, thousand cubic meters (cubic yards)	18 (23)	150 (200)
Lumber, thousand cubic meters (board feet)	1.6 (660)	13 (5600)
Electricity, megawatt hours per year	0-20,000	100-127,000
Diesel fuel, cubic meters (thousand gallons)	640 (170)	5700 (1500)
Gasoline, cubic meters (thousand gallons)	640 (170)	5700 (1500)

Possible mitigation measures are generally the same for all alternatives and are summarized by resource category below. No impacts on land use and aesthetic and scenic resources were identified; therefore, mitigation measures would not be necessary.

5.20.1 Pollution Prevention/Waste Minimization

The U.S. Department of Energy is responding to Executive Order 12856 and associated DOE orders and guidelines by reducing the use of toxic chemicals; improving emergency planning, response, and accident notification; and encouraging the development and use of clean technologies and the testing of innovative pollution prevention technologies. Program components include waste minimization, source reduction and recycling, and procurement practices that preferentially procure products made from recycled materials. The pollution prevention program at the Hanford Site is formalized in a Hanford Site Waste Minimization and Pollution Prevention Awareness Program Plan.

The SNF program activities would be conducted in accordance with this plan and implementation of the pollution prevention and waste minimization plans would minimize the generation of waste during SNF management activities.

5.20.2 Socioeconomics

The level of predicted employment for SNF activities at the Hanford Site is not large enough in comparison with present Hanford, local, or regional employment to produce a boom-bust impact on the economy.

5.20.3 Cultural (Archaeological, Historical, and Cultural) Resources

To avoid loss of cultural resources during construction of SNF facilities on the Hanford Site a cultural resources survey of the area of interest would be conducted by PNL Cultural Resources staff. Assuming no such resources were found, construction would proceed. If, however, during construction (earth moving) any cultural resource is discovered, construction activities would be halted and the PNL Cultural resources staff called upon to evaluate and determine the appropriate disposition of the find.

To avoid loss of cultural resources during operation, such as unauthorized artifact collection, workers could be educated through programs and briefing sessions to inform them of applicable laws and regulations for site protection. These educational programs would stress the importance of preserving cultural resources and specifics of the laws and regulations for site protection. The exact location of cultural resources are not identified by the PNL Cultural Resources group; therefore, any such artifact collection would be in an area discovered by the worker(s).

5.20.4 Geology

Soil loss would be controlled during construction using standard dust suppression techniques on disturbed soil and by stockpiling with cover where necessary. Following construction, soil loss would be controlled by revegetation and relandscaping of disturbed areas. Any soil that might become contaminated as a result of SNF management activities could be remediated using methods appropriate to the type and extent of contamination.

5.20.5 Air Resources

To avoid impacts associated with emissions of fugitive dust during construction activities, exposed soils would be treated using standard dust suppression techniques. New facility sources of pollutant emissions to the atmosphere would be designed using best available technology to reduce emissions to as low as reasonably achievable.

5.20.6 Water Resources

The impacts to surface and groundwater sources could be minimized through recycling of water, where feasible, and with clean-up of excess process water before release to ground or surface water.

5.20.7 Ecology

To avoid impacts to endangered, candidate, or state-identified sensitive species, pre-construction surveys would be completed to determine the presence of these species or their habitat. Within six months of ground breaking, DOE would again consult with the U.S. Fish and Wildlife Service to determine current species listings and perform a biological survey of the proposed SNF site. The presently proposed site at Hanford has been surveyed and no currently listed species were found. While not endangered, stands of Big Sagebrush habitat are diminishing generally and Hanford would expect to implement its habitat replacement program to provide areas on at least a 2 to 1 basis to mitigate habitat loss. In addition, areas disturbed would, as appropriate, be seeded with native plant species.

5.20.8 Noise

Generation of construction and operations noise would be reduced, as practicable, by using equipment that complies with EPA noise guidelines (40 CFR Parts 201-211). Construction workers and other personnel working in environments exceeding EPA-recommended guidelines during SNF storage construction or operation would be provided with earmuffs or earplugs approved by the Occupational Safety and Health Administration (29 CFR Part 1910). Because of the remote location of the Hanford SNF activities, there would be no noise impacts with respect to the public for which mitigation would be necessary.

5.20.9 Traffic and Transportation

At sites with increasing traffic concerns, DOE could encourage use of high-occupancy vehicles (such as vans or buses), implementing carpooling and ride-sharing programs, and staggering workhours to reduce peak traffic.

5.20.10 Occupational and Public Health and Safety

Although no radiological impacts on workers or the public were evident from the evaluation of routine SNF activities at Hanford, further improvement in controls to protect both workers and the general public is a continuing activity. The as low as reasonably achievable (ALARA) principle would be used for controlling radiation exposure and exposure to hazardous/toxic substances. Hanford would continue to refine its current emergency planning, emergency preparedness, and emergency response programs in place to protect both workers and the public.

5.20.11 Site Utilities and Support Services

No mitigation measures beyond those identified for ground disturbance activities associated with bringing power and water to the SNF site would appear necessary. In those cases use of standard dust suppression techniques and revegetation of disturbed areas would mitigate ground disturbance impacts.

5.20.12 Accidents

The Hanford Site maintains an emergency response center and has emergency action plans and equipment to respond to accidents and other emergencies. These plans include training of workers, local emergency response agencies (such as fire departments) and the public communication systems and protocols, readiness drills, and mutual aid agreements. The plans would be updated to include consideration of new SNF facilities and activities. Design of new facilities to current seismic and other facility protection standards would reduce the potential for accidents, and implementation of emergency response plans would substantially mitigate the potential for impacts in the event of an accident.

6. LIST OF PREPARERS

Rosanne L. Aaberg, dose calculations. B.S. (Chemical Engineering) University of Washington. Seventeen years of experience in dose calculations, and EIS preparation.
John C. Abbott, affected environment and environmental impacts. BA. (Geography) Southwest Texas State University, M.S. (Conservation of Natural Resources) University of Texas at San Antonio. Over seventeen years of experience in the preparation of NEPA documents, ecological risk assessment evaluations, regulatory compliance activities, and other program oversight activities.
John M. Alvis, Jr., facility descriptions. B.S. (Nuclear Engineering) and M.S. (Nuclear Engineering) Texas A&M University. Six years of experience in reviewing safety analyses, licensing submittals, and contributing to the development of safety policies and guidance. Assisted in the technical review of licensee documents for NRC.
Larry K. Berg, meteorology. B.S. (Meteorology) Pennsylvania State University. One year of experience in analyzing air quality and air resource parameters.
Frances M. Berting, fuel inventories. BA. (Physics) Oberlin College, MA. (Physics) Smith College, Ph.D. (Materials Science) University of Virginia. Characterization of high temperature gas-cooled reactor spent fuel, characterization of N Reactor spent fuel, and experience with non-destructive and destructive examination of irradiated fuel elements. Prepared NRC annual reports on fuel performance at commercial power plants and a report on commercial spent fuel reracking.
Charles A. Brandt, ecological characterization. B.S. (Zoology) Oregon State University, Ph.D. (Zoology) Duke University. Over ten years of experience as a terrestrial ecologist involved in ecological restoration, ecological risk and impact assessment, and conservation biology. Extensive experience in preparation and analysis of NEPA-related documentation.
Mitchel E. Cunningham, spent nuclear fuel management. B.S. (Nuclear Engineering) and M.S. (Nuclear Engineering) Oregon State University. Several years of experience in such projects as the behavior of spent fuel during both inert and air dry storage, investigating in-reactor fission gas release, and the development of integrated computer codes for predicting nuclear fuel rod behavior.

Colbert E. Cushing, deputy project manager, ecological resources. B.S. (Fisheries Management) and M.S. (Limnology) Colorado State University, Ph.D. (Limnology) University of Saskatchewan. Thirty-four years of experience in freshwater ecological research in streams and radioecology, and over twenty years of experience in EIS preparation. Teach university classes in stream ecology and writing journal articles.

Phillip M. Daling, transportation impacts. B.S. (Physical Metallurgy) Washington State University. Related experience includes performing transportation impact calculations for various EIS and environmental assessments and in support of environmental documentation for over ten years.

James F. Donaghue, materials and waste management. B.S. (Civil Engineering) University of Arkansas, J.D. Golden Gate School of Law. Nine years of experience in environmental planning compliance activities. Reviewed EISs and prepared portions of EISs and environmental assessments for Air Force construction projects. Involved in the analysis of alternatives and writing for the DOE Environmental Restoration Programmatic EIS.

Elizabeth A. Flores, materials and waste management. B.S. University of Connecticut, MA. (Environmental Studies) Yale University. Twelve years of experience in environmental protection and waste management. Assistant Director for Connecticut Department of

Environmental Protection for RCRA program.

Stephen Gajewski, regulatory framework and requirements. BA. (English) and BA. (Psychology) Gonzaga University. J.D. University of Washington. Over fourteen years of experience in geotechnical operations planning, land management and environmental regulatory compliance, including quality assurance on commercial power reactors, onshore and offshore oil and gas exploration, industrial hygiene program development and training, and environmental strategic planning.

Clifford S. Glantz, non-radiological air quality impacts. B.S. (Physics and Atmospheric Sciences) State University of New York at Albany, M.S. (Atmospheric Sciences) University of Washington. Twelve years of experience in the analysis of non-radiological air quality impacts.

Richard J. Guenther, alternatives and facilities descriptions. B.S. (Engineering Physics), M.S. (Nuclear Engineering), and Ph.D. (Nuclear Engineering) Oregon State University. Over fifteen years of experience testing and evaluating nuclear fuels to determine their characteristics and performance under reactor operating conditions, wet and dry interim storage, and long-term storage in a monitored retrievable or geologic storage environment.

George V. Last, cultural resources and land use. B.S. (Geology) Washington State University. Eighteen years of experience in geological research and cultural resources studies. Extensive experience in preparation and review of NEPA-related documents.

John P. McDonald, water quality and related consequences. A. .S. (Computer Science) and A.S. (Arts and Science) Columbia Basin College, B.S. (Geology) Eastern Washington University. Four years of experience in conceptual model development of groundwater flow systems, collection of hydraulic head data, and determination of groundwater flow rate and direction, hydraulic testing to determine aquifer properties, testing and maintenance of the waterborne portion of a multiple environmental media computer model, and application of numerical and analytic computer models to environmental problems

Emmett Moore, project manager. B.S. (Chemistry) Washington State University, Ph.D. (Physical Chemistry) University of Minnesota. Twenty years of experience in environmental regulation, participation in and management of the preparation of environmental permits and documentation (NEPA). University professor of physics, chemistry, and environmental sciences.

Iral C. Nelson, deputy project manager, environmental consequences. B.S. (Mathematics) University of Oregon, MA. (Physics) University of Oregon, diplomate, American Board of Health Physics. Thirty-eight years of experience in various aspects of health physics (radiation protection) and twenty years of experience in conducting NEPA reviews and preparing NEPA documentation.

Ronald C. Phillips, geology and water resources. B.S. (Biology) Wheaton College, M.S. (Botany) Florida State University, Ph.D. (Botany) University of Washington. Wetlands ecologist including delineation and mitigation of freshwater wetlands. Several years of experience in the preparation and review of categorical exclusion documents, review of environmental assessments, and preparation of biological assessments.

Kathleen Rhoads, air quality and accident analysis. B.S. (Microbiology) and M.S. (Radiological Sciences) University of Washington. Nineteen years of experience in the analysis of risk assessment variables, estimation of radiation does following routine or accidental release of radionuclides to the environment, and evaluation of health effects from energy production.

Chikashi Sato, water quality and related consequences. B.S. (Chemical Engineering) Fukushima National College of Technology, M.S. (Environmental Health Engineering) University of Kansas, Ph.D. (Environmental Engineering) University of Iowa. Thirteen years of experience in university teaching, application of the Multimedia Environmental Pollutant Assessment System (MEPAS), and performance of fate and transport analysis at waste sites.

Dillard B. Shipler, Introduction and review. B.S. (Mathematics and Science) Southern Oregon College, M.S. (Physics) University of Wisconsin-Milwaukee, other studies at University of Oregon, Oregon State University, Reed College, University of Nevada, and University of Washington. More than thirty years of experience in the planning and management of major programs on regulatory compliance, radiological protection, environmental impact assessment, radiological waste management, and environmental safety and health protection.

Donna J. Stucky, socioeconomics. BA. (Economics) Pacific Lutheran University, M.S. (Agricultural Economics) Purdue University. Two years of experience in the compilation of economic data relating to eastern Washington State.

Betty Tegner, editor. BA. (English) University of Washington, MA. (English) California Polytechnical State University. Previous experience in journalism and university teaching. Five years of experience in technical editing.

Gene Whelan, water quality and related consequences. B.S. (Civil Engineering) Pennsylvania State University, M.S. (Mechanics and Hydraulics) University of Iowa, Ph.D. (Civil and Environmental Engineering) Utah State University. Seventeen years of experience in multimedia contaminant environmental exposure assessments.

Mona K. Wright, cultural resources and land use. BA. (Anthropology) Eastern Oregon State College, MA. (Anthropology) Washington State University. Fifteen years experience in cultural resource management, Federal regulations including the National Historic Preservation Act, the NEPA, Executive Order 11593, the Archaeological Resources Protection Act of 1979, and the

Native American Grave Protection and Repatriation Act, and historic and prehistoric site identification and recording.

ATTACHMENT A

FACILITY ACCIDENTS

Methods used to evaluate facility accidents associated with implementing the alternatives for SNF storage at Hanford are discussed in this attachment. The selection of radiological accidents for the analysis was based on information available in previously published safety or National Environmental Policy Act documents, as described in Section 5. 15. Analyzed releases of nonradiological hazardous materials were based on actual or expected inventories at SNF management facilities using conservative release assumptions. Industrial construction and operational accidents are also evaluated based on the person-years needed to build and operate SNF facilities.

A.1 Radiological Accidents

The GENII computer code (Napier et a!. 1988) was used to perform calculations for each facility to estimate the consequences of radionuclide releases to the atmosphere for onsite workers, members of the public at accessible locations on or near the site, individual residents at the site boundary, and the population within 80 km of the release location. Dose calculations used standard assumptions for the Hanford Site (Schreckhise et a!. 1993), and health effects were estimated using recommendations of the International Commission on Radiological Protection in its Publication 60 (ICRP 1991). The risks of cancer and other long-term stochastic health effects as estimated by ICRP (1991) are based on populations exposed to relatively high doses of radiation at high dose rates. For estimating risk to populations where the total doses are below 20 rad, the ICRP recommended a low-dose reduction factor equal to 2. In this analysis, where accidents would yield individual dose estimates greater than 20 rad, the ICRP risk factors are used without the low dose correction to obtain the potential health effects.

Individual doses were estimated based on exposure of the receptor during the entire release, except where the release was sufficiently tong that it could be divided into short-term and long-term components. In that case, onsite workers and members of the public at accessible onsite locations were assumed to remain in the path of the plume for the duration of the short-term component. The exposure duration for onsite individuals was assumed to be two hours, corresponding to the maximum time required to evacuate the Hanford Site in the event of an accident, and no ingestion pathways were considered. Offsite individuals were assumed to be exposed during the entire release, regardless of the accident duration. Because protective action guidelines specify mitigative actions to prevent consumption of contaminated food, the dose to offsite individuals and populations was estimated both with and without the food ingestion pathways. Reduced exposure to the plume or to contaminated ground surface as a result of early evacuation of offsite populations was not considered for the purposes of this analysis, although such action would certainly be taken in the event of a severe accident at the site.

Individual dose calculations were performed using atmospheric dispersion parameters that represented 95 percent conditions (i.e., the air concentrations used would not be exceeded more than S percent of the time). In the case of collective dose, the area surrounding the source was divided into 16 directions and 10 sectors by distance, and the dose was calculated for only the direction resulting in maximum collective exposure. Dose to the population was calculated using both 50 percent and 95 percent atmospheric dispersion parameters.

A.1.1 No Action Alternative

The No Action Alternative consists of fuel storage at existing Hanford facilities, including the 100-K Area wet storage basins; T Plant and a low-level burial ground in the 200-West Area; the 308, 324, 325, and 327 buildings in the 300 Area; and the Fast Flux Test Facility in the 400 Area. Maximum reasonably foreseeable accidents determined by Previously published analyses were used for this evaluation, and the impacts of these accidents were reevaluated using a consistent set of parameters for the spectrum of receptors required for this document.

A.1.1.1 105-KE and 105-KW Basin Wet Storage. Airborne releases from the fuel

storage pool are bounded by a postulated accident for the 105-ICE and l05-KW Basins. In the accident, a cask is dropped and overturned in the fuel transfer area, with broken fuel elements spilling out of the cask, within the pool building, but away from the pool. The scenario assumes that the shipping cask ruptures, exposing all of the broken fuel elements in three canisters: 42 fuel elements each containing 22.5 kilograms (50 pounds) of fuel. The probability of this accident is estimated as 10(-4) to 10(-6) per year. The analysis assumes lO-year-old fuel-grade fuel (12 percent of plutonium content is Plutonium.240). The source term is calculated by multiplying the inventory at risk by the release fraction. The calculation of the release fractions assumes the fuel heats but does not melt. Also, site evacuation is assumed, giving a two-hour time for calculation of the onsite release factor. The offsite release factor was calculated using an eight-hour release time. The calculated release quantity was 61 grams (0.14 pounds) for onsite exposure and 244 grams (0.54 pounds) for offsite exposure, resulting in the radionuclide releases listed in Table A-1. Recalculation of the doses for this analysis yields the results in Table A-2.

Table A-1. Estimated radionuclide releases for a dropped fuel casket accident in the 105-K wet storage basins.

Table A-2. Consequences of 105-KE Basin cask drop accident.

A cask drop involving broken fuel elements falling out of the cask would most likely be observed by the workers, who would also be alerted by area radiation alarms and the radiation monitor in attendance of a change in radiation intensity. The assumed 12 workers would likely be in Special Work Permit protective clothing, but typically would not be wearing respiratory protection. The workers would immediately evacuate the area to reduce their exposure to direct radiation (by increasing their distance from the source), for which their clothing provides no protection. Once at a distance, they would move upwind of the postulated airborne release before beginning decontamination procedures. Assuming the workers evacuate within 1 to 2 minutes, their dose would range from about 70 to 140 rem. Using risk factors cited previously, the maximum probability of an individual contracting a fatal cancer from a dose of 140 rem would amount to about 0.06. The collective worker dose for such a scenario would amount to about 1800 person-rem for which one fatal cancer would be inferred. It should be noted, however, the risk factors used are not generally intended to be applied to large acute doses and such acute doses might produce minor near term adverse health effects.

Recent preliminary analyses, based on updated information on the ability of the lOS-K Basins to withstand natural forces indicate that seismic-induced damage at the 105-K Basins could, under some circumstances, result in radiation exposure to the public and workers greater than that indicated in this EIS. The underlying concern is whether the fuel in its present condition could become uncovered by loss of the basin water thereby resulting in larger releases of radionuclides to the atmosphere; in the present analysis the fuel is assumed to remain covered. A scenario in which the fuel would remain exposed to the air and allowed to burn is not considered a reasonably foreseeable accident for the time period covered by this EIS.

---

a. cute doses of this magnitude are in the lower end of the range of doses that might produce symptoms of acute radiation syndrome in humans.

A.1.1.2 Liquid Release Scenario for 105-KE or 105-KW Basin. Accidental liquid releases from the 105-K Basins are bounded by seismic events or other mechanical disruption of the basin or its water supply system. The most probable scenario is a break in an 8-inch water supply line that overfills the storage pool causing water to overflow onto the surrounding soil (Bergsman 1995). The flow is assumed to continue for 8 hours before the supply is shut off, resulting in release of 2300 cubic meters (600,000 gallons) of water and 60% of the radionuclide inventory m the pool water. The inventory released from the 105-ICE Basin is assumed to be 13 Ci tritium, 0.029 Ci cobalt-60, 9.2 Ci strontium-90, 0.042 Ci cesium-134, 12 Ci cesium-l37/barium-137m, 0.0098 Ci plutonium-238, and 0.056 Ci plutonium-239.

The corresponding radionuclide inventory m the 105-KW Basin overflow pond is assumed to be as follows: 0.48 Ci tritium, 0.0013 Ci cobalt-60, 0.0031 Ci cesium-134, 0.22 Ci cesium-137, 1.1 Ci strontium-90, 5.9E-06 Ci plutonium-238, and 3.lE-05 Ci plutonium-239. The overflow is assumed to leach through the subsurface environment to the Columbia River. Because the transmission rate of the soil is estimated as 570 centimeters per day [based on DOE's Programmatic Environmental Impact Statement (PEIS) (Schramke 1993)], a leaching rate of 26.3 centimeters per day (10 inches per day) will not result in a ponded situation; therefore, the entire 2300 cubic meters (600,000 gal) of overflow will leach into the soil over an eight-hour period. Contaminants are assumed to travel through the vadose zone, through the saturated zone to the Columbia River and in the Columbia River to receptors downstream. The flow discharge in the Columbia River is assumed to be under low-flow conditions of 1000 cubic meters per second (36,000 cubic feet per second) (Whelan et al. 1987), which represents the most conservative case for maximizing surface water concentrations. As a conservative assumption, the removal of water from the Columbia River is assumed to be 100 meters (328 feet) downstream of the point of entry of the contaminant into the river. The assessment addressed recreational activities (e.g., boating, swimming, fishing) in the Columbia River and use of the water as a drinking-water supply and for bathing, irrigation, etc. The collective risk of fatal cancer from the spill at the 105-KW Basin was estimated as approximately 1.1 x 10.13 fatal cancers for the maxiinum pathway and radionuclide (ingestion of plutonium-239 in fish) at 2800 years. The cumulative risk from all radionuclides and pathways amounted to approximately 6 x 10(-13) fatal cancers. The corresponding risks from a spill at the 105-KE Basin were 2 x 10(-10) fatal cancers for the maximum nuclide and pathway (also from ingestion of plutonium-239 in fish), and about 6 x 10.10 fatal cancers for all radionuclides and pathways (Whelan et al. 1994).

The overflow scenario described in the previous paragraph has been extrapolated to include a larger release because of recent concerns about the effects of a seismic event severe enough to breach joints in the basin. A crack in the basin would potentially release all of the basin water and perhaps some of the sludge to the subsurface environment, where it would be available for leaching to groundwater and transport to the Columbia River. Because the liquid overflow scenario assumes release of over half of the basin water, the risk to a downstream individual from release of all the basin water would be less that twice that estimated for the overflow scenario. Radionuclides in the sludge would be much less mobile and would leach into groundwater slowly, providing time for remediation and mitigation measures as necessary. Even if significant quantities of sludge remained in the subsurface soil for an extended period prior to clean up, the risk to the downstream individuals and population would not likely be substantially higher than that estimated for the overflow scenario.

This accident would not likely present any hazard to workers at the basin because the scenario is liquid to ground to groundwater and on to the Columbia River and does not involve a source of exposure to the close-in workers.

A.1.1.3 308 Building. The maximum reasonably foreseeable accident for airborne

releases related to fuel storage at the 308 Euilding is dropping a transfer basket while moving fuel from the reactor core to the storage pool (WHC 1990). It was conservatively estimated that 13 fuel elements would have their cladding damaged, resulting in the release of 100 percent of the krypton-85 to the environment in S minutes. The probability of this accident is estimated as l0(-2) to 10(-4) per year. In the Original Safety Analysis Report, the resulting dose was estimated at 0.013 rem to the worker, 8.6 x l0(-4) rem to the onsite individual, and 8.6 x lO(-5) rem at the Site boundary. Collective dose to the population was not reported in the SAR. The individual doses correspond to a probability of fatal cancer of 5.2E-06 per year for the worker, 4.3E-07 per year for the onsite member of the public, and 4.3E-08 per year at the site boundary.

This information is provided in more detail in WHC (1990), which, however, does not detail the total quantity of krypton-85 released in any of its accident scenarios. Because release quantities for krypton-85 were not available, the consequences of this accident were not re-evaluated for this analysis. Note that the SAR worker evaluation is for an individual in the facility who is assumed to evacuate within S minutes. This is a somewhat different analysis from those for the other worker consequences presented for the Hanford Site, which assume a worker remains outside the facility at the point of maximum air concentration for a period of up to 2 hours.

A transfer basket drop that results in damage to 13 fuel elements would most likely be observed by the workers, who would also be alerted by area radiation alarms and the radiation monitor in attendance of a change in radiation intensity. The assumed 12 workers would likely be in Special Work Permit protective clothing, but typically would not be wearing respiratory protection. The workers would immediately evacuate the area to reduce their exposure to direct radiation (by increasing their distance from the source), for which their clothing provides no protection. Once at a distance, they would move upwind of the postulated airborne release before beginning decontamination procedures. It was estimated (WHC 1990) that the workers would receive a dose of 13 millirem. The collective worker dose would amount to about 0.2 person-rem, and no latent cancer fatalities would be predicted for these workers.

A.1.1.4 324 Building. The greatest potential safety concern at the 324 Building comes

from a safety assessment of the current levels of potentially highly mobile radioactive material in B-Cell (PNL 1992a). The potential failure of the 324 Building exhaust ventilation system in a 0.1 g seismic event, along with shaking of highly mobile holdup material in the 324 Building hot cells, could cause a total release of 610 Ci of cesium- 137 and 310 Ci of strontium-90 within 12 hours. Of this total, approximately 55 percent (340 Ci of cesium-137 and 170 Ci of strontium-90) would be released in the first two hours. The probability of the initiating seismic event is 4 x 10A per year, and the other events leading to the release are assumed in this analysis to occur with certainty. The consequences of this accident are presented in Table A-3. In comparison to this accident, other potential releases from the building are judged to be insignificant, or they have been determined to be less probable because of radioactive material containment or handling frequency. The consequences associated with this accident are a result of existing contamination in the 324 Building hot cells, and neither its likelihood nor its severity depend on the presence of spent fuel in the facility. The actual contribution of spent fuel to releases from the accident is assumed to be negligible compared with that of other sources.

A seismic event that causes the failure of the 324 Building exhaust ventilation system and releases significant quantities of non-spent nuclear fuel-related radioactive materials from the building could occur at any time, whether or not there were workers in the building. An earthquake of sufficient intensity to cause the ventilation failure would surely be noticed by any workers in the building. In all likelihood, area radiation alarms would also sound. The assumed 50 workers would immediately evacuate the building and move to a position upwind of the building. Although speculative, the workers might receive as much as 25 rem before reaching a completely safe zone. If that were the case, they would probably be restricted from further radiation worker pending results of reading their dosimeters and completion of a medical evaluation. The maximum probability of an individual contracting a fatal cancer from such a dose would amount to about 0.02. The postulated collective dose would amount to about 1300 person-rem, from which one latent cancer fatality might be inferred. Based only on the estimated initiating earthquake frequency, the chances of these consequences occurring would be about 1 in 5,000 per year.

Table A-3. Consequences of a seismic event at the 324 Building.

A.1.1.5 325 Building. A severe earthquake, without subsequent fire, is the maximum

reasonably foreseeable accident for the 325 Building (PNL 1992b). It is postulated that an earthquake would cause windows to break but not cause general or local structural collapse. Doors may be jammed open after building evacuation, leaving additional openings for unfiltered releases. Building power or ventilation could be lost. Further damage would be caused to glove boxes and the contents of shelves and cabinets. The expected effects are considered to be the most severe that could result from a 0.135 g horizontal acceleration, corresponding to the

2 x 10(-4)per year seismic event for which protection is required by DOE design criteria for a new structure.

Radionuclide releases associated with this accident are listed in Table A-4. It should be noted that the environmental releases associated with the earthquake scenario are from all sources in the 325 Building; fuel storage activities account for only a small fraction of the total. Because these releases consist of a variety of chemical forms, the dose factors used for calculation of the consequences represented the maximum dose for all radionuclides in the total release. The consequences of this accident are presented in Table A-5.

An earthquake that results in openings for unfiltered releases from the 325 Building releasing significant quantities of non-spent nuclear fuel-related radioactive materials could occur at any time, whether or not there were workers in the building. An earthquake of sufficient intensity to cause damage to the ventilation system and possibly glove boxes and windows would surely be noticed by any workers in the building. Whether area radiation monitors alarmed or not, the assumed 50 workers would immediately evacuate the building and, once outside, would move to a position upwind of the building. Although speculative, the workers might receive as much as 3 rem before reaching a completely safe zone. The maximum probability of latent fatal cancer for such a dose would be 0.001. The postulated collective dose would amount to about 150 person-rem, from which no latent cancer fatalities would be inferred.

A.1.1.6 327 Building. The postulated maximum reasonably foreseeable accident for

fuel storage at the 327 Building consists of mechanical damage to fuel pins and subsequent fire involving reactive fuel within a hot cell (WHC 1987). Because of the variety of activities that can occur in the hot cells, specific details of the accident were not postulated. The mechanical damage would breach the pin cladding and immediately release the gaseous fission products in the fuel-cladding gap. The subsequent fire would cause complete reaction of reactive fuel forms.

Table A-4. Radionuclide releases for the 325 Building earthquake scenario. Table A-5. Consequences of a seismic event at the 325 Building.

Fission products are released to the environment through the ventilation system, which includes HEPA and activated charcoal filtration. The frequency of this accident is estimated as 10(-4) to lO(-6) per year. The hot cell inventory and the fraction of the inventory released are shown in Table A-6.

The previous analysis evaluated the most extreme case for damaged material containing the maximum aflowable limits of fission products that had not been vented to release fission gases. In this case, fuel materials involved are assumed to be nonreactive in water and to contain a maximum fission product inventory of 6.5 x 106 Ci including 2500 Ci of halogens. Radionuclide releases from the fuel into the basin water and thence into the air above the water are based on U.S. Nuclear Regulatory Commission Regulatory Guide 1.25, which addresses accidents involving spent fuel in a storage pool. The consequences of the accident as evaluated for this document are listed in Table A-7.

Table A-6. Assumed inventories and release fractions for a 327 Building hot cell fire. Table A-7. Consequences of 327 Building hot cell fire.

This accident involves mechanical damage to fuel pins, subsequent fire within a hot cell, and releases of radioactive material to the intact filtered ventilation system and on to the atmosphere. There would be no added source of radiation exposure to the close-in worker at the hot cell.

A.7.1.7 200-West Area Low-Levei Waste Btirial Grounds. The only accident

postulated to have any significant radiological releases in the Burial Ground safety analysis report is briefly described as a vehicle impact on one or more EBR II casks followed by a fire (Saito 1992). Two vehicle impact scenarios were discussed in the document:

1. Severe impact or collision followed by a short-duration fire caused by a vehicular accident in the trench.
2. Extremely severe impact or collision followed by a long duration fire.

The consequences of the latter accident were evaluated for fuels containing maitmum inventories of either fission product or transuranic radionuclides. The probability of the accident is estimated to be 9.8 x 10-6 per year. The consequences of the less severe accident would be approximately an order of magnitude lower. The radionuclide releases for accident scenario 2 are shown in Table A-8; the accident consequences as re-evaluated for this document are presented in Table A-9. The maximum fission product inventory fuel yielded the highest consequences for offsite receptors where the ingestion pathway was considered. The maximum transuranic inventory was associated with higher consequences for the inhalation and external exposure pathways.

Table A-8. Radionuclide releases for spent nuclear fuel storage at 200-West Burial Ground, accident scenario 2- extremely severe impact with long duration fire.

The severe impact or collision followed by fire as postulated here might have serious-to-fatal nonradiological consequences to drivers and passengers of the vehicles involved. It is assumed that two drivers and two passengers are involved, These individuals would evacuate the area, if they were able. Because it cannot be assured that after the collision either drivers

Table A-9. Consequences of the cask impact accident and fire at 200-West Burial Ground.

or passengers would be able to evacuate the area to a safe distance from radiological consequences, the worst case is assumed, that the four individuals perish in this accident principally from trauma caused by the collision and fire. The likelihood of these consequences occurring are estimated at 1 chance in 100,000 per year.

A.1.1.8 T Plant. The maximum scenario for fuel storage at T Plant is a dropped fuel

assembly inside the building (Jackson and Hanson 1978). The probability associated with this accident is estimated to be 2.8 x 10(-3) per year. The release estimates assume damage to a fraction of the wafers in the dropped fuel module containing 4-year-cooled Shippingport PWR Core II fuel (a conservative assumption because the fuel has now been cooled for approximately 20 years). Other release assumptions include the following:

- 10% of nonvolatile radionuclides in broken fuel are released to the building floor
- 0.1% of the released particulate matenal is resuspended in the building
- All of the volatile krypton-85 is released to the building atmosphere
- Building filtration removed 98.6 percent of the particulate materials from the effluent exiting the stack.

Release estimates for this scenario are presented in Table A-10 and the consequences of the release are listed in Table A-11.

Because workers evacuate the canyon area when fuel assemblies are being moved to or from the casks or pool, there would be no opportunity for impacts on workers from a dropped fuel assembly in fuel storage at T Plant.

Table A-10. Releases for damaged assembly of Shippingport Core II fuel with 4-year decay at T Plant.

Table A-11. Consequences of fuel assembly damage at T Plant. A.1.1.9 Fast Flux Test Facillty (FFTF). The accident scenario for the handling and storage of irradiated FFTF fuel in the Fuel Storage Facility (FSF) is a liquid metal fire (Gantt 1989). The accident scenario is a spill of 11,793 kg of liquid sodium and subsequent fire. The spill is initiated by either an internal event or a seismic event that causes a break in the piping between the FSF and heat exchangers. The liquid sodium is assumed to ignite spontaneously and burn, releasing aerosols to the atmosphere. The probability of this accident is estimated to be 10(-4) to 10(-6) per year.

The radionuclide release is from cesium that has been leached from the fuel into the sodium. It is assumed for this accident that 0.1 percent of the elements are breached and that the sodium contains 0.9 uCi cesium- 134 per gram of sodium and 5 uCi cesium-137 per gram of sodium. It is assumed that 35 percent of the sodium and cesium aerosols generated in the fire are released to the atmosphere. The total activity released is estimated as 3.7 Ci cesium- 134 and 25 Ci cesium-137. The consequences of the accident as estimated are listed in Table A-12. Onsite individuals (workers and members of the public at onsite access locations) were assumed to be exposed during 0.4 percent of the total release, because the spilled sodium would require over 20 days to burn completely, and onsite individuals were assumed to be evacuated within 2 hours.

Table A-12. Consequences of liquid metal fire at the Fast Flux Test Facility. An internal event or a seismic event that causes a break in the piping between the FSF and heat exchangers could occur whether workers were present or not. The event would surely be noticed by any workers in the building. In all likelihood, area radiation alarms would also sound. The assumed 50 workers would immediately evacuate the building and, once outside, would move to a position upwind of the building. Because this is an accident that involves a slow release of material to the atmosphere, it is speculated that dose to the close-in workers would not exceed 0.1 rem from this accident. The postulated collective dose would amount to about 5 person-rem, from which no latent cancer fatalities would be expected.

A.1.2 Decentralization Alternative

The Decentralization Alternative involves construction of several new facilities at Hanford, including new dry storage for spent fuel or a combination of new wet and dry storage. Options are also included for several types of fuel processing prior to storage. The consequences of new facilities are based on previously evaluated accidents for similar installations, adapted for the conditions and location of these facilities as assumed in this analysis.

A.1.2.1 New Wet Storage. This accident scenario is the same as that described for a

dropped fuel container at the 100-K Basins. The releases are assumed to be the same as for the accident previously described (see Table A-1), but the evaluation was repeated for potential location of the new facility adjacent to the 200-East Area. The accident frequency in the No Action Alternative is also assumed for this alternative because the quantity of fuel handled in either case would be the same. The consequences of this accident for a new facility are shown in Table A- 13.

A maximum reasonably foreseeable liquid release scenario has been postulated for the new pool storage facility for wet storage of nuclear fuels. The leak is based on a 20-cm (8-inch) water-supply pipe breaking inside of the pool building and releasing 7600 liters per minute (2000 gallons per minute). The flow is not shut off for 8 hours, resulting in 3600 cubic meters (960,000 gal) being added to the pool. Because the pool cannot handle this amount of liquid, there is an overflow of 2300 cubic meters (600,000 gal) in this 8-hour period. Because the trans-missidn rate of the soil is estimated as 570 centimeters per day (220 inches per day) [based on DOE's Programmatic Environmental Impact Statement (PEIS) (Schramke 1993)], a leaching rate of 26.3 centimeters per day (10 inches per day) will not result in ponding; therefore, the entire volume of overflow will leach into the soil over an 8-hour period. The basin overflow does contain 61 percent of the basin-water radionuclide inventory, which is estimated as 1.8 Ci. The specific radionuclide inventory in the overflow pond is assumed to be as follows: 0.48 Ci tritium, 0.0013 Ci cobalt-60,'0.031 Ci cesium-134, 0.22 Ci cesium-137, 1.1 Ci strontium-90, 5.9E-06 Ci plutonium-238, and 3.lE-05 Ci plutonium-239. All of the constituents in this assessment are radionuclides. Contaminant migration is through the vadose zone, through the saturated zone to the Columbia River, and in the Columbia River to receptors downstream. The flow discharge in the Columbia River is assumed to be under low-flow conditions of 1000 cubic meters per second (36,000 cubic feet per second) (Whelan et al. 1987), which represents the most conservative case for maximizing surface water concentrations. As a conservative assumption, the removal of water from the Columbia River is assumed to be 100 meters (328 feet) downstream of the point of entry of the contaminant into the river. The assessment addressed recreational activities (e.g., boating, swimming, fishing) in the Columbia River and use of the water as a drinking-water supply and for bathing, irrigation, etc. The overall risk of fatal cancer from this accident was found to be less than 10 chances in a billion. (Whelan et al. 1994).

Table A-13. Consequences of cask drop accident at new wet storage facility adjacent to the 200-East Area.

A cask drop involving broken fuel elements falling out of the cask at a new wet storage facility would be tile same as discussed in Section A. 1. 1. 1. No prompt radiation illness or latent cancer fatalities would be~redictcd for workers in this scenario.

The accident scenario at the 105-ICE and 105-KW Basins and its results described under the No Action Alternative would also be applicable under the Decentralization Alternative prior to transport of fuel to a new storage facility.

A.1.2.2 New Dry Storage - Small Vault or Cask Facility. The maximum reasonably

foreseeable accident for the dry storage facility is assumed to be the same as that for a previously evaluated accident involving transport of FFTF fuel (DOE 1986b). This accident is used as a surrogate for a dry storage facility accident involving an impact by either an internal or external initiator that results in a fire. The release associated with this accident is estimated at 5.4E + 02 Ci, based on the hypothetical scenario of six FFTF fuel assemblies irradiated to 150 MWD/Kg being subjected to a severe impact followed by a fire. The fuel pins rupture on impact or on heating in the fire, which burns for an hour before being extinguished. The probability of such an accident resulting in b~ach of the transport cask is estimated to be 9 x 10(-7)or lower for 100 onsite shipments of FFw fuel. The estimated frequency for this accident in tile Decentralization Alternative has been adjusted to 6 x 10(-6) per year based on the quantity of fuel that would be handled in loading the dry storage facility. Volatiles, particulates, and noble gases are released to the atmosphere. The estimated radionuclide releases are listed in Table A-14, and the radiological consequences are presented in Table A-15.

Table A-14. Estimated radionuclide releases for cask impact accident and fire at new dry storage facility, based on FFTF fuel transport.

Table A-15. Consequences of cask impact accident with fire at new dry storage facility.

An internal or external initiator that causes a breach followed by fire in a dry storage facility would surely be noticed by nearby workers. In all likelihood, area radiation alarms would also sound. The assumed 12 workers would immediately evacuate the area and, once at a safe distance, would move to a position upwind of the building. Evacuation time to that location would be measured in minutes. The dose to close-in workers is speculated to be about 3 rem. The maximum probability of latent fatal cancer from such a dose would be 0.001. The postulated collective dose would amount to about 36 person-rem, from which no latent cancer fatalities would be expected.

A.1.2.3 New Fuel Stabilization Facility. The maximum reasonably foreseeable

radiological accident for fuel processing (either calcine or solvent extraction) is a uranium metal fire in a storage vessel (DOE l986b; Bergsman 1995). The frequency of this accident is estimated at 10A to l0~ per year. Releases for the accident from a new facility adjacent to the

200-East Area are listed in Table A-16. The total release assumes that fuel burns for a period of 20 hours; therefore, doses to onsite receptors were calculated on the basis that they were exposed for 2 hours (or 10 percent of the total release, assuming a constant release rate for the duration of the fire). The consequences of the accident are listed in Table A-17.

This accident involves a uranium fire in a storage vessel with releases of radioactive material to the atmosphere. There would be no added source of radiation exposure of the close-in worker in the processing facility.

A.1.3 1992/1993 Planning Basis Alternative

Accidents and consequences would be essentially the same as those for the Decentralization Alternative.

A.1.4 Regionalization Alternative

Accidents and consequences would be essentially the same as for the Decentralization Alternative. The accident frequencies for a cask impact and fire at handling and storage facilities were adjusted to account for the quantity of imported or exported fuel handled in each of the suboptions at a receiving and canning facility or in loading storage facilities. For Regionalization A (all fuel except defense fuel would be shipped offsite) the frequency was assumed to be the same as in Decentralization (6E-06 per year). The frequency in Regionalization B (Western fuel comes to Hanford) is slightly higher (7E-06) because of the additional fuel that would be handled. The Regionalization Alternative is assigned a lower frequency (5E-06) when all SNF is shipped offsite.

Table A-16. Estimated airborne radionuclide release from shear/leach/ calcine stabilization facility as a result of maximum reasonably forseeable accident (uranium metal fire in storage vessel).

Table A-17. Consequences of uranium metal fire at fuel stabilization facility.

A.1.5 Centralization Alternative

The Centralization Alternative consists of two options at Hanford - a minimum option in which all DOE spent fuel at Hanford is transported offsite to another location for interim storage, and a maximum alternative that would result in storage of all DOE spent fuel at Hanford. Accident scenarios for the minimum option would include those discussed under the No Action Alternative prior to shipment of the fuel offsite. In addition, N reactor and SPR fuel would be stabilized prior to shipment in a facility simflar to the shear/leach/calcine facility discussed under the Decentralization Alternative. The uranium metal fire accident discussed under that alternative is assumed to be the maximum reasonably foreseeable accident for a stabilization facility in this case as well. The estimated frequency for the cask impact and fire at storage or canning and shipping facilities has been adjusted to 5 x 10(-6) per year based on the quantity of fuel that would be handled in the centralization minimum alternative.

The maximum option contains suboptions for wet or dry fuel storage with processing similar to those for the Decentralization Alternative, and the consequences are expected to be essentially the same as those described previously. The estimated frequency for the cask impact and fire at a receiving and canning or dry storage facility has been adjusted to 8 x l0~ per year based on the quantity of imported fuel that would be handled in the Centralization Alternative, maximum option. The only additional installation that would be included in this option is the Expended Core Facility (ECF), which would be relocated from the INEL. The consequences of accidents at this facility are discussed in Volume 1, Appendix D of this document. It should be noted that the accident evaluation for the ECF at Hanford in Appendix D uses assumptions that are different from those used for the Hanford accidents in this attachment and therefore the risks associated with the ECF at Hanford cannot be compared directly with those for the other Hanford facilities presented here. The consequences of the ECF accidents using Hanford Site assumptions would be higher than those presented in Appendix D.

A.2 Nonradiological Accidents

For purposes of the analysis, a worst-case accident scenario was developed for each existing and planned facility. The details of the nonradiological accident scenario are presented in this section. The scenario involves a chemical spili within a building, followed by an environmental release from the normal exhaust system. It is assumed that the building remains intact but containment measures fail, allowing release to occur through the ventilation system. It is assumed that all, or a portion of, the entire inventory of toxic chemicals stored in each building is released. The environmental releases are modeled and the hypothetical concentrations at three receptor locations are compared to toxicological limits.

A.2.1 Chemical Lists

Chemical inventory and chemical emissions lists have been developed provided by alternative and facility (Bergsman 1995). These chemical lists are of three basic types. The first type is a "worst-case chemical inventory," prepared to comply with the Emergency Planning and Community Right-To-Know Act reporting requirement. For facilities that store SNF, this lists which ones are of particular interest. The second type, presented in the Facility Costs section, is a general statement listing proposed process chemicals. The third type of list is an estimate of proposed liquid effluents and airborne emissions, presented in the Facility Discharges section. Effluent and emissions data are not presented for every option.

A.2.2 Baseline Chemical Inventory Based on Existing Facilities

A baseline inventory of chemicals kept in SNF facilities was developed from chemical Inventories for these facilities that were compiled to comply with the Emergency Planning and Community Right-To-Know Act. The existing storage facilities are 105-ICE Basin, 105-KW Basin, PUREX (202A), T Plant (22 IT), 2736-ZB Building, 200W low-level burial grounds, Fast Fuel Test Facility (FFTF) (403 Building), 308 Building, 324 Building, 325 A&B Building, and 327 Building. The Emergency Planning and Community Right-To-Know Act lists used are from 1992.

Because most facilities have various missions, the need for an inventory of chemicals at these facilities may not be related to the storage of SNF. The assumption is made that the existing inventories represent the amounts and types of chemicals that may be needed in the future.

Table A-15 lists chemicals by facility, the regulated reportable quantity (RQ) in the event of an environmental release, the maximum quantity stored, its physical state (gas, solid, liquid), the reference where the chemical is listed, the hypothetical release fraction (1 for gases, 0.1 for liquids, and 0.01 for solids), the calculated total hypothetical chemical release, and the chemical's probable use.

In the table, a solid frame around a number indicates that a stored quantity exceeds the reportable quantity for that chemical; a double-lined frame indicates that a conservative hypothetical accidental release would exceed the reportable quantity. A total of seventeen chemicals fail in the latter category and have the highest probability to be released to the air. These seventeen chemicals are the ones that would demand the highest attention in an emergency plan.

Because a reportable quantity has itt been defined for every chemical, the inherent toxicity of each chemical was also considered in assessing its importance. The release fractions used in the accidental spill scenario are conservative, higher than those reported in the literature by as much as three orders of magnitude (Hickey et al. 1991).

A.2.3 Proposed Facilities

Table A-19 is primarily derived from the Facility Costs section of the engineering design data (Bergsman 1995). However, the 105-KE Basin is used as a surrogate for a baseline chemical inventory for the wet storage facility because the Facility Cost section lists only sodium hydroxide and suffuric acid.

Table A-19 lists chemicals by facility, the regulated reportable quantity (RQ) in the event of an environmental release, the maximum quantity stored, its physical state (gas, solid, liquid), the reference where the chemical is listed, the hypothetical release fraction (1 for gases, 0.1 for liquids, and 0.01 for solids), the calculated total hypothetical chemical release, and the chemical's probable use. In the table, a solid frame around a number indicates that a stored quantity exceeds the reportable quantity for that chemical; a double-lined frame indicates that a conservative hypothetical accidental release would exceed the reportable quantity. A total of six chemicals fall in the latter category and have the highest probability to be released to the air. These six chemicals are the ones that would demand the highest attention in an emergency plan.

A.2.4 Atmospheric Modeling

Effects to onsite workers, the nearest point of pubic access, and the public at the nearest offsite residence were estimated using the computer model EPlcode (DOE 1993b). EPicode uses a straight line Gaussian plume model and characteristics of an individual chemical to estimate downwind concentrations independent of direction. The 95 percent meteorological parameters were used to determine the wind speeds and stability class used for the simulation. In each case, stability class F was used. Wind speeds of 0.89 meters per second (2.0 miles per hour) were used for calculating effects to an onsite worker, the nearest point of public access, and at the nearest offsite residence. Other criteria used in the model simulations can be found in DOE (1993a).

Table A-18. Baseline Chemical Inventory for Existing Facilities in SNF Storage Locations (Page 1)

Table A-18. Page 2 Table A-18. Page 3 Table A-18. Page 4 Table A-18. Page 5 Table A-19. Baseline Chemical Inventory for Proposed Facilities.(Page 1) Table A-19. (Page 2) Table A-19. (Page 3) A.2.5 Toxicological Limits

Results from the EPlcode model were compared to available Emergency Response Planning Guideline (ERPG) values, Immediately Dangerous to Life and Health (IDLH) values, and Threshold Limit Values/Time-Weighted Averages. In the absence of these values, toxicological data for similar health endpoints, obtained from the Registry of Toxic Effects for Chemical Substances (RTEC), are used.

Emergency Response Planning Guidelines are estimates of airborne concentration thresholds above which one can reasonably anticipate observing adverse effects (DOE 1993b). Emergency Response Planning Guideline values are specific for a substance and are divided into three general severity levels: ERPG.l, ERPG-2, and ERPG-3. ERPG-1 values result in an unacceptable likelihood that one would experience mild transient adverse health effects or perception of a clearly defined objectionable odor (DOE 1993b). ERPG-2 values result in an unacceptable likelihood that one would experience or develop irreversible or other serious health effects or symptoms that could impair one's ability to take protective action (DOE 1993b). ERPG-3 values result in an unacceptable likelihood that one would experience life-threatening health effects (DOE 1993b).

For many chemicals, ERPG levels are not defined. In these instances, Threshold Limit Value/Time-Weight Average (TLV/TWA) values are substituted for ERPG-l values. Ten percent of Immediately Dangerous to Life or Health (IDLH) values are substituted for ERPG-2 values, and IDLH values are substituted for ERPG-3 values (DOE 1993b).

Data from RTEC were used for eight chemicals. Acute toxicity data were utilized to generate exposure limits to approximate the ERPG endpoints--irritation/odor, irreversible health effects, and death.

in Chapter 7 of this Appendix

ATTACHMENT B

EVALUATION OF OPTION FOR FOREIGN PROCESSING OF SPENT
NUCLEAR FUEL CURRENTLY LOCATED AT THE HANFORD SITE

B.1 Description of Foreign Processing Alternative

This option was considered in response to a public comment requesting that foreign processing of N Reactor spent nuclear fuel (SNF) from the Hanford Site be addressed as a reasonable alternative to domestic stabilization and storage. Under this alternative, the SNF currently stored in basins at the 100-K Area of the Hanford Site would be packaged for shipment to an overseas facility where it would be processed. Only production reactor fuel stored at the 100-K Basins was considered in this analysis because it represents a large quantity of relatively homogenous material that would require stabilization in order to be suitable for 40-year storage. Small quantities of other types of fuel currently stored at Hanford either would not require stabilization or would have sufficiently different characteristics that they could not be stabilized efficiently by a single-process facility.

This analysis assumes that high-level waste (HLW) arising from the process would be returned to Hanford for interim storage, although it could potentially be stored overseas until a domestic repository was available in which to permanently dispose of it. Similarly, uranium and plutonium resulting from the processing were presumed to be returned to Hanford for interim storage; however, these materials could also be stored overseas until a decision is made on their disposition by the U.S. Department of Energy (DOE).

The following analysis was undertaken despite substantial uncertainties concerning the feasibility of long-distance transport of SNF in its current condition from the Hanford Site. Approximately half of the SNF is currently stored underwater at the 100-K West Basin in sealed, vented containers, and the remaining fuel is at 100-K East Basin in containers that are open to water. Efforts to characterize the physical and chemical state of the SNF are just getting underway, and those studies may reduce the uncertainties associated with long-distance transport of this SNF.

The SNF shipment would be required to meet national and international regulations specifying integrity of the cask seal in the event of internal pressure build-up, acceptable gas concentrations inside the cask, and allowable quantities of dispersible radionuclides. Because the defense production reactor SNF suffered damage during handling and discharge from the reactors, and because it was not designed for long-term durability in wet storage, a substantial fraction of the fuel elements have degraded during the time since reactor operations ceased (ranging from 7 to more than 20 years). The Hanford SNF in its present condition may not meet these requirements because of the quantity of dispersible radionuclides in damaged and corroding SNF, or because of heat generation and possible buildup of gases within the shipping container that might result from reactions between SNF and water in the wet overpack.

If the Hanford fuel were not able to meet the transportation requirements, the overseas processing alternative would necessitate additional expense and risk to stabilize the fuel or to divide the shipments into smaller quantities than assumed for the present analysis, perhaps to the extent that it might prove to be impractical altogether. The overland transport evaluation presented in Volume 1, Appendix I of this EIS assumed that Hanford SNF was in a stabilized form prior to shipment, as described in this appendix. Because of the uncertainties surrounding the feasibility of long-distance transport of Hanford SNF in its present condition, and to be consistent with the overland transport analysis in Appendix I, the SNF for overseas shipment is also presumed to be stabilized prior to shipment or is limited to elements that are sufficiently intact that the requirements of the transportation regulations could be met using a wet overpack shipping system. The shipment quantities assumed in the overseas transport analysis include the total mass of SNF estimated to be in the K Basins, although some of the SNF is known to exist as corrosion products and sludge, which would not be suitable for shipment without prior treatment to convert them into a less dispersible form.

B.2 Methods and Assumptions

The following sections describe the methods used to evaluate potential consequences of the overseas processing option. The analysis focuses on the activities associated with transportation of the SNF to the United Kingdom (U.K.) for processing and return of the waste and products to the U.S. The analysis also includes activities at Hanford to prepare the SNF for shipment, as well as those associated with transport and processing of the SNF within the U.K., to the extent that information was available. Information from an overseas processing facility located in the U.K. was used as the basis for this evaluation (BNFL 1994). However, the use of those facilities as a representative case would not preclude processing of SNF from Hanford at another suitable overseas installation.

B.2.1 Shipping Scenarios

Potential shipping scenarios are described in this option for transporting irradiated N Reactor fuel from the Hanford Site to the U.K., and the return of separated plutonium, uranium, and HLW to Hanford. All scenarios assume stabilization and packaging, as necessary, of the SNF currently stored in the 100-K Area Basins on the Hanford Site. From the 100 Area, the SNF would be loaded for onsite or offsite transport as required for each scenario. Offsite transport would take place via either barge, truck, or rail to a port designated as a "facility of particular hazard" in accordance with 33 CFR 126, where the shipment would be loaded onto a ship for overseas transport. The overseas segment of the shipment was assumed to utilize purpose-built ships typical of those employed by the representative processing facility in the U.K. for shipping SNF (BNFL 1994). Such a system would likely be necessary if Hanford SNF were to be shipped without prior stabilization because alternative carriers would presumably not have either the equipment or expertise required for long-distance transport of metallic SNF in a wet overpack. If the SNF were stabilized before shipment, a variety of commercial or military shipping options might be available (see DOE 1995 for a discussion of those options).

After processing of the SNF, the products and wastes were assumed to be returned to Hanford for interim storage via the same U.S. seaport at which the initial shipments exited the country. The three materials addressed in the analysis for the return shipments are plutonium, uranium, and HLW. It was assumed that the separated plutonium and uranium would be converted to oxide forms and shipped to the U.S. aboard a purpose-built ship similar to that used for transporting the irradiated fuel. Other transport options might also be available for these materials, including use of military or commercial ships or aircraft. High-level waste was assumed to be processed to a stable form (borosilicate glass encased in stainless steel canisters) before shipment. This section provides descriptions of the shipping scenarios, transportation and packaging systems, radiological characteristics of the shipments, transportation routes, and port facilities that were examined in this analysis.

B.2.1.1 Port Selection. Ports evaluated for the foreign processing option were chosen to minimize either

the overland or ocean segments of the shipments and to provide a reasonable range of alternative transportation modes between the Hanford Site and the port (i.e., barge, truck, or rail). For the purposes of this evaluation, two potential West Coast U.S. ports (Seattle/Tacoma, Washington, and Portland, Oregon) and one potential East Coast port (Norfolk, Virginia) were evaluated for the overland transportation analysis. Population densities along the routes to these ports are representative of those in the vicinity of many major U.S. seaports. In addition, the port of Newark, New Jersey, was included in the port accident analysis to estimate the consequences of an accident in a location with a very high surrounding population.

B.2.1.2 Overseas Transport. The routing for overseas transport from West Coast U.S. ports would include

transit via the Columbia River or Puget Sound to the Pacific Ocean, a southerly route through the Panama Canal or around Cape Horn in South America, and then north to the U.K. The route around the cape is considered because it maximizes the distance that a shipment might be required to travel, and therefore, provides an upper bound for risks associated with the ocean transport segment. However, a route via the Panama Canal would be preferable for West Coast shipments because it avoids potential risk associated with the added distance and adverse weather conditions that might be encountered during transport around the cape. Transport via an East Coast U.S. port would be directly across the Atlantic Ocean to the U.K. The total distance for ocean transport via the West Coast is approximately 7,000 nautical miles via the Panama Canal or 17,000 nautical miles via Cape Horn; that for the East Coast is approximately 3000 nautical miles.

B.2.1.3 Overland Transport Scenarios. Overland transport between the Hanford Site and overseas shipping

ports was evaluated for three different scenarios, as described in the following sections.

B.2.1.3.1 Barge to Portland, Transoceanic Shipment to the U.K. This scenario begins with cask

loading operations at the Hanford Site 100-K Area Basins. The shipping casks would be loaded with SNF and prepared for truck transport to the Port of Benton barge slip near the 300 Area of the Hanford Site. After arrival at the barge slip, the shipping casks would be transloaded onto the barge via crane and then secured to the deck of the barge. After a full load of casks was secured, the barge would depart for the Port of Portland, Oregon, traveling down the Columbia River through routinely navigated shipping channels. At the Port of Portland, the shipping casks would be lifted off the barge and placed aboard a ship for the overseas segment of the journey. The shipping casks would then be secured, and the ship would depart for the U.K. After processing of the SNF, the HLW shipments were assumed to return via Portland, where the material would be transloaded onto a rail car and transported to Hanford for interim storage. Shipments of uranium and plutonium oxide would be returned to Hanford by truck.

B.2.1.3.2 Truck/Rail to the Port of Seattle, Transoceanic Shipment to the U.K.

The first leg of this scenario is different from the barge-to-Portland scenario in that the shipping casks would be loaded at the K Basins and shipped directly to the Port of Seattle, Washington, for transloading onto the ocean-going vessel. The overland leg would consist of either truck or rail shipments. It was assumed that one shipping cask would be transported per truck shipment or two casks per rail shipment. After arrival at the Port of Seattle, the shipping casks would be transloaded onto the ocean-going vessel and when a shipload of casks had been loaded, the ship would sail through Puget Sound and the Strait of Juan de Fuca to the Pacific Ocean, travel south via either the Panama Canal or Cape Horn, and then north to the U.K. After processing, the uranium, plutonium, and vitrified HLW would be returned to the U.S. by ship via Seattle and finally to Hanford by truck or rail.

B.2.1.3.3 Truck/Rail to the Port of Norfolk, Virginia, Transoceanic Shipment to the U.K.

This scenario would be similar to the truck/rail to Seattle scenario except the intermediate port would be Norfolk, Virginia. Similar to the Port of Seattle scenario, the shipping casks would be loaded aboard the ocean-going vessel and shipped to the U.K. This shipping scenario maximizes the overland transport leg and minimizes the ocean travel distance. As with the other two shipping scenarios, the solidified HLW, plutonium oxide, and uranium oxide materials were assumed to be returned to Hanford via Norfolk.

B.2.2 Shipping System Descriptions

This section presents descriptions of the shipping cask and truck, rail, and barge shipping systems that are used in the three potential shipping scenarios. The information presented focuses on the parameters important to the impact calculations, namely the cargo capacities and radionuclide inventories.

The shipping cask assumed to be used for the SNF shipments from Hanford to the U.K. is a standard design routinely used for commercial SNF transport (BNFL 1994). The cask could transport approximately 5 tons of intact fuel (with a smaller capacity for damaged fuel). The loaded cask weight is about 46 tons, so it was assumed that one cask could be transported per highway shipment and two per rail shipment. The capacities of the barge and ship were assumed to be 24 casks each. A total of 17 transoceanic shipments would be required to accommodate the 408 caskloads that would be necessary to ship all Hanford SNF. The actual number of shipments required would depend on the number of casks available, or on procurement of a sufficient number of new casks to provide for efficient shipment of Hanford SNF on a reasonable schedule.

The radionuclide inventories for the SNF shipments were determined using the information on N Reactor fuel inventories presented in Bergsman (1994). The resulting radionuclide inventories for the three types of shipments (truck, rail, and barge/ship) are presented in Table B-1.

The return shipments of HLW and plutonium and uranium oxide were assumed to be shipped via the same routes used for overseas shipment of Hanford SNF. For the barge to Portland option, these materials were assumed to be returned to the U.S. by ship to the Port of Portland, where HLW shipping casks would be transloaded onto a barge and uranium and plutonium onto trucks for transport to Hanford. Similarly for the other options, the materials would be transported by ships to the ports of Norfolk or Seattle, transloaded onto truck or rail shipping systems, and transported to Hanford.

The number of shipments of solidified HLW was estimated using assumed shipping cask capacities for HLW. It is estimated that a total of 500 containers of vitrified HLW, each weighing about 500 kg, would result from processing the N Reactor SNF (BNFL 1994). The U.K. processing facility has designed a new 110-ton shipping cask for vitrified HLW that would be capable of carrying 21 HLW containers per shipment. Therefore, about 24 caskloads would be required to return the HLW to the U.S. This material was assumed to be transported to a U.S. port facility in one shipment and then transloaded onto a rail car for the overland shipment segment (the HLW cask is too large to be transported by regular truck service). The actual number of shipments required would depend on the number of HLW casks available or on procurement of a sufficient number of new casks to provide for efficient return shipment of HLW on a reasonable schedule.

The radionuclide inventories for the solidified HLW shipments are presented in Table B-1. These inventories were calculated by dividing the total quantity of each radionuclide shipped to the U.K. (exclusive of uranium and plutonium) by the number of HLW casks (24) to be returned to the U.S.

Table B-1. Facility and transport mode radionuclide inventory development[a]

Radionuclide	Curies/ MTU	Grams/ MTU	Total Curies in SNF	Curies/Shipment[b]				Curies/Shipping Cask[c]

a. Radionuclide inventory taken from Bergsman (1994) and represents 10-year cooled Mark 1A fuel, in which Pu-240 constitutes 16% of total plutonium.

b. Curies/shipment inventories assume 1 cask per truck shipment, 2 truck casks per rail, and 24 truck casks per barge shipment.

c. Curies/cask inventories are based on one cask per truck and/or rail shipment.

d. HLW - Solidified high level waste; inventory assumes 100% removal of plutonium and uranium. High-level waste to be shipped only by barge (24 casks per barge) or rail (1 cask per rail car).

e. Plutonium and uranium oxide inventories assume 100% removal, and the number of shipments has been adjusted to reflect conversion from metal to oxide. Plutonium and uranium oxide to be shipped by barge and truck only.

The number of shipments of uranium and plutonium oxide were estimated using standard U.S. shipping equipment for uranium and plutonium. The estimated quantities to be shipped include 2,360 tons of purified uranium oxide and 6.5 tons of plutonium oxide generated from processing the K Basin SNF. For this analysis, it was assumed that the plutonium oxide would be transported by truck in a Type B package with a capacity of 35 kg/shipment. This results in a total of 186 caskloads of plutonium oxide. The vehicle for transport of plutonium was assumed to be a Safe-Secure Trailer/Armored Tractor specifically designed for shipment of special nuclear materials within the U.S. The uranium oxide was assumed to be transported by truck in shipping systems with a capacity of 10,000 kg/shipment. This would require a total of 236 caskloads of uranium oxide. One caskload per truck shipment for overland segments was assumed. One sea shipment of uranium oxide and one of plutonium oxide were assumed to be required.

The radionuclide inventories for the plutonium oxide and uranium oxide shipments are presented in Table B-1. The inventories were determined by dividing the total quantities of uranium and plutonium to be shipped to the U.K. by the respective numbers of caskloads presented above.

B.2.3 Transportation Route Information

The overland transportation routes assumed for this analysis are described in the following section. The descriptive information includes the shipping distances and population density data. These data were developed using the HIGHWAY (Johnson et al. 1993a) and INTERLINE (Johnson et al. 1993b) computer codes for truck and rail shipments, respectively, and are used to calculate transportation impacts. These data are summarized below for each transport segment described in Section B.2.2. No population data are presented for the ocean segments because once at sea, the exposed population becomes essentially zero.

Hanford to Seattle, Washington: The truck and rail shipping distances from Hanford to Seattle were determined to be 277 km (172 miles) and 716 km (445 miles), respectively. The large difference in shipping distance arises from the fact that the rail route is not a direct link to Seattle, but travels from Hanford to Vancouver, Washington and then to Seattle. For the highway route, the shipment travels through 88.1% rural areas (weighted population density 4.5 persons/km2), 10% in suburban areas (359 persons/km2) and 1.9% in urban population zones (1870 persons/km2). The rail route travels through 74.1% rural areas (9.8 persons/km2), 19% in suburban zones (415.5 persons/km2), and 6.9% in urban areas (2226 persons/km2).

Hanford to Norfolk, Virginia: The truck and rail shipping distances from Hanford to Norfolk were determined to be 4585 km (2849 miles) and 4984 km (3097 miles), respectively. For the highway route, the shipment travels through 84.5% rural areas (7.3 persons/km2), 13.4% in suburban areas (365 persons/km2) and 2.1% in urban population zones (2299 persons/km2). The rail route travels through 83% rural areas (7.8 persons/km2), 14.5% in suburban zones (360.4 persons/km2), and 2.4% in urban areas (2149 persons/km2).

Hanford to Portland, Oregon: The only option evaluated for using the Port of Portland was to barge the SNF to Portland, where it would be transloaded onto the ship. The distance and population density information for this shipment was approximated using INTERLINE (Johnson et al. 1993b), which evaluates potential rail routes, because the rail lines closely follow the Columbia River in which the barge would be operating. Consequently, the route data for a barge shipment would be similar to that for a rail shipment. The rail data are thought to be more conservative than actual barge data because the rail lines pass closer to the city centers along the river than would a barge.

B.2.4 Description of Methods Used to Estimate Consequences

This section describes the methods used to estimate consequences of normal and accidental exposure of individuals or populations to radioactive materials. The RADTRAN 4 (Neuhauser and Kanipe 1992) and RISKIND (Yuan et al. 1993) computer codes were used to calculate the transportation impacts, and the GENII software package (Napier et al. 1988) was used to estimate the consequences of port accidents. The MICROSHIELD external dosimetry software (Grove Engineering 1988) was used to determine approximate external dose rates for shipping containers as input to the transportation consequences. Nonradiological impacts from both incident-free transport and accidents were also evaluated.

The output from computer codes, as total effective dose equivalent (TEDE or dose) to the affected receptors, was then used to express the consequences in terms of potential latent cancer fatalities (LCF). Recommendations of the International Commission on Radiological Protection (ICRP 1991) for low dose, low dose rate radiological exposures were used to convert dose as TEDE to LCF. The conversion factor applied to adult workers was 4 x 10-4 LCF/rem TEDE, and that for the general population was 5 x 10-4 LCF/rem TEDE. The general population was assumed to have a higher rate of cancer induction for a given radiation dose than healthy adult workers because of the presence of more sensitive individuals (e.g., children) in the general population.

The estimated LCF for potential accidents was multiplied by the expected accident frequency per year, per shipment, or for the entire duration of the foreign processing operation, to provide a point estimate of risk consistent with those reported in the remainder of this EIS. Incident-free transportation or normal facility operations were assumed to occur (i.e., they have a frequency of 1.0); therefore, the cumulative risks associated with normal operations would be identical to the predicted number of latent cancer fatalities for the duration of the operation.

Nonradiological incident-free and accident impacts were also evaluated. Nonradiological incident-free impacts consist of fatalities from pollutants emitted from the vehicles. Nonradiological accident impacts are the fatalities resulting from potential vehicular accidents involving the shipments. Neither of these two categories of impacts are related to the radiological characteristics of the cargo. Estimates of these nonradiological impacts were derived by multiplying the unit risk factors (fatalities per mile of travel) by the total shipping distances for all of the shipments in each shipping option. Nonradiological unit risk factors for incident-free transport were taken from Rao et al. (1982), and for vehicular accidents were taken from Saricks and Kvitek (1994).

B.2.4.1 RADTRAN 4 Description. The RADTRAN 4 computer code (Neuhauser and Kanipe 1992) was used to

perform the analyses of the radiological impacts of routine transport, the integrated population risks of accidents during transport of irradiated N-Reactor SNF to the U.K., and the return of vitrified HLW, plutonium oxide, and uranium oxide from the U.K. to Hanford. RADTRAN was developed by Sandia National Laboratories (SNL) to calculate the risks associated with the transportation of radioactive materials. The original code was written by SNL in 1977 in association with the preparation of NUREG-0170, Final Environmental Statement on the Transportation of Radioactive Material by Air and Other Modes (NRC 1977). The code has since been refined and expanded and is currently maintained by SNL under contract with DOE. RADTRAN 4 is an update of the RADTRAN 3 (Madsen et al. 1986) and RADTRAN 2 (Taylor and Daniel 1982, Madsen et al. 1983) computer codes.

The RADTRAN 4 computer code is organized into the following seven models (Neuhauser and Kanipe 1992):

- material model
- transportation model
- population distribution model
- health effects model
- accident severity and package release model
- meteorological dispersion model
- economic model.

The code uses the first three models to calculate the potential population dose from normal, incident-free transportation and the first six models to calculate the risk to the population from user-defined accident scenarios. The economic model is not used in this study.

B.2.4.1.1 Material Model. The material model defines the source as either a point source or as a line

source. For exposure distances less than twice the package dimension, the source is conservatively assumed to be a line source. For all other cases, the source is modeled as a point source that emits radiation equally in all directions.

The material model also contains a library of 59 isotopes each of which has 11 defining parameters that are used in the calculation of dose. The user can add isotopes not in the RADTRAN library by creating a data table in the input file consisting of eleven parameters.

B.2.4.1.2 Transportation Model. The transportation model allows the user to input descrip-

tions of the transportation route. A transportation route may be divided into links or segments of the journey with information for each link on population density, mode of travel (e.g., trailer truck or ship), accident rate, vehicle speed, road type, vehicle density, and link length. Alternatively, the transportation route also can be described by aggregate route data for rural, urban, and suburban areas. For this analysis, the aggregate route method was used for each potential origin-destination combination. The origin-destination combinations addressed in this analysis were discussed in Section B.2.1.

B.2.4.1.3 Health Effects Model. The health effects model in RADTRAN 4 is outdated and is replaced by

hand calculations. The health effects are determined by multiplying the population dose (person-rem) supplied by RADTRAN 4 by a conversion factor.

B.2.4.1.4 Accident Severity and Package Release Model. Accident analysis in RADTRAN 4 is performed

using the accident severity and package release model. The user can define up to 20 severity categories for three population densities (urban, suburban, and rural), each increasing in magnitude. Eight severity categories for SNF containers that are related to fire, puncture, crush, and immersion environments are defined in NUREG-0170 (NRC 1977). Various other studies also have been performed for small packages (Clarke et al. 1976) and large packages (Dennis et al. 1978) that also can be used to generate severity categories. The accident scenarios are further defined by allowing the user to input release fractions and aerosol and respirable fractions for each severity category. These fractions are also a function of the physical-chemical properties of the materials being transported.

B.2.4.1.5 Meteorological Dispersion Model. RADTRAN 4 allows the user to choose two different

methods for modeling the atmospheric transport of radionuclides after a potential accident. The user can input either Pasquill atmospheric-stability category data or averaged time-integrated concentrations. In this analysis, the dispersion of radionuclides after a potential accident is modeled by the use of time-integrated concentration values in downwind areas compiled from national averages by SNL.

B.2.4.1.6 Incident-Free Transport. The models described above are used by RADTRAN 4 to determine

dose from incident-free transportation or risk from potential accidents. The public and worker doses calculated by RADTRAN 4 for incident-free transportation are dependent on the type of material being transported and the transportation index (TI) of the package or packages. The TI is defined in 49 CFR 173.403(bb) as the highest package dose rate in millirem per hour at a distance of 1 m from the external surface of the package. Dose consequences are also dependent on the size of the package, which as indicated in the material model description, will determine whether the package is modeled as a point source or line source for close-proximity exposures.

B.2.4.1.7 Analysis of Potential Accidents. The accident analysis performed in RADTRAN 4 calculates

population doses for each accident severity category using six exposure pathway models. The exposure pathways are inhalation, resuspension, groundshine, cloudshine, ingestion, and direct exposure. This RADTRAN 4 analysis assumes that any contaminated area is either mitigated or public access controlled so the dose via the ingestion pathway equals zero. The consequences calculated for each severity category are multiplied by the appropriate frequencies for accidents in each category and summed to give a total point estimate of risk for a radiological accident. The parameters used to calculate the frequencies and consequences of transportation accidents are presented in Section B.2.4.2.

B.2.4.2 RADTRAN 4 Input Parameters. RADTRAN 4 input parameters for calculating routine population

doses include route information (shipping distances, population densities, and fractions of travel in rural, suburban, and urban areas), numbers of shipments, dose rate, and parameters that define the population exposure characteristics. The route information and numbers of shipments were presented in Section B.1.2 and will not be repeated here. The remaining exposure parameters are described below.

RADTRAN 4 uses the dose rate at 1 m (referred to as the TI) in calculating dose to the public and worker. All of the SNF and HLW shipments in this analysis were assumed to be at the regulatory maximum dose rate, which is 10 mrem per hour at a distance of 2 m from the cask surface. This would be equivalent to a TI of 13 (or a dose rate of 13 mrem/hr at 1 m from the surface). Although it is likely that many of these shipments will have significantly smaller TI values, the use of the regulatory maximum value is bounding because it cannot be exceeded.

Because shipments of plutonium oxide and uranium oxide would have much smaller dose rates than SNF or HLW, preliminary shielding calculations were performed to derive more realistic values. The computer code MICROSHIELD (Grove Engineering 1988) was used to perform these calculations. Both types of shipments were modeled as cylindrical sources with cylindrical shields. The parameters used in these calculations are shown below:

- Plutonium oxide: The plutonium source was assumed to be 12.7 cm in diameter and 127 cm in length. Shielding was assumed to be provided by a 1-cm thick steel shield and an 8-cm thickness of solid hydrogenous material. The source inventory was the same as that shown in Table B-1.

- Uranium oxide: The uranium source was modeled as a single large container although the shipment will most likely be composed of several smaller containers. The source dimensions were assumed to be 114 cm in diameter and 370 cm in length. The source was assumed to be surrounded by a 1-cm thick steel cylinder and a 3-cm thick shield of solid hydrogenous material. The source inventory was shown in Table B-1.

The dose rate at 1 m from the surface of the plutonium oxide shipment was calculated to be 0.019 mrem/hr. Because this was increased by a factor of five to provide a bounding estimate, the TI value for these shipments was set to 0.1 mrem/hr. The dose rate for the uranium oxide shipments was calculated to be 0.0049 mrem/hr. This was also increased by a factor of five to 0.025 mrem/hr for conservatism.

Table B-2 is a list of input parameters that are used by RADTRAN 4 in the calculation of population dose for incident-free transportation. Many of the parameters are default values in the RADTRAN 4 code. Those that are not default values are identified and their sources are provided in footnotes to the table.

The potential receptors include workers and the general public. Worker doses include those received by the truck, rail, or barge crew and package handlers aboard the barge. Although RADTRAN models package handlers as persons who handle packages during intermediate stops, the routine doses to this group were assumed to apply to personnel who inspect the shipping containers aboard the barge. The equations used to calculate these doses assume that a five-person team spends approximately 0.5 hr per handling operation (or per inspection tour of the shipping casks). Although not exact, this is believed to be a reasonable approximation.

Table B-2. Input parameters for analysis of incident-free impacts[a]

Parameter	Rail	Barge	Truck
Dose rate 1 m from vehicle/package (mrem/h)[b]	13.1	13.1	13.1
Length of package (m)	3.0	3.0	3.0
Exclusive use	No	Yes	Yes
Velocity in rural population zone (km/h)[c]	64.4	16.09	88.6
Velocity in suburban population zone (km/h)[b]	40.3	8.06	40.3
Velocity in urban population zone (km/h)[c]	24.2	3.20	24.2
Number of crewmen	5	2	2
Distance from source to crew (m)	152	45.70	10.0
Stop time per km (h/km)[c]	0.033	0.01	0.011
Persons exposed while stopped[c]	100	50	50
Average exposure distance while stopped (m)[c]	20.0	50.0	20.0
Number of people per vehicle on link[c]	3	0	2
Traffic count passing a specific point-rural zone,one-way[c]	1.0	0	470
Traffic count passing a specific point-suburban zone,one-way[c]	5.0	0	780
Traffic count passing a specific point-urban zone,one-way[c]	5.0	0	2,800

a. Values shown are shipment-specific unless otherwise noted.
b. These values were used for SNF and HLW shipments. See text for the derivation of TI values for plutonium oxide (0.1 mrem/hr) and uranium oxide shipments (0.025 mrem/hr).
c. Default values from RADTRAN (Neuhauser and Kanipe 1992 and Madsen et al. 1983).

Public doses include doses to persons on the highway or railway (this category is not applicable to barge shipments as indicated in the RADTRAN documentation), doses to persons who reside near the highway, railway, or river, and doses at stops (for barge transport, this was assumed to include stops at navigation locks in dams).

For all three shipping modes, the doses to passengers were assumed to be 0.0 because there would be no passengers traveling with the shipments. In addition, there were assumed to be no intermediate storage needs for the shipments, and the doses to in-transit storage personnel were set equal to 0.0.

Information needed to characterize the potential routes between Hanford and the U.K. include the shipping distances, population densities in rural, suburban, and urban areas along the routes, and fractions of total shipping distance that travel through rural, suburban, and urban areas. These data were presented in Section B.2.3.

B.2.4.3 RISKIND Description. RISKIND (Yuan et al. 1993) was used to calculate doses to the maximum

individual and the public for both rail and truck transportation accidents. RISKIND was originally developed to model incident-free and accident conditions during transportation of SNF. The code was specifically designed to model accidental releases based on data contained in the NRC modal study (Fischer et al. 1987). RISKIND is designed to calculate the dose to individuals or groups of individuals for each of the severity categories identified in the modal study and provide probability-weighted dose risk, acute fatality, latent fatality, and genetic effect values. The probability-weighted dose risk values are calculated by multiplying and summing the dose for each severity category times the fraction of accidents within each severity category. Health effects are calculated by multiplying probability-weighted dose risk values by appropriate conversion factors. For this analysis, point estimates of risk for latent cancer fatalities were estimated as described in Section B.2.4.

The code is comprised of subroutines or models used to calculate radiological exposures to individuals at specific receptor locations. The information used to calculate these exposures can be performed using the default values contained in RISKIND or using receptor-specific data, supplied by the user. The exposure calculations are performed based on the receptor location, exposure conditions (i.e., inhalation and ingestion intake rates), and meteorological conditions.

RISKIND can be used to model all environmental exposure pathways based on the duration of the exposure. That is, for acute or short-term exposures, RISKIND can calculate exposures from initial plume passage or loss of shipping-cask shielding. For chronic or long-term exposures, RISKIND calculates exposures from ground deposition and ingestion from the food-chain pathways.

A radiological source inventory is contained internal to RISKIND that is based on fuel type, cooling times, and burnup rates. An analyst can input other radiological source inventories to calculate scenario-specific exposures. The radiological source inventory for this analysis is shown in Table B-1.

To calculate doses to the receptor, cask accident responses for both truck and rail, and release fractions have been incorporated into RISKIND. This information is based on the NRC modal study (Fischer et al. 1987). As discussed earlier, all shipments will be performed using Type B shipping containers; therefore, it is appropriate to use RISKIND to calculate the dose to the maximally exposed individual for all waste forms.

B.3 Radiological Dose to Workers

The following sections describe expected radiological consequences to workers during transportation and processing of N-Reactor SNF from Hanford.

B.3.1 Worker Dose from Pre-Shipment Activities at Hanford

Packaging of the K-Basin SNF for temporary wet storage was estimated to result in worker doses of approximately 140 person-rem (5.5 x 10-2 LCF) over a period of about 2 years. The activities covered by this estimate include repacking fuel assemblies in both K-East and K-West Basins and disposing of empty canisters (DOE 1992). The consequences of preparing the fuel for overseas shipment were assumed to be similar for the purposes of this evaluation. If stabilization of the fuel prior to shipment were necessary, an additional 180 person-rem might be accumulated by onsite workers over a 4-year period, resulting in 7.0 x 10-2 LCF (see Section 5.12.5 of this appendix). Consequences of air emissions from the storage or stabilization facilities to nearby workers would be much lower than those from direct exposure of workers in these facilities (see Section 5.7 of this appendix).

The consequences of accidents at the wet storage facility or the stabilization facility are discussed in Section 5.15 of this appendix. Air emissions from a fuel handling accident at the 100-K Basins or a uranium fire at the stabilization facility would result in a point estimate of risk to the nearby workers of <1.4 x 10-7 LCF or <8.3 x 10-12 LCF per year of operation, respectively. The estimated frequency for both accidents is between 1 x 10-6 and 1 x 10-4 per year. Operations at the K Basins to package SNF for shipment would last approximately 2 years, and the stabilization facility would require 4 years to process all of the K Basin SNF. The consequence to workers that might be directly involved in such accidents is highly speculative, and is addressed in Attachment A-Facility Accidents.

B.3.2 Worker Doses from Transportation to U.S. Ports

This section discusses the results of the worker impact calculations for truck, rail, and barge shipments to and from the U.K. These doses were calculated using the RADTRAN 4 computer code (Neuhauser and Kanipe 1992). The RADTRAN 4 program uses a combination of meteorological, demographic, health physics, transportation, packaging, and material factors to analyze risks associated with both normal transport (incident-free) and various user-selected accident scenarios. The RADTRAN 4 computer code description for both routine and accident impacts was presented in Section B.2.4.

The results of the incident-free transportation impact calculations are presented in Table B-3. The radiological impacts are presented in terms of the population dose (person-rem) received by exposed workers and the projected health effects calculated to occur in the exposed population. As shown, no excess fatalities were calculated to result from any of the five transportation options considered in this study.

As shown in Table B-3, the transportation option to U.S. ports that results in the lowest worker population doses is that involving barge shipments to the Port of Portland. This option is closely followed by the option of shipping by rail to the Port of Seattle. The option involving truck transport to the Port of Seattle is the third lowest option. The option of shipping by rail to the Port of Norfolk is next, followed by the option of shipping by truck to the Port of Norfolk. This result is intuitively obvious because the shipping distances are much longer from Hanford to Norfolk than to the other ports.

Table B-3. Results of incident-free transportation impact calculations for workers.

Option and material	Radiation doses, person-rem	Latent cancer fatalities
Barge to Portland		
SNF	3.0E+00	1.2E-03
HLW	1.8E-01	7.0E-05
Pu	7.7E-02	3.1E-05
U	5.3E-02	2.1E-05
TOTAL	3.3E+00	1.3E-03
Truck to Seattle		
SNF	6.0E+00	2.4E-03
HLW (Rail)	3.8E-01	1.5E-04
Pu (Truck)	4.5E-02	1.8E-05
U (Truck)	3.4E-02	1.3E-05
TOTAL	6.5E+00	2.6E-03
Rail to Seattle		
SNF	3.2E+00	1.3E-03
HLW (Rail)	3.8E-01	1.5E-04
Pu (Truck)	4.5E-02	1.8E-05
U (Truck)	3.4E-02	1.3E-05
TOTAL	3.7E+00	1.5E-03
Truck to Norfolk		
SNF	1.0E+02	4.2E-02
HLW (Rail)	1.5E+00	5.9E-04
Pu (Truck)	7.7E-01	3.1E-04
U (Truck)	5.8E-01	2.3E-04
TOTAL	1.1E+02	4.3E-02
Rail to Norfolk		
SNF	1.3E+01	5.0E-03
HLW (Rail)	1.5E+00	5.9E-04
Pu (Truck)	7.7E-01	3.1E-04
U (Truck)	5.8E-01	2.3E-04
TOTAL	1.5E+01	6.1E-03

In general, the shipments of N Reactor SNF to the U.K. would produce the highest doses of all the materials. This is attributed primarily to the higher number of N Reactor SNF shipments than the other materials. Also, it can be seen that rail shipments generally result in lower worker doses than truck shipments. This is because the exposure distances between the source and crew are much longer for rail shipments than for truck shipments. Similarly, the crew doses for rail and barge shipments are approximately comparable.

Maximum individual doses to workers from incident-free transport were calculated using the RISKIND computer code, consistent with the approach described in Volume 1, Appendix I. The maximally exposed workers for truck shipments were found to be the truck drivers (two-person crew), who were assumed to drive shipments for up to 2,000 hour per year. The maximally exposed worker for rail shipments was a transportation worker in a rail yard who spent a time- and distance-weighted average of 0.16 hours inspecting, classifying, and repairing railcars and was assumed to be present for all of the radioactive shipments.

The maximum incident-free exposure calculations for workers were performed for each shipping option. The results are 1.46 person-rem for the barge to Portland option, 2.0 person-rem for the option of shipping to Seattle by truck, 1.03 person-rem for the option of shipping to Seattle by rail, 35.3 person-rem for the option of shipping to Norfolk by truck, and 17.9 person-rem for the option of shipping to Norfolk by rail.

B.3.3 Worker Dose from Port Activities

The following sections describe expected radiological consequences to workers from in-port activities for transport of SNF to the U.K. The consequences for return of HLW, uranium, and plutonium are expected to be similar to, or lower than, those for initial shipment of SNF to the U.K. because of the smaller number of HLW shipments required for return to the U.S. Radiological consequences of normal transport of uranium and plutonium would be small compared with those for SNF and HLW.

B.3.3.1 Consequences of Normal Port Activities. Consequences to workers during handling and loading

activities in ports are based on commercial experience during the last three quarters of 1994. Over this period, workers handled two shipments consisting of 16 loaded casks, and 1 shipment consisting of 5 empty casks. The collective dose to the 30 workers involved was 0.024 person-rem, with the maximum individual receiving 0.016 rem. Assuming that handling of the empty casks did not contribute measurably to that total, the expected collective dose from handling a single loaded cask is estimated to be on the order of 0.001 rem to the maximally exposed worker and 0.0015 person-rem total to all workers. The consequences for loading and unloading of 408 casks during shipment from the U.S. to the U.K. would therefore be approximately 1.2 person-rem to all workers over the expected 5-year campaign. Accounting for an additional two handling activities per cask at the Hanford Site and at the U.K. process facility would roughly double that estimate, resulting in a collective dose of 2.4 person-rem and a potential for 9.8 x 10-4 LCF for all shipments. The maximum dose to an individual worker, assuming that worker were involved in handling all 408 casks at one point in the shipping sequence, would be on the order of 0.4 rem over 5 years.

B.3.3.2 Consequences of Accidents During Port Activities. The consequences of accidents during port

transit were estimated based on the highest activity N Reactor SNF (Bergsman 1994). The assumed radionuclide content of a single shipping cask is based on a loading of 5 MTU (see inventory for truck shipments in Table B-1). Representative ports on the West and East Coasts of the U.S. (Seattle-Tacoma, Washington; Portland, Oregon; Norfolk, Virginia; and Newark, New Jersey) were used for this analysis, based on relative population densities and suitability for handling of SNF shipments. Newark was included in this part of the analysis because of its relatively large surrounding population (adjacent to New York City), whereas the ports of Seattle-Tacoma, Portland, and Norfolk are located in somewhat smaller population centers. In a previous analysis, the collective consequences of in-port accidents were shown to be proportional to the surrounding population (DOE 1995).

The consequences (as radiation dose to individuals and populations and corresponding LCF were evaluated for a range of accident severities leading to airborne release of radioactive material, corresponding to the accident categories and radionuclide release fractions used for the overland transportation analysis (Volume 1, Appendix I, Table I-28). The overall accident frequency associated with each accident category was calculated using the conditional probability for that severity category, multiplied by the overall frequency with which a shipping accident would occur (as estimated by DOE 1994, Table E-8). The consequences (as LCF) for each severity category were multiplied by the corresponding frequency with which an accident in that category would occur to obtain a point estimate of risk for each accident category. The total risk per shipment was then calculated as the sum of risks over all accident severity categories. The frequencies for airborne release accidents evaluated using 95% atmospheric dispersion (stable) conditions (those that would not be exceeded more than 5% of the time) were assumed to be 10% of those evaluated using 50% (neutral) dispersion conditions, which are assumed to be the typical or expected conditions. The risk to U.S. ports for shipping all Hanford SNF overseas is the total risk per shipment times 17 shipments. The risk to U.K. ports is assumed to be comparable to that at U.S. ports.

The port accident analyses assume that the contents of a single cask were involved in any given accident. The probability that multiple casks could be breached in the event of an accident is smaller than that for a single cask, and the consequences would be proportional to the number of casks involved. Because of the construction of the special purpose ships, with eight segregated holds each containing at most three casks, an accident that would involve more than three casks is not considered to be reasonably foreseeable.

The consequences to an individual at a distance of 100 m, assumed to be a port worker, was estimated for applicable exposure pathways including inhalation, external dose from submersion in the plume, and external exposure from radionuclides deposited on the ground for a period of 2 hours. The point estimates of risk for an accident at the Port of Portland are estimated to be 6.1 x 10-11 to 1.0 x 10-09 LCF for 1 to 17 shipments, respectively. The corresponding point estimates of risk for Seattle/Tacoma (based on wind data from Seattle-Tacoma airport and the population within 50 miles of the Port of Tacoma) ranged from 4.7 x 10-11 to 8.0 x 10-10 LCF. The point estimates of risk to workers at East Coast ports were similar - ranging from 6.1 x 10-11 to 1.0 x 10-09 LCF at Norfolk and 5.3 x 10-11 to 9.0 x 10-10 LCF at Newark.

The maximum reasonably foreseeable accident was a category 6 accident, which has a frequency of 1.3 x 10-7 per port transit, and which was evaluated for stable atmospheric conditions resulting in a cumulative frequency of 2.2 x 10-7 for all 17 SNF shipments. The dose to the port worker was estimated to be 1.7 rem at Seattle/Tacoma, 1.9 rem at Newark, and 2.1 rem at Portland and Norfolk. The corresponding probability of LCF ranged from 6.8 x 10-4 and point estimates of risk, from 1.5 x 10-9 to 1.8 x 10-9 LCF.

B.3.4 Worker Dose from Ocean Transport to the United Kingdom

The following sections describe radiological consequences to workers from normal transport operations and accidents during overseas shipments of SNF from the Hanford Site to the U.K.

B.3.4.1 Consequences of Normal Ocean Transit. The primary impact of routine (incident-free) marine

transport of SNF is potential radiological exposure to crew members of the ships used to carry the casks. Members of the general public and marine life would not receive any measurable dose from the SNF during incident-free marine transport of the casks. While at sea, the crew dose would be limited to those individuals who might enter the ship's hold during transit and receive external radiation in the vicinity of the packaged SNF. At all other times, the crew would be shielded from the casks by the decking and other structures of the vessel. The number of entries and inspections would be a function of the transit time from the port of loading to the port of off-loading.

External radiation from an intact shipping package must be less than specified limits that control the exposure of the handling personnel and general public. These limits are established in 49 CFR Part 173. The limit of interest is a 10 mrem/hr dose rate at any point 2 m from the outer surfaces of the transport cask. This limit applies to exclusive-use shipments, i.e., a shipment in which no other cargo is loaded on the platform used for the transportation casks, not that the ship is an exclusive-use vessel, although this would not be a limitation for the commercial special purpose ships assumed for this analysis.

It is anticipated that the external dose rates at the outside of the transport casks would be much less than the regulatory limits. It was estimated that the N Reactor SNF considered in this analysis would fall within the design envelope of the internationally licensed casks routinely used by the U.K. facility for SNF transport (BNFL 1994). However, estimates of dose during normal transportation have been made assuming dose rates at the regulatory limits, using analyses performed for transport of foreign research reactor SNF as a basis (DOE 1995). These analyses may be used to develop an upper bound of the doses anticipated to be received by ships crews during transport of the N Reactor SNF. Actual doses would be expected to be lower than these estimates.

B.3.4.1.1 Bounding Dose Calculations. Calculations performed to estimate bounding radiation doses during routine cask inspections aboard ship (DOE 1995) provided information from which an inspection dose factor (IDF) could be determined of 6 x 10-5 rem y minute-1 y cask-1 y day-1 y person-1, based on an average distance of 5.5 m. Because the ship crews are highly trained and the ships are designed for SNF transport, it was assumed that inspection of each of the eight holds on the ship (each containing three casks) would take no longer than 15 minutes, or an average of 5 minutes per cask for the total 24 casks. The total inspection time per day would be 2 hours. If an inspection crew were assumed to consist of two members of the ship's crew, the bounding dose per daily inspection would be

6 x 10-5 (IDF) x 5 minutes x 24 casks = 0.007 rem y person-1 y day-1 (1)

Assuming a travel time from an eastern U.S. port of 10 days, the estimated maximum dose received by each member of a two-person inspection crew would be 0.07 rem. This value would not exceed the 0.1 rem dose limit for a member of the general public. The transit time for a shipment originating on the West Coast of the U.S. could be up to five times longer, resulting in a dose per shipment of 0.35 rem. This value would exceed the 0.1 rem dose limit for a member of the general public. However, because the ship's crews are trained and issued dosimeters, it is presumed that they would be considered radiation workers. Although it is not clear at this time if radiation exposure of the ship's crew would fall under the jurisdiction of the U.K. or U.S. radiation protection standards, these standards are identical for both countries (5 rem per year, with an administrative control level of 2 rem per year). Therefore, the maximum possible dose received by individual workers during ocean transit would be well within the limits of the U.S. and U.K. radiation protection standards for workers.

Complete transport of the SNF to the U.K. for processing would require 17 shipments of 24 casks. The collective dose to crew members responsible for conducting inspections on the transport ships during fuel transport from the U.S. East Coast would be

(0.007 rem y person-1 y day-1) x 2 persons x (10 days y trip-1) x 17 trips = 2.4 person-rem (2)

Based on this bounding estimate of the collective dose to the ship's crew for transportation of the SNF, an upper limit of approximately 0.001 LCF would be expected among the ship's crew from exposure to external radiation from the SNF transport casks. If all shipments originated at a western U.S. port, the collective dose could be up to 12 person-rem with a corresponding consequence of 0.005 LCF.

The above analysis does not consider the return of the processed SNF products and waste from the U.K. to the U.S. It was projected that the number of shipments containing these products would be fewer than the number of SNF shipments. However, as a bounding estimate the same number of return shipments and similar external dose rates, at the regulatory limit, might be assumed. Under those circumstances, an upper limit of 0.01 LCF would be expected among the ships' crews from exposure to the external radiation during all shipments.

B.3.4.1.2 Commercial Fuel Transport Experience.

Information on radiation doses to ships' crews during transport of commercial fuel, gathered from actual crew dosimeters, supports the statements above that actual doses to the crew would be lower than the calculated bounding doses. The average individual dose during one voyage was 0.001 rem, with a maximum individual dose of 0.022 mrem. The collective dose to the ship's crew for one voyage was about 0.038 person-rem. On that basis, the crew's collective dose for 17 SNF shipments would be 0.65 person-rem. A comparison of bounding dose estimates and commercial transport experience is shown in Table B-4. Based on these results, less than 0.0003 LCF would be expected among ships' crews from radiation exposure during SNF transport, and approximately 0.0005 LCF would be expected from radiation exposure during transport of SNF and the subsequent return of processing products and waste.

Table B-4. Comparison of bounding and typical ship crew's doses.

	Bounding Dose Calculations	Commercial Fuel Transport Experience
Individual dose, rem	0.07 - 0.35	0.001 typical 0.022 maximum
Collective dose, person-rem		
- 17 SNF shipments	2.4 - 12	0.65
- < 17 round trips	< 24	< 1.3

B.3.4.2 Consequences of Accidents During Ocean Transit.

The consequences of accidents during ocean transit would likely be similar to those of port workers who are near the scene of an accident (see Section B.3.3.2). Individuals in the immediate vicinity of the impact would probably not survive an accident severe enough to cause release of radioactive materials from a SNF shipping cask. Effects on the ocean environment would not be expected to be discernable because of the degree of dispersion in the event of an airborne release.

B.3.5 Worker Dose from Return of Processing Products to the United States

Return of HLW to the U.S. is assumed to result in cumulative worker doses that are bounded by those incurred in the initial SNF shipments to the U.K. However, the distribution of dose among individual workers may differ because of the different configuration and radionuclide content of the HLW canisters. As noted in Section B.2.4.2, the dose rates associated with plutonium and uranium shipments are substantially below the regulatory maximum that was assumed for the SNF and HLW shipments.

B.4 Consequences to Members of the Public

The following sections describe expected consequences to the public from various activities involved in transporting N Reactor SNF to the U.K.

B.4.1 Public Impacts from Pre-Shipment Activities at Hanford

Activities at Hanford prior to preparation of N Reactor SNF for shipment would result in generally small consequences to the public, as discussed in Section 5.7 of this appendix. The removal and packaging of SNF at the basins was estimated to result in offsite consequences comparable to those observed during initial segregation of the fuel, or approximately 2 x 10-5 to 3 x 10-4 (1 x 10-11 to 1.5 x 10-10 probability of LCF) mrem to the maximally exposed offsite individual (DOE 1992).

The risk from accidents involving handling of N-Reactor SNF at the 100-K Basins was also presented in Section 5.15 of this appendix. The consequences to the maximally exposed offsite individual were estimated as 2.5 x 10-4 LCF, with an associated point estimate of risk equal to <2.5 x 10-8 fatal cancers per year (assuming an accident frequency <1 x 10-4 per year). The consequences to the population within 80 km (50 miles) were estimated as 0.4 LCF for 50% (neutral) atmospheric dispersion conditions and 6.9 LCF for 95% (stable) atmospheric dispersion (conditions that would not be exceeded more than 50% or 5% of the time, respectively). The corresponding point estimates of risk amounted to <4.0 x 10-5 and <6.9 x 10-4 LCF per year, respectively.

B.4.2 Public Impacts from Transportation Activities

This section presents the analysis of the public incident-free radiological exposures, radiological accident risks, and nonradiological impacts from transporting radioactive materials to and from the U.K. Members of the public exposed to radiation include persons on the highway, railroad, or waterway with the shipment, persons residing near these transport links, and persons at intermediate stops along the route (such as refueling stops and stops at rail classification yards). The RADTRAN 4 computer code was used to perform these calculations. A description of RADTRAN 4 was presented in Section B.2.4. The following sections present the results of the incident-free exposure calculations, description of the accident-analysis input parameters, the results of the accident risk impact calculations, and the evaluation of nonradiological impacts.

B.4.2.1 Results of Incident-Free Transportation Impact Calculations. The results of the public dose

calculations, developed using the RADTRAN 4 computer code and the input parameters described in Section B.2.4, are presented in Table B-5.

Table B-5. Results of public incident-free exposure calculations.

Option and material	Radiation doses, person-rem	Latent Cancer Fatalities
Barge to Portland		

SNF	3.4E-01	1.7E-04
HLW	6.7E-03	3.4E-06
Pu	3.7E-02	1.9E-05
U	2.9E-02	1.4E-05
TOTAL	4.1E-01	2.1E-04
Truck to Seattle		
SNF	1.5E+01	7.6E-03
HLW (rail)	1.9E-01	9.6E-05
Pu (truck)	2.5E-02	1.2E-05
U (truck)	1.9E-02	9.3E-06
TOTAL	1.5E+01	7.7E-03
Rail to Seattle		
SNF	1.6E+00	8.1E-04
HLW (rail)	1.9E-01	9.6E-05
Pu (truck)	2.5E-02	1.2E-05
U (truck)	1.9E-02	9.3E-06
TOTAL	1.9E+00	9.3E-04
Truck to Norfolk		
SNF	2.5E+02	1.3E-01
HLW (rail)	7.0E-01	3.5E-04
Pu (truck)	4.1E-01	2.1E-04
U (truck)	3.1E-01	1.6E-04
TOTAL	2.5E+02	1.3E-01
Rail to Norfolk		
SNF	5.9E+00	3.0E-03
HLW (rail)	7.0E-01	3.5E-04
Pu (truck)	4.1E-01	2.1E-04
U (truck)	3.1E-01	1.6E-04
TOTAL	7.3E+00	3.7E-03

From a domestic transportation perspective, the lowest-impact option is one that includes rail shipments of SNF from Hanford to the Port of Seattle. This option is followed closely by the option of moving SNF from Hanford to the Port of Portland by barge. The third lowest domestic transportation option is that involving SNF shipments to Seattle by truck. The highest impact options are those involving shipments from Hanford to the Port of Norfolk. Obviously, the lowest impact domestic transportation option would be that involving the shortest shipping distances (i.e., Hanford to Seattle or Portland). Some of the impacts of the long domestic transportation links would be offset by subsequent reductions in the lengths of the ocean shipment segments. Consequently, the rankings of the options presented in Table B-5 do not necessarily represent the rankings that would result if the ocean segments of the shipments were included. However, public routine doses are not significant for ocean voyages because the separation distance between the ship and the nearest exposed population is greater, resulting in extremely low radiation dose rates.

The results in Table B-5 demonstrate that barge shipments of SNF (and HLW) would produce lower public routine doses than truck or rail shipments. This is attributed primarily to the lower traffic volumes on waterways relative to railroads and highways, generally greater separation distances between barges and the public relative to the separation distances between highways/ railroads and the public, as well as the increased per-shipment capacities of barges relative to truck and rail shipments (resulting in fewer shipments).

Table B-5 also demonstrates that rail shipments would produce lower public routine doses than equivalent truck shipments. This can be seen by comparing the SNF shipment impacts for truck shipments to Seattle (15 person-rem) and rail shipments to Seattle (1.6 person-rem). Even though the rail shipping route from Hanford to Seattle is much longer than the truck route (277 km and 716 km), the total public routine doses are smaller. As with barge shipments, this is attributed to lower traffic volumes, larger separation distances, and increased shipment capacity for rail shipments.

Maximum individual doses to members of the public from incident-free transport were calculated using the RISKIND computer code, which is consistent with the approach described in Volume 1, Appendix I. For rail shipments, three potential exposure scenarios were evaluated by RISKIND, as described in Volume 1, Appendix I. The maximally exposed members of the public from incident-free truck transport were also determined using three potential exposure scenarios (see Volume 1, Appendix I).

The maximum incident-free exposure calculations for members of the public were performed for each shipping option. The results are 0.28 person-rem for the barge to Portland option, 0.20 person-rem for the option of shipping to Seattle by truck, 0.28 person-rem for the option of shipping to Seattle by rail, 0.20 person-rem for the option of shipping to Norfolk by truck, and 0.28 person-rem for the option of shipping to Norfolk by rail.

B.4.2.2 Assessment of Public Impacts from Transportation Accidents. Radiological accident impacts

are presented in this section as integrated population risks (i.e., accident frequencies multiplied by consequences integrated over the entire shipping campaign), as well as the consequences of the maximum reasonably foreseeable accident. Population risk calculations were performed using the RADTRAN 4 computer code (Neuhauser and Kanipe 1992). The consequences of the maximum reasonably foreseeable accident were calculated using the RISKIND computer code (Yuan et al. 1993). Separate sections are provided for the integrated population risk (i.e., RADTRAN 4) calculations and the maximum reasonably foreseeable accident consequence (i.e., RISKIND) calculations.

B.4.2.2.1 Integrated Population Risk Assessment. For this analysis, risk is defined as the product

of the frequency of occurrence of an accident involving a shipment and the consequences of an accident. Consequences are expressed in terms of the radiological dose and LCF from a release of radioactive material from the shipping cask or the exposure of persons to radiation that could result from damaged package shielding. The frequency of an accident that involves radioactive materials is expressed in terms of the expected number of accidents per unit distance integrated over the total distance traveled. The response of the shipping cask to the accident environment and the probability of release or loss of shielding, is related to the severity of the accident.

The frequencies of occurrence of transportation accidents that would release significant quantities of radioactive material are relatively small because the shipping casks are designed to withstand specified transportation accident conditions (i.e., the shipping casks for all the materials shipped in this analysis were assumed to meet the Type B packaging requirements specified in 49 CFR 174 and 10 CFR 71). Accidents on the road and railways are difficult to totally eliminate. However, because the shipping casks are capable of withstanding certain accident environments, including mechanical and thermal stress, only a relatively small fraction of accidents involve conditions that are severe enough to result in a release of radioactive materials.

Should an accident involving a shipment occur, a release of radioactive material could occur only if the cask were to fail. A failure would most likely be a small gap in a seal or small split in the containment vessel. For the radioactive material to reach the environment, it would have to pass through the split in the cask or through the failed seal. Materials released to the environment would be dispersed and diluted by weather action and a fraction would be deposited on the ground (i.e., drop out of the contaminated plume) in the surrounding region. Emergency response crews arriving on the scene would evacuate and secure the area to exclude bystanders from the accident scene. The released material would then be cleaned up using standard decontamination techniques, such as excavation and removal of contaminated soil. Monitoring of the area would be performed to locate contaminated areas and to guide cleanup crews in their choice of protective clothing and equipment (e.g., fresh-air equipment and filtered masks). Access to the area would be restricted by federal and/or state radiation control agencies until it had been decontaminated to safe levels.

The RADTRAN 4 computer code was used to calculate the radiological risk of transportation accidents involving radioactive material shipments. The RADTRAN 4 methodology was summarized previously. For further details, refer to the discussions presented by RADTRAN III (Madsen et al. 1986) and RADTRAN 4: Volume 2 -- Technical Manual (Neuhauser and Kanipe 1992).

There are five major categories of input data needed to calculate potential accident transportation risk impacts using the RADTRAN 4 computer code. These are: 1) accident frequency, 2) release quantities, 3) atmospheric dispersion parameters, 4) population distribution parameters, and 5) human uptake and dosimetry models. Accident frequency and release quantities are discussed below, the remaining parameters have been discussed in previous sections.

Accident Frequency. The frequency of a severe accident is calculated by multiplying an overall accident rate (accidents per truck-km or per rail-km) by the conditional probability that an accident would involve mechanical and/or thermal conditions that are severe enough to result in container failure and subsequent release of radioactive material. Overall accident rates per kilometer of truck or rail travel were taken from Saricks and Kvitek (1994). State-specific accident rates were used in this study. For the Portland and Norfolk options, a composite weighted-average accident rate was developed using the state-specific accident rates in Saricks and Kvitek (1994), and travel fractions through each state that were derived from the HIGHWAY and INTERLINE results.

For this analysis, six shipment-specific severity categories were defined, with category 1 as the least severe and the higher categories (2-6) representing increasingly severe conditions. The conditional probabilities of encountering accident conditions in each severity category were taken from a U.S. Nuclear Regulatory Commission (NRC) document (Fischer et al. 1987). Those conditional probabilities were developed based on reviews of accident records and statistics compiled by various state and federal agencies. The conditional probability for a given severity category is defined as the fraction of accidents that would fall into that severity category if an accident were to occur. The conditional probabilities for truck and rail shipments were determined using a binning process described in Volume 1, Appendix I of this EIS. The derivation of the accident rates and conditional probabilities used in this analysis are discussed below. [The conditional probabilities for barge accidents were taken directly from Pippen et al. (1995)].

As discussed above, severity category levels were defined to model the response of the various shipments to accidents. Severity category 1 was defined as encompassing all accidents that are within the type B package envelope that would not be severe enough to result in failure of the shipping cask (i.e., accidents with zero release). The higher categories (2-6) were defined to include more severe accidents, and thus may lead to a release of radioactive material. The derivation of the severity category schemes and conditional probabilities of accidents in each severity category are discussed below for each shipping cask or container type. Table B-6 presents the conditional probabilities of the various severity categories that were used in this analysis.

Release Fractions. Release fractions (array RFRAC in RADTRAN 4) are used to determine the quantity of radioactive material released to the environment as a result of an accident. The quantity of material released is a function of the severity of the accident (i.e., thermal and mechanical conditions produced in the accident), the response of the shipping container to these conditions, and the physical and chemical properties of the material being shipped. The basis for the release fractions used in this analysis are discussed below and summarized in Table B-7.

Release fractions for N Reactor fuel shipments were taken from Volume 1, Appendix I of this EIS. The table of release fractions for metallic fuels was used (Table I-28). All of the released material was assumed to be in respirable form for this assessment. Release fractions for damaged N Reactor SNF were modeled the same as for undamaged fuel. This is because it was assumed that some form of stabilization would occur prior to shipment of damaged SNF. Stabilization was assumed to provide a level of containment for damaged SNF, such as placement in an overpack container, to replace the containment boundary that was provided by the failed N Reactor SNF cladding. Stabilization was also assumed to include some form of treatment to minimize the likelihood of a pyrophoric reaction involving the metallic uranium and to prevent the accumulation of an explosive concentration of hydrogen gas that may be generated by the fuel elements.

Table B-6. Accident severity categories and conditional probabilities.

Mode	Conditional probability by severity category					
	1	2	3	4	5	6

Table B-7. Release fractions used for assessment of accident impacts.

Material	Release fraction by severity category					
	1	2	3	4	5	6
SNF[a]						
Gases	0.0	9.9E-03	3.3E-02	3.9E-01	3.3E-01	6.3E-01
Cesium	0.0	3.0E-08	1.0E-07	1.0E-06	1.0E-06	1.0E-05
Ruthenium	0.0	4.1E-09	1.4E-08	2.4E-07	1.4E-07	2.4E-06
Particles	0.0	3.0E-10	1.0E-09	1.0E-08	1.0E-08	1.0E-07
HLW[a]	HLW release fractions are the same as those for SNF					
Pu oxide						
Particles	0.0	1.0E-06	1.0E-05	1.0E-04	1.0E-03	1.0E-02
U oxide						
Particles	0.0	1.0E-06	1.0E-05	1.0E-04	1.0E-03	1.0E-02

a. These release fractions were applied to truck and rail shipments of SNF and HLW. Release fractions for barge shipments were multiplied by 1/24, 1/12, 1/6, 1/3, and 1 for severity categories 2 through 6, respectively, to reflect the number of shipping casks that are damaged in each category.

A different, but related, set of release fractions were used for barge shipments of N Reactor SNF. The relationship deals with the potential involvement of multiple shipping casks in a barge carrying 24 of them. It is overly conservative to assume that all 24 shipping casks would fail in minor barge accidents. In the lower severity categories, the accident conditions are not severe enough to damage all 24 shipping casks. In fact, in the lowest severity category that results in a release, only the shipping casks in the vicinity of the collision would be affected. Consequently, the release fraction for severity category 2 was multiplied by 1/24 to reflect the assumption that only one of the total of 24 shipping casks aboard the barge would be damaged. Category 3 release fractions were multiplied by 1/12 to reflect the assumption that two shipping casks out of 24 would be damaged in the accident. The release fractions for severity categories 4, 5, and 6 were multiplied by 1/6, 1/3, and 1 to reflect the assumption that 4, 8, and all 24 casks would be damaged, respectively.

Release fractions for HLW shipments were assumed to be the same as those for SNF shipments. The difference is that the strength and durability of the vitrified HLW form was taken into account by assuming that not all of the materials released are in respirable or dispersable form. RADTRAN 4 default values for "immobilized" radionuclides were used to model the dispersable and respirable fractions of the released material. This means that the fraction of released material that is in dispersable form is 1.0E-06, and the respirable fraction is 5.0E-02 (Neuhauser and Kanipe 1992). The HLW release fractions for barge shipments were adjusted similarly to those for SNF to account for the fraction of casks that were assumed to be damaged in the six severity categories.

For plutonium and uranium oxide shipments, no data were readily available. Therefore, the release fractions presented in Table B-7 are representative approximations. It was assumed that 10% of the material released from the plutonium and uranium shipment accidents is in dispersable form and 5% of that is in respirable form, based on recommendations made by Neuhauser and Kanipe (1992) for shipment of small powder materials.

B.4.2.2.2 Consequences of Maximum Reasonably Foreseeable Accidents. The dose to the maximum individual and the collective population dose from the maximum reasonably foreseeable accident was calculated for each type of shipment, i.e., SNF, solidified HLW, and plutonium and uranium oxide. The quantity and radiological constituents of each waste form are discussed in Chapter 2.0 of this appendix.

The computer code RISKIND (Yuan et al. 1993) was used to calculate the dose to the maximum individual and the population.

RISKIND Input Parameters. This analysis evaluates the consequences of accidents involving truck or rail shipments. A separate assessment was not performed for barge shipments to Portland because of the similarity between the rail and barge routing data (see Section B.2.3). The radiological inventories developed in Table B-1 have been used to calculate the dose to the maximum individual and the public. For all analyses, inhalation doses were calculated for each of the NRC modal study severity categories, assuming the maximum individual was located 100 m from the point of release and neutral weather conditions (i.e., Atmospheric Stability Class = D and 4 m/s wind speed). To determine the maximum individual dose for each of the material types, the calculated dose for each of the NRC modal study categories (20) were binned into the accident severity categories shown in Table B-6. The results of the RISKIND calculations for each severity category are presented in Table B-8.

An accident frequency (accidents per year) and probable accident location by population zone (i.e., rural, suburban, and urban) were developed for each campaign, based on the type of material, transportation mode, transportation routing information, and state-specific transportation accident data. For this analysis a campaign is defined as the total number of shipments required to transport all of the material from the point of origin to the destination.

For each of the transportation modes, existing transportation model computer codes, i.e., HIGHWAY (Johnson 1993a; population data revised in 1994) and INTERLINE (Johnson 1993b; population data revised in 1994) were used to develop the route-specific information required for the accident analyses.

The information required to calculate the accident frequencies included the total number of shipments per campaign, the campaign duration, the total shipping distance, population zone-specific accident rates by state, and the conditional probabilities shown in Table B-6. The population zone-specific accident frequencies are calculated using the state-specific accident data (accidents per kilometer) for each of the population zones contained in Saricks and Kvitek (1994) and the distance traveled in each of the population zones. The resulting adjusted accident rates are shown in Table B-9. The values in this table were used to select the maximum reasonably foreseeable accident scenario.

Table B-8. RISKIND calculated doses summarized by severity categorya.

Severity Categoryb	Truck			Rail	
	Spent Nuclear Fuel (rem)	Pu Oxide (rem)	U Oxide (rem)c	Spent Nuclear Fuel (rem)	Solidified HLWd (rem)
1e	2.36E-05	2.36E-05	2.36E-05	2.36E-05	2.36E-05
2	8.59E-03	3.91E-04	2.36E-05	1.30E-01	1.26E-01
3	5.01E-02	1.25E-03	2.36E-05	8.53E-01	8.39E-01
4	9.39E-02	1.23E-02	2.36E-05	2.96E-01	1.26E-01
5	1.18E-01	1.23E-02	2.36E-05	9.80E-01	8.39E-01
6	2.60E-01	1.23E-01	2.36E-05	1.27E+00	8.39E-01

a. Maximum individual doses are in BOLD. (These doses were estimated in the event an accident occurs; i.e.,

they were not multiplied by the corresponding accident frequencies).
b. Severity categories are defined in Table B-6.
c. Only external doses were calculated.
d. The quantity of HLW released has been adjusted because of the immobilized form of the material. The adjustment, 1.0E-06, was taken from RADTRAN 4 (Neuhauser and Kanipe 1992).
e. Although, no material would be released, an external dose is calculated as a result of changes in the cask shielding caused by an accident impact.

The calculated maximum individual doses were cross referenced with the accident frequencies in Table B-9, and the maximum individual doses for reasonably foreseeable accidents (i.e., the accident frequency is greater than 1 x 10-7/year) have been reported.

The population dose from the maximum reasonably foreseeable accident is also provided. These analyses are based on the same assumptions used to calculate the dose to the maximally exposed individual. The location of the accident (or population zone) is the same as the accident location used to calculate the maximum individual doses.

The population densities for each of the impacted population zones were developed using HIGHWAY (Johnson 1993a) and INTERLINE (Johnson 1993b).

Table B-9. Summary of route-specific accident rates.

B.4.2.3 Results of Transportation Accident Impact Calculations. The results of the integrated population risk assessment are presented in Table B-10. The lowest impact option is that in which SNF is shipped from Hanford to the Port of Seattle by rail. The Port of Seattle by truck option is the next highest followed in order by the rail option to Norfolk, truck to Norfolk, and then barge to Portland. The impacts for all of the options are dominated by the SNF shipments to the U.K. and plutonium oxide return shipments to Hanford, primarily because the quantities and forms of these materials are more vulnerable to accidental releases and represent higher radiotoxicities than vitrified HLW and uranium oxide. Shipments of vitrified HLW were determined to present the lowest impacts of all the materials because of the reasons given plus the immobilized form of the material relative to the other materials.

Shipments by barge are shown in Table B-10 to result in relatively higher accident impacts than shipments by rail or truck. This is because the inventories of radioactive materials transported by barge, and the resulting potential accident releases, are at least an order of magnitude greater than for truck and rail shipments. Because the accident rates for the three modes are comparable, this results in a higher per shipment (or per-km) accident risk for barge than the other modes. This higher per-shipment risk more than offsets the risk reduction attributable to fewer barge

Table B-10. Results of transportation accident risk assessmenta.

a. Reported values are point estimates of risk; i.e., the accident frequency multiplied by the consequences that would be expected if an accident occurred.

shipments so, overall, barge accident risks appear to be higher than truck or rail transport risks. However, in comparing the magnitudes of the accident risks in Table B-8 to the public routine exposures in Table B-5, it can be seen that the accident risks are lower than the routine public exposures. Consequently, it may be concluded that transportation accident risk impacts are insignificant contributors to the total impacts of the transportation options.

The results of the maximum reasonably foreseeable accident consequence assessment are provided in Tables B-11 through B-14. The results in these tables were generated using the RISKIND computer code. The following paragraphs discuss the results of the maximally exposed individual consequence assessment for each material. This is followed by a discussion of the results of the collective dose calculations.

N Reactor SNF. As discussed in Section 2.0, SNF will be loaded into shipping casks at the K Basins and transported by barge, truck, or rail to ocean ports for shipment to the U.K. Two shipping modes and three transportation routes were evaluated. The radiological source inventory used in the analysis was shown in Table B-1. The release fractions used here were taken from Volume 1, Appendix I of this EIS (see Table B-7). The results of the evaluation are shown in Table B-11.

As can be seen in Table B-11, for reasonably foreseeable events (i.e., the accident frequency is greater than 1.0E-07/year), the dose received by the maximally exposed individual from a rail accident ranges from 9.80E-01 to 1.27E+00 rem depending on the location of the individual and transportation route. The potential LCF range from 4.90E-04 to 6.35E-04. The accident frequency also varies based on the transportation route and accident location from 1.27E-07 to 1.91E-06/year. Table B-11 also presents the dose received by the maximally exposed individual from a truck accident. The dose to the maximally exposed individual ranges from 1.18E-01 to 2.60E-01 rem, depending on the location of the individual and transportation route. The accident frequency also varies based on the transportation route and accident location from 1.23E-07 to 1.02E-05/year. The potential LCF range from 5.90E-05 to 1.30E-04.

Collective doses to the public were also calculated for each of the transport modes and transportation route (see Table B-11). For this analysis, it was assumed that the accident occurred in the same location as that determined in the maximum individual dose calculations. The population dose from a rail accident ranges from

3.18E+00 to 3.27E+02 person-rem depending on the accident location, population density, and transportation route.

The doses to population from a truck accident range from 1.37E-01 to 9.44E+02 person-rem. The potential LCF range from 1.59E-03 to 0.170 for rail and 6.85E-05 to 4.72E-1 for truck.

Table B-11. Calculated maximum individual and population radiological doses and latent cancer fatalities based on accident location and frequency of SNF shipments.

Transportation Route	Mode	No. of ship-mentsa	Accident frequency (per year)b	Accident location: population zonec	Maximum individual TEDEd (rem)	Maximum individual LCFe	Population TEDEd (person-rem)	Population LCFe
Hanford, Washington to Portland, Oregon	Truck	408	1.23E-07	Urban	2.60E-01	1.30E-04	1.01E+02	5.05E-02
Hanford, Washington to Seattle, Washington			1.02E-05	Rural	1.18E-01	5.90E-05	1.37E-01	6.85E-05
Hanford, Washington to Norfolk, Virginia			1.43-06	Urban	2.60E-01	1.30E-04	9.44E+02	4.72E-01
Hanford, Washington to Portland, Oregon	Rail	204	3.46E-07	Rural	9.80E-01	4.90E-04	3.18E+00	1.59E-03
Hanford, Washington to Seattle, Washington			1.27E-07	Urban	1.27E+00	6.35E-04	3.39E+02	0.170
Hanford, Washington to Norfolk, Virginia			1.91E-06	Urban	1.27E+00	6.35E-04	3.27E+02	0.164

a. Assumes one truck cask per truck shipment and two truck casks per rail shipment.
b. Accident frequency based on the number of shipments, campaign duration, one-way shipping distance, and conditional probability.
c. Accident location is based on population zone where the maximum individual dose occurs.
d. TEDE - 50-year total effective dose equivalent.
e. LCF - Latent cancer fatalities. Calculated on dose (rem) to maximum individual or population, i.e., 5.0E-04 LCF/rem

Table B-12. Calculated maximum individual and population radiological doses and latent cancer fatalities based on accident location and frequency for plutonium oxide shipments.

Transportation Route	Mode	No. of Ship.	Accident Frequency (per year)b	Accident Location: Population Zonec	Maximum Individual TEDEd (rem)	Maximum Individual LCFse	Population TEDEd (rem)	Population LCFse
Portland, Oregon to Hanford, Washington	Truck	186	1.22E-07	Urban	1.23E-01	6.15E-05	1.88E+01	9.40E-03
Seattle, Washington to Hanford, Washington			1.01E-05	Rural	1.23E-02	6.15E-06	3.46E-03	1.73E-06
Norfolk, Virginia to Hanford, Washington			1.42E-06	Urban	1.23E-01	6.15E-05	1.77E+01	8.85E-03

a. Assumes one cask per truck shipment.
b. Accident frequency based on the number of shipments, campaign duration, one-way shipping distance, and conditional probability.
c. Accident location is based on population zone where maximum individual dose occurs.
d. TEDE - 50 year Total Effective Dose Equivalent.
e. LCFs - Latent cancer fatalities. Calculated based on dose (rem) to maximum individual or population, i.e., 5.0E-04 LCFs/rem

Plutonium Oxide. The separated plutonium oxide was assumed to be returned to its point of origin (i.e., Hanford). This material was assumed to be transported to a U.S. port (Seattle, Portland, or Norfolk) by ocean-going ship and offloaded to a Safe-Secure Trailer/Armored Tractor for subsequent highway shipment to Hanford (one container per shipment).

The results of this analysis are provided in Table B-12. The dose, to the maximally exposed individual from the maximum reasonable foreseeable accident, ranges from 1.23E-02 to 1.23E-01 rem, depending on the location of the individual and transportation route. The potential LCF ranges from 5.90E-06 to 5.90E-05. The accident frequency ranges from 1.22E-07 to 1.01E-05/year depending on the transportation route and accident location.

The potential population doses from the maximum reasonably foreseeable accident have also been calculated and are shown in Table B-12. Assuming that the accident occurs in the same location or population zone as that determined for the maximally exposed individual, the population dose ranges from 3.46E-03 to 1.88E+01 person-rem. The potential LCF range from 1.73E-06 to 9.40E-03.

Uranium Oxide. As with plutonium oxide, uranium oxide resulting from SNF processing was assumed to be returned to Hanford. This material was assumed to be transported by ship to a port facility where it would be offloaded onto a truck for subsequent highway transport to Hanford. As with the plutonium oxide, only truck accidents were evaluated. The calculated dose received by the maximum individual from a truck accident is 2.36E-05 rem (see Table B-13). The potential LCF are 1.18E-08. The accident frequency ranges from 1.23E-07 to 1.01E-05 per year depending on the transportation route and accident location.

The potential collective dose ranges from 3.65E-06 to 1.98E-03 person-rem depending on the location and transportation route. The potential LCF range from 1.83E-09 to 9.90E-07 and also depend on the accident location and transportation route.

Solidified High-Level Waste. Following separation of all plutonium and uranium from the N Reactor fuel, the resulting HLW was assumed to be vitrified and poured into canisters. These canisters were assumed to be shipped in rail shipping casks by ship to a U.S. port facility and offloaded to rail cars at the port; therefore, only rail accidents were evaluated for shipments of HLW. The radiological source inventory used in the analysis was shown in Table B-1 and the release fractions were shown in Table B-7. Because the waste material that has been solidified in glass logs was considered to be "immobilized" material, the fraction of released material that is also dispersable and the fraction that is also respirable were adjusted, as discussed in Section 4.2.2.1.

Table B-13. Calculated maximum individual and population radiological doses and latent cancer fatalities based on accident location and frequency for uranium oxide shipments.

Transportation route	Mode	No. of ship-ments[a]	Accident frequency (per year)[b]	Accident location: population zone[c]	Maximum individual TEDE[d] (rem)	Maximum individual LCF[e]	Population TEDE[d] (person-rem)	Population LCF[e]
Portland, Oregon to Hanford, Washington	Truck	236	1.23E-07	Urban	2.36E-05	1.18E-08	1.98E-03	9.90E-07
Seattle, Washington to			1.01E-05	Rural	2.36E-05			

Hanford, Washington						1.18E-08	3.65E-06	1.83E-09
Norfolk, Virginia to Hanford, Washington			1.43E-06	Urban	2.36E-05	1.18E-08	1.86E-03	9.3E-07

a. Assumes one cask per truck shipment.
b. Accident frequency based on the number of shipments, campaign duration, one-way shipping distance, and conditional probability.
c. Accident location is based on the population zone where maximum individual dose occurs.
d. TEDE - 50-year total effective dose equivalent.
e. LCF - Latent cancer fatalities. Calculated on dose (rem) to maximum individual or population, i.e., 5.0E-04 LCF/rem.

The calculated dose to the maximally exposed individual and population are shown in Table B-14. The dose to the maximally exposed individual was 8.39E-01 rem and the potential latent cancer fatalities would be 4.20E-04. The accident frequency varies by route and ranges from 1.25E-07 to 1.88E-06/year.

The population doses are also shown in Table B-14. The collective dose ranges from 3.48E+00 to 1.42E+03 person-rem. The potential latent cancer fatalities range from 1.74E-03 to 0.710.

B.4.2.4 Assessment of Nonradiological Impacts. Nonradiological accident impacts consist of fatalities that may result from traffic accidents involving the shipments to and from the offshore processing facility. Nonradiological incident-free impacts are those resulting pollutants emitted from the vehicles. These impacts are not related to the radioactive nature of the materials being transported. In fact, the number of estimated injuries and fatalities would be the same even if the cargo were not radioactive materials. This section uses unit risk factors to estimate the nonradiological impacts associated with the five shipping scenarios considered in this evaluation.

The potential for accidents involving shipments of materials to and from an offshore processing facility is assumed to be comparable to that of general truck, rail, and barge transport in the U.S. Nonradiological accident unit risk factors were taken from Saricks and Kvitek (1994) to calculate nonradiological accident impacts. These risk factors, in units of fatalities-per-km of travel in rural and urban population zones, were multiplied by the total distance traveled in each zone by all of the shipments and then summed to calculate the expected number of nonradiological fatalities. The unit risk factor for travel in suburban zones was represented by the average of the rural and urban unit risk factors given by Saricks and Kvitek (1994).

Impacts to the public from non-radiological causes are also evaluated. This includes fatalities resulting from pollutants emitted from the vehicles during normal transportation. Based on the information contained in Rao et al. (1982), the types of pollutants that are present and can impact the public are sulfur oxides (SOx), particulates, nitrogen oxides (NOx), carbon monoxide (CO), hydrocarbons (HC), and photochemical oxidants (Ox). Of these pollutants, Rao et al. (1982) determined that the majority of the health effects are from SOx and the particulates. Unit risk

Table B-14. Calculated maximum individual and population radiological doses and latent cancer fatalities based on accident location and frequency for solidified high level waste shipments

Transportation Route	Mode	No. of ship-ments.a	Accident frequency (per year)b	Accident location: population zonec	Maximum individual		Population	
					TEDEd (rem)	LCFe	TEDEd (person-rem)	LCFe
Portland, Oregon to Hanford, Washington	Rail	24	3.39E-07	Rural	8.39E-01	4.20E-04	3.48E+00	1.74E-03
Seattle, Washington to Hanford, Washington			1.25E-07	Urban	8.39E-01	4.20E-04	1.42E+03	7.1E-01
Norfolk, Virginia to			1.88E-06	Urban	8.39E-01	4.20E-04	1.37E+03	6.8E-01

Hanford, Washington

a. Assumes one cask per rail shipment.
b. Accident frequency based on the number of shipments, campaign duration, one-way shipping distance, and conditional probability.
c. Accident location is based on population zone where maximum individual dose occurs.
d. TEDE - 50-year total effective dose equivalent.
e. LCF - Latent cancer fatalities. Calculated on dose (rem) to the maximum individual or population, i.e., 5.0E-04 LCF/rem.

factors (fatalities per kilometer) for both truck and rail shipments were developed by Rao et al. (1982) for travel in urban population zones (1.0E-07/km and 1.3E-07/km truck and rail respectively). These unit risk factors were combined with the total shipping distance in urban population zones to calculate the nonradiological incident-free impacts to the public.

The results of the nonradiological accident and incident-free impact calculations for the five potential shipping scenarios are presented in Table B.15. The values reported in the table represent the sum of the impacts from all of the shipments and include the impacts from shipments carrying cargo as well as those from empty return shipments.

B.4.3 Dose to the Public from Port Activities

Normal port activities during transport of N Reactor SNF are not expected to have any consequences for members of the public other than port workers, as discussed in Section 3.3.

The consequences of accidents during port transit were estimated using the same assumptions described for worker consequences in Section 3.3.2. Collective point estimates of risk to the population within 50 miles (80 km) of each location was estimated for an accident at the dock and on the approach to the port. The point estimate of risk to an individual at 1600 m (1 mile) was also estimated for applicable exposure pathways as described in Attachment A of this appendix. Consequences for populations and individuals are reported, both with and without the risk from ingestion of locally grown foods because protective action guidelines would require mitigative actions if the projected dose exceeded specified levels. Individual consequences assume 95% atmospheric dispersion, whereas consequences to populations are estimated for both 50% and 95% atmospheric dispersion.

Table B.15. Nonradiological transportation impacts of offshore processing scenarios

Shipping scenario	Accident impacts, fatalities	Incident-free impacts, fatalities
Barge to Portland	1.1E-02	2.1E-03
Seattle by Truck	8.9E-03	1.2E-03
Seattle by Rail	1.2E-02	3.4E-03
Norfolk by Truck	1.3E-01	1.6E-02
Norfolk by Rail	1.2E-01	1.5E-02

The consequences of port accidents were estimated in a manner similar to that used for overland transportation impacts. The contents of one shipping cask were assumed to be involved in an accident (see Table B-1), with radionuclide releases according to the release fractions reported in Table B-7. The dose and resulting LCF were calculated for each of the six accident severity categories. The point estimates of risk included the consequences as LCF for accidents of each severity category multiplied by the frequency with which an accident of that severity would occur. The accident frequencies for each severity category were assumed to be the overall accident rate per port transit (3.2 x 10-4) multiplied by the conditional probability for accidents in each severity category listed in Table B-6 (DOE 1994). The total accident risk for an individual or population was then estimated as the sum of risks for all accident severity categories. Risks for accidents evaluated at 95% (stable) atmospheric dispersion were assumed to be 10% lower than those at 50% (neutral) dispersion.

The results for accidents at the four representative ports are shown in Table B-16, with estimated risks for individual residents and populations within 80 km (50 miles). Point estimates of risk for the individual resident ranged from 6.2 x 10-13 to 1.3 x 10-11 LCF if no locally grown food were considered; results for all exposure pathways including ingestion were 3.5 x 10-11 to

7.8 x 10-10 LCF.

Collective point estimates of risk to the population within 50 miles of Portland, Oregon were 5.2 x 10-9 to 4.9 x 10-6 LCF assuming 50% atmospheric dispersion conditions and 1.0 x 10-8 to 8.3 x 10-6 LCF for 95% atmospheric dispersion. Corresponding results for the population in the vicinity of Newark are 2.3 x 10-8 to 4.9 x 10-5 LCF assuming 50% atmospheric dispersion and 1.5 x 10-8 to 8.4 x 10-5 LCF for 95% atmospheric dispersion. Consequences for the collective populations of Seattle-Tacoma and Norfolk fell between the estimates for the other two ports.

The maximum reasonably foreseeable accident was a category 6 accident, which has a frequency of 1.3 x 10-7 per port transit, and which was evaluated for either neutral or stable atmospheric conditions resulting in a cumulative frequency of 2.2 x 10-6 or 2.2 x 10-7, respectively for 17 SNF shipments. Dose and risk estimates for the maximum reasonably foreseeable accident are presented in Table B-17. The dose to the resident member of the public ranged from an estimated 0.02 to somewhat over 1 rem for all ports, depending on whether locally grown food was considered as an exposure pathway. The corresponding probability of LCF ranged from 9.0 x 10-6 to 6.5 x 10-4 and point estimates of risk, from 2.0 x 10-12 to 1.4 x 10-10 LCF. The collective consequences to the populations within 80 km (50 mi) of the ports

Table B-16. Point estimate of risk[a] of latent cancer fatalities from port accidents.

Port location	Portland, Oregon		Seattle-Tacoma, Washington		Norfolk, Virginia		Newark, New Jersey	
Exposure Pathways	All pathways	Inhalation + external	All pathways	Inhalation + external	All pathways	Inhalation + external	All pathways	Inhalation + external

1 Shipment	2.4E-07	5.2E-09	6.0E-08	1.4E-09	1.1E-07	2.5E-09	2.9E-06	6.5E-08
17 Shipments	4.0E-06	8.9E-08	1.0E-06	2.3E-08	1.9E-06	4.3E-08	4.9E-05	1.1E-06
Population within 80 km (50 miles) of dock - 95% (stable) atmospheric conditions								
1 Shipment	4.5E-07	1.0E-08	2.3E-07	5.1E-09	3.3E-07	7.4E-09	5.0E-06	1.5E-08
17 Shipments	7.6E-06	1.8E-07	3.9E-06	8.8E-08	5.6E-06	1.3E-07	8.4E-05	2.5E-07
Population within 80 km (50 Miles) of Harbor Approach - 95% (stable) Atmospheric Conditions								
1 Shipment	4.9E-07	1.0E-08	1.2E-07	2.8E-09	2.5E-07	5.8E-09	4.9E-06	1.1E-07
17 Shipments	8.3E-06	1.7E-07	2.0E-06	4.7E-08	4.3E-06	9.8E-08	8.3E-05	1.9E-06

a. Point estimate of risk is defined as the consequences to the receptor or population (as LCF) of an accident of a given severity category (assuming the accident occurs), multiplied by the frequency per shipment with which an accident of that severity would occur. The risks for accidents of all severity categories are then summed to obtain the total risk per shipment.

ranged from 2.0 x 10-3 to 380 LCF assuming the accident occurs, depending on the location of the accident (port or harbor approach) and the exposure pathways considered. The corresponding point estimates of risk for latent fatal cancers amounted to 4.4 x 10-9 to 8.2 x 10-5.

B.4.4 Dose to the Public from Ocean Transport to the United Kingdom

This analysis expects no dose to members of the public resulting from incident-free ocean transport of N Reactor SNF to the U.K. The ships carrying the fuel are owned and operated by the commercial vendor, and its shipboard crews are assumed to be classified as radiation workers for the purposes of this analysis.

The effects of losing a cask at sea are estimated to be comparable to those evaluated for shipment of foreign research reactor SNF to the U.S. (DOE 1994), based on similar shipping inventories of long-lived radionuclides per cask. The maximum dose to an individual for a cask lost in coastal waters was expected to be 11 mrem/year if the cask were left in place until all its contents dispersed. The corresponding consequences to marine biota were 0.24 mrad/year for fish, 0.32 mrad/year for crustaceans, and 13 mrad/year for mollusks. The consequences resulting from loss of a cask in the deep ocean would be many orders of magnitude lower than estimates for coastal waters.

The probability of accident on the open ocean was estimated to be 4.6 x 10-5 per shipment for an average duration voyage of about 20 days in transporting SNF from foreign research reactors to the U.S. (DOE 1995). The frequency of accidents for overseas shipment of SNF and process materials via special-purpose ships would likely be within a factor of two or three of this estimate. However, that frequency applies to commercial freight shipping experience, and it is possible that the use of special-purpose ships could result in a different accident rate. Using the commercial freight accident rate given above, the probability of an accident on the open ocean involving transport of SNF (17 ocean shipments), HLW (1 shipment), uranium oxide (1 shipment), and plutonium oxide (1 shipment) was calculated to be about 9.2E-04, integrated over all the shipments.

Table B-17. Consequences and risk to the public surrounding port facilities from maximum reasonably foreseeable accidents involving SNF shipments at or near the ports.

Port Location	Portland, Oregon		Tacoma, Washington		Norfolk, Virginia		Newark, New Jersey

B.5 Legal and Policy Considerations

B.5.1 Policy Considerations

For a general discussion of the policy considerations associated with DOE's management of SNF, see Section 2 of Volume 1. Several policy considerations bear on the evaluation of international shipment and processing of SNF.

The primary consideration in international shipment of nuclear materials is concern for unauthorized diversion of such materials to foreign weapons programs (nuclear proliferation). This concern is mitigated, but not eliminated, because SNF is not directly useable in simple nuclear weapons. Stringent safeguards exist for overseas transportation of nuclear materials. Highly enriched uranium has been transported overseas for research purposes, and SNF from research reactors has been returned to the U.S. for disposition. Although such return shipments have not occurred routinely since 1988, DOE is considering resumption of such shipments in support of U.S. efforts to remove highly enriched uranium SNF from international commerce. Two such shipments were completed on an urgent relief basis in 1994, and additional shipments may resume on completion of an evaluation by DOE (1995).

DOE (1993) has evaluated the safety and policy issues associated with overseas transport of plutonium and concluded that such shipments could be made safely and securely within the context of current national and international regulations for transport of radioactive materials (including special nuclear materials). The report (DOE 1993) addresses risks to the public and the environment, emergency response requirements, safeguards, and the regulatory framework within which such shipments could be made.

The overseas transportation of SNF and eventual return of vitrified wastes and end products contemplated in this alternative would be managed in accordance with well defined and demonstrated practices. However, a decision to implement the overseas transportation and processing option will require close examination of various policy and international documents that address plutonium stockpiling and the exchange of nuclear materials.

Other major policy considerations are the comparative risk of overseas shipment and return versus strictly domestic transportation and management of SNF and the involvement of a foreign population and environment in the foreign processing alternative. A decision to implement the BNFL option would be likely to generate controversy over the perception of transferrring environmental problems overseas. Transportation risks are addressed in Sections B.3 and B.4 of this attachment.

The representative facility used for this analysis (British Nuclear Fuels facility operations in Sellafield, U.K.) began in the 1940s with the same primary mission as Hanford. This commercial facility processes large volumes of SNF from several foreign countries. Round trip shipments and management of SNF and waste products would therefore be undertaken within a demonstrated regulatory, technical, and physical infrastructure.

B.5.2 Applicable Laws, Regulations, and Other Requirements

B.5.2.1 General. This discussion is limited to regulatory considerations associated with the

round trip domestic and overseas transportation of SNF and other hazardous and radioactive materials. For a discussion of general laws and regulation governing the management of SNF, see Section 2.2 of this appendix. State and local requirements will not be discussed here because the shipments of SNF under consideration would be in interstate or foreign commerce and federal provisions would govern. Internal DOE Orders also are not discussed.

The significant international and federal laws and regulations that apply to the transportation of hazardous and radioactive materials include the following laws:

- International Convention on the Safety of Life at Sea of 1960 (as amended)
- Atomic Energy Act (42 U.S.C. 2011 et seq.)
- Hazardous Transportation Materials Act (49 U.S.C. 1801 et seq.)
- Resource Conservation and Recovery Act, as amended by the Hazardous and Solid Waste Amendments (42 U.S.C. 26901 et seq.)
- Executive Order 12898 (Environmental Justice)
- Executive Order 12114 (Environmental Effects Abroad of Major Federal Actions).

B.5.2.2 Domestic Packaging and Transportation. Transportation of hazardous and radioactive

materials, substances, and wastes are governed by the regulations of the U.S. Department of Transportation (DOT) (49 CFR 171-178, 383-397), the U.S. Nuclear Regulatory Commission (NRC) (10 CFR 71), and the U.S. Environmental Protection Agency (EPA) (40 CFR 262, 265).

United States DOT regulations contain requirements for identifying a material as hazardous or radioactive. These regulations interface with NRC and EPA regulations for identifying material, but the DOT regulations govern hazard communication via placarding, labeling, reporting, and shipping requirements (see especially 10 CFR 71.5, in which DOT regulations are applied to shipping of radioactive materials by NRC regulations).

Nuclear Regulatory Commission regulations address packaging design and certification requirements. Certification is based on safety analysis report data on the packaging design for various hypothetical accident conditions.

General overland carriage is governed by specific regulations dealing with packaging notification, escorts, and communication. There are specific provisions for truck and for rail. For carriage by truck, the carrier must use interstate highways or state-designated preferred routes. Department of Transportation regulations found in 49 CFR 397.101 establish routing and driver training requirements for highway carriers of packages containing "highway-route-controlled quantities" of radioactive materials. Spent nuclear fuel shipments constitute such controlled shipments. For carriage by rail car, each shipment by the railroad must comply with 49 CFR 174 Subpart K "Detailed Requirements for Radioactive Materials."

B.5.2.3 Overseas Transportation. To the extent feasible, the NRC and DOT conform their

regulations to the model regulations of the International Atomic Energy Agency. These model international regulations are also incorporated into the International Maritime Dangerous Goods Code, which was developed to supplement the International Convention on the Safety of Life at Sea, to which the U.S. is a signatory. Transportation risk in the global commons must be evaluated in accordance with Executive Order 12114 (Environmental Effects Abroad of Major Federal Actions).

Transportation of dangerous cargoes through the Panama Canal is governed by the International Maritime Dangerous Goods Code (IMDG) and is addressed in 35 U.S.C. 113. General provisions for passage through the Panama Canal are found at 35 U.S.C. 101-135. General regulations governing navigation, including the applicability of the International Regulations for the Prevention of Collisions at Sea (1972), are found throughout Title 33 of the CFRs.

Relevant regulations applying to transport of SNF by vessel are found in 10 CFR Parts 71 and 73 (NRC) and 49 CFR Part 176 (DOT). These regulations address prenotification to the U.S. Coast Guard for inspection, and provide specifications for packaging, labelling, and other preparation for shipment. A Certification of Competent Authority must be obtained in compliance with International Atomic Energy Agency requirements. Specific provisions are made for stowage, including package surface temperature limitations, spacing, and total aggregate volume and number of freight containers.

B.6 Environmental Justice

For analytical purposes, three modes of transportation were selected for evaluation: 1) truck or rail to a port on Puget Sound (such as Tacoma, Washington); 2) barge to a Columbia River port in the vicinity of Portland, Oregon; or 3) rail or truck across the country to an East Coast port. The East Coast port of reference was assumed to be Norfolk, Virginia (Hampton Roads). These three modes are considered to provide a reasonable range of ports and transportation options for evaluation.

The DOE draft Environmental Impact Statement on the Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor (FRR) Spent Nuclear Fuel (DOE/EIS-0218D) provides information on the numbers and spatial locations of minority and low-income populations surrounding the ports of interest identified above and the Hanford Site. Because the FRR EIS (see Section A.2) utilized somewhat different analytical methodologies for environmental justice purposes than those utilized in this document, some data may vary. The reasons for such variations are explained in Section L-3.5 of Appendix L of this document. Utilizing demographic data entirely from the FRR EIS for the purposes of this attachment, allows for comparison of the sites of interest under consistent definitions and assumptions because the ports identified above were not demographically evaluated in Appendix L of this EIS. The reader is referred to the draft FRR EIS for maps locating the spatial distribution of minority and low income populations.

Table B-18 lists information on selected populations of interest for regions surrounding the Hanford loading facility and ports. Regions surrounding each port are areas that lie at least partially within a 16-km (10-mile) radius of the port. Eighty kilometers (50 miles) is used for Hanford. Population characteristics shown in the table were extracted from detailed, block-group statistical population data of the 1990 census. A block group usually includes 250 to 550 housing units.

Because the impacts as a result of transportation and facility operations are small and reasonably foreseen accidents present no significant risk, no reasonably foreseeable adverse impacts have been identified to the surrounding population. Therefore, no disproportionately high and adverse effects would be expected for any particular segment of the population, including minority and low-income populations.

Table B-18. Characterization of populations residing near candidate facilities (Hanford Site and candidate ports of embarkation[a]).

Facility	Total population within 16 km of facility	Total minority populati within 16 km of facilit		Households within 16 km of facility	Low income households within 16 km of facility	
	Number	Number	Percent	Number	Number	Percent
Hanford, Washington[c]	383,934	95,042	24.8	136,496	57,667	42.2
Tacoma, Washington	511,575	85,341	16.7	198,458	83,101	41.9
Portland, Oreg	356,064	54,704	15.4	146,047	66,186	45.3
Norfolk, Virgi	681,864	300,179	44.0	206,464	90,723	43.9

a. Data based on draft FRR EIS (DOE/EIS-0218D).

b. Hispanic origin individuals can be of any race.

c. In the case of the Hanford loading facility, a radius of 80 km rather than 16 km was used to define the nearby population.

B.7 Cost

The cost estimate for the foreign processing option, as provided by the representative facility, includes the full service of transporting the SNF from the Hanford Site to the U.K. facility, processing the material into recovered uranium and plutonium and HLW, packaging these products appropriately for return to the U.S., storing the packaged materials pending shipment, and transporting the materials back to the U.S. (BNFL 1994). The proposal provides only a range of total cost ($1.3 - $2 billion), with no breakdown of those costs into the principal cost elements. Thus, there is no detailed estimate of costs for the individual parts of the full service package. The above estimate does not include costs incurred at Hanford to package and stabilize the fuel, if necessary, prior to shipment, or to manage degraded fuel and sludge that may not be suitable for overseas shipment.

1. INTRODUCTION

The U.S. Department of Energy (DOE) has prepared the Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement (SNF and INEL EIS) to assist its management in making two decisions. The first decision, which is programmatic, is to determine the management program for DOE spent nuclear fuel. The second decision is on the future direction of environmental restoration, waste management, and spent nuclear fuel management activities at the Idaho National Engineering Laboratory.

Volume 1 of the EIS, which supports the programmatic decision, considers the effects of spent nuclear fuel management on the quality of the human and natural environment for planning years 1995 through 2035. DOE has derived the information and analysis results in Volume 1 from several site-specific appendixes. Volume 2 of the EIS, which supports the INEL-specific decision, describes environmental impacts for various environmental restoration, waste management, and spent nuclear fuel management alternatives for planning years 1995 through 2005.

This Appendix B to Volume 1 considers the impacts on the INEL environment of the implementation of various DOE-wide spent nuclear fuel management alternatives. The Naval Nuclear Propulsion Program, which is a joint Navy/DOE program, is responsible for spent naval nuclear fuel examination at the INEL. For this appendix, naval fuel that has been examined at the Naval Reactors Facility and turned over to DOE for storage is termed naval-type fuel. This appendix evaluates the management of DOE spent nuclear fuel including naval-type fuel. Naval spent nuclear fuel examination is addressed in Appendix D; Section 5.16 of this appendix includes relevant environmental consequences from Appendix D.

In addition to this introduction, Appendix B contains the following chapters:

- Chapter 2 - Background: Describes INEL spent nuclear fuel facilities, the regulatory framework for spent nuclear fuel management at the INEL, and the INEL spent nuclear fuel management program.
- Chapter 3 - Spent Nuclear Fuel Management Alternatives: Describes the DOE-wide spent nuclear fuel management alternatives as the INEL would implement them, and provides a summary comparison of potential environmental consequences for each alternative, as described in Chapter 5.
- Chapter 4 - Affected Environment: Describes the INEL site and the surrounding environment that DOE spent nuclear fuel management actions could affect.
- Chapter 5 - Environmental Consequences: Provides the results of environmental consequence analyses for each spent nuclear fuel management alternative.
- Chapter 6 - References

Volume 1 contains a list of acronyms and abbreviations and a glossary that is applicable to this appendix.

2. BACKGROUND

This chapter contains an overview of the Idaho National Engineering Laboratory (INEL) facilities and historic events related to spent nuclear fuel, a description of the regulatory framework for the actions evaluated in this document, and an overview of the current spent nuclear fuel management program at the INEL.

2.1 Overview

The following sections provide a general overview of the INEL including its history, current activities, and mission as they relate to spent nuclear fuel management and future decisions.

2.1.1 History of Spent Nuclear Fuel Activities

The U.S. Atomic Energy Commission, a predecessor of the U.S. Department of Energy (DOE), established the INEL, formerly the National Reactor Testing Station, to build, test, and operate various types of nuclear reactors, support plants, and associated equipment. Since its establishment in 1949 (see Table 2-1), DOE and its predecessor agencies have built 52 reactors at the INEL. The major DOE programs at the site have included test irradiation services, uranium recovery from highly enriched spent fuels, calcination of liquid radioactive waste, light-water-cooled reactor safety testing and research, operation of research reactors, environmental restoration, and storage and surveillance of solid transuranic wastes. In support of the DOE reactor research program and as part of the spent nuclear fuel reprocessing program, the INEL has received spent nuclear fuel from more than 30 offsite sources, including naval reactors, university reactors, commercial reactors, and DOE research reactors, as well as fuels fabricated in the United States and irradiated in foreign reactors (DOE 1993).

The Experimental Breeder Reactor-I, now a National Historic Landmark, maintains a key place in the history of nuclear power in the United States. In December 1951, this reactor generated the first usable electricity from a nuclear reactor. The Experimental Breeder Reactor-I also demonstrated that a nuclear reactor could actually produce more fuel than it consumes.

Of special significance to spent nuclear fuel is the history of the Idaho Chemical Processing Plant. From 1953 to 1992, this plant recovered usable uranium from spent nuclear fuel from United States government reactors. The plant operated for 39 years as a full-scale production facility. But in April 1992, DOE decided to phase out reprocessing for material recovery, resulting in the shutdown of the reprocessing operation.

Table 2-1. INEL spent nuclear fuel history.

Year	Event
1949	National Reactor Testing Station established
1951	Site reactor first to generate electricity from nuclear fission
1953	ICPPa began operation
1953	Test of first submarine nuclear reactor
1957	Expended Core Facility constructed
1965	DOE contract with Public Service Company of Colorado (Fort St. Vrain)
1974	Site became Idaho National Engineering Laboratory
1980	DOE contracted to receive Public Service Company of Colorado (Fort St. Vrain) spent nuclear fuel
1992	Decision to discontinue reprocessing of spent nuclear fuel at ICPPa announced
1992	DOE creates Office of Spent Fuel Management
1993	Court order of June 28, 1993 issued

a. ICPP = Idaho Chemical Processing Plant.

Spent naval nuclear fuel handling at the Naval Reactors Facility originated in 1957 with the construction of the Expended Core Facility. The original building contained a water pit and shielded cells, which are connected to the water pit by transfer tunnels. The Expended Core Facility examines spent nuclear fuel from operating naval ships and from prototype naval reactors. The examinations support research and development for naval fuel quality improvement. Over the years, the Navy made additions and improvements at the Naval Reactors Facility site, including the construction and operation of three prototype reactors and facilities for training naval nuclear powerplant operators. The Naval Nuclear Propulsion Program is placing the prototype reactors, which have reached the ends of their useful lives, in layup. All training is expected to end before DOE issues the Record of Decision for this Environmental Impact Statement (EIS). Expended Core Facility activities are continuing. Appendix D describes the Naval Reactors Facility in more detail.

In 1965 the United States entered into a contract with Public Service Company of Colorado, with which the United States agreed to lease special nuclear material to Public Service Company of Colorado for fuel at the Fort St. Vrain Nuclear Power Plant. In 1980, the United States and Public Service Company of Colorado modified the 1965 contract, requiring DOE to accept returned Fort St. Vrain spent nuclear fuel at the INEL. From 1980 to 1986, Public Service Company of Colorado made approximately 120 shipments of Fort St. Vrain spent nuclear fuel to the INEL.

In 1974 the National Reactor Testing Station became the Idaho National Engineering Laboratory. The INEL mission broadened to include research and engineering for nonnuclear programs and environmental restoration and waste management activities.

In the early 1980s, pursuant to the West Valley Demonstration Project Act (42 USC 2021a) and a court order, DOE agreed to accept 125 special case commercial reactor spent nuclear fuel assemblies located at the state-owned Western New York Nuclear Service Center. DOE began a project to demonstrate the viability of a transportable spent nuclear fuel storage cask, with the intention of shipping the fuel to the INEL. Based on this, New York State Energy Research and Development Authority, which has jurisdiction over the center, has allowed continued storage until DOE obtained U.S. Nuclear Regulatory Commission Certificates of Compliance, which have been issued. The fuel remains at West Valley awaiting the Record of Decision for this EIS.

In addition to the naval and INEL-generated fuel on the site, some special-case spent nuclear fuel, such as fuel from university reactors, has been shipped directly to the Idaho Chemical Processing Plant for storage. Damaged fuel from the 1979 Three Mile Island accident was shipped directly to Test Area North for examination and storage as part of a research mission.

In 1990, DOE issued an Environmental Assessment and Finding of No Significant Impact for

Public Service Company of Colorado shipments of Fort St. Vrain spent nuclear fuel to the INEL. The State of Idaho challenged the adequacy of the Environmental Assessment and, in June 1993, the United States District Court for the District of Idaho found for the State and ordered DOE to prepare this EIS. A DOE appeal of the order resulted in a December 1993 amendment that governs the DOE schedule and obligation for preparing the EIS.

2.1.2 Current Activities at Spent Nuclear Fuel-Related Facilities

Six major facility areas at the INEL (Figure 2-1) store spent nuclear fuel: Argonne National Laboratory - West, Idaho Chemical Processing Plant, Naval Reactors Facility, Power Burst Facility, Test Area North, and Test Reactor Area. Spent fuel at the INEL is kept in a variety of dry and wet configurations. The total amount of spent nuclear fuel at the INEL accounts for about 10 percent (by weight of heavy metal) of the spent nuclear fuel in the DOE complex (DOE 1993).

Figure 2-1. Major facility areas located at the Idaho National Engineering Laboratory site.

Table 2-2 lists the primary INEL spent nuclear fuel storage facilities, the types of fuel in storage, and the storage configurations. Figure 2-2 indicates the relative proportion of fuel at these facilities. The number and variety of wet and dry storage configurations currently in use at the INEL is largely the result of the different purposes for the facilities (e.g., at-reactor storage, storage research and development, reprocessing, and fuel research and development). The condition of the spent nuclear fuel in storage is generally good with the notable exception of the fuel in the Underwater Fuel Storage Facility (CPP-603). The following paragraphs briefly describe each primary facility area that manages spent nuclear fuel.

The Argonne National Laboratory - West generates spent nuclear fuel as a result of research and development activities related to advanced reactor design. DOE has brought small quantities of spent nuclear fuel from other reactors to this facility to support these activities. Reactors at Argonne National Laboratory - West are the Experimental Breeder Reactor II, the Transient Reactor Test Facility, the Zero Power Physics Reactor, and the Neutron Radiography Reactor. Storage facilities include both wet (including molten sodium) and dry configurations.

The Idaho Chemical Processing Plant historically received spent nuclear fuel from many onsite and offsite reactors for reprocessing (i.e., the recovery of uranium for reuse). However, DOE decided to phase out reprocessing activities in 1992. The new mission for this facility area is receipt and storage, plus research and development of technologies in support of the disposition of spent nuclear fuel. The Idaho Chemical Processing Plant stores virtually all types of spent nuclear fuel except production reactor fuel [i.e., fuel from Hanford Site and Savannah River Site (SRS) production reactors]. It stores nonproduction aluminum-based spent nuclear fuel. This facility uses both wet and dry storage configurations.

The Naval Reactors Facility includes the Expended Core Facility, which receives and examines naval spent nuclear fuel to support fuel development and performance analyses. In addition, the Expended Core Facility removes structural support material from fuel assemblies before the transfer of the fuel portion to the Idaho Chemical Processing Plant for interim storage.

Table 2-2. Major INEL spent nuclear fuel storage facilities.

Facility(a)	Storage Type(b)	Fuel Type(c)							
		1	2	3	4	5	6a	6b	6c
Argonne National Laboratory - West									
Experimental Breeder Reactor II	Liquid sodium						-		
Hot Fuel Examination Facility	Dry						-		
Neutron Radiography Reactor	Wet						-		
Radioactive Scrap and Waste Facility	Dry						-		
Transient Reactor Test Facility	Dry							-	
Idaho Chemical Processing Plant									
Underwater Fuel Storage Facilityd	Wet	-	-				-	-	
Irradiated Fuel Storage Facility	Dry				-				
Fuel Storage Area/Fluorinel Dissolution	Wet	-	-				-	-	

Process Cell							
Underground Storage Facility	Dry			-			
Naval Reactors Facility							
Expended Core Facility	Wet	-			-		
Expended Core Facility Rail Siding	Dry	-					
Power Burst Facility							
Power Burst Facility Storage Canal	Wet					-

Advanced Reactivity Measurement Facility	Wet		-				
Coupled Fast Reactivity Measurement Facility	Wet		-				
Advanced Test Reactor Canal	Wet		-				
Test Area North							
Test Area North Pool	Wet				-		
Test Area North Pad	Dry				-		

a. This table lists the major spent fuel storage facilities. Other facilities (e.g., laboratories) might periodically contain small quantities of spent nuclear fuel.

b. Wet storage involves water-filled pools. Dry storage involves a variety of configurations (e.g., casks, wells, buildings).

c. The spent fuel types are as follows:

1. Naval-type fuel
2. Savannah River Site production fuels and other aluminum-clad fuels
3. Hanford Site production fuels
4. Graphite fuels
5. Special case commercial fuels

6a. Experimental reactors - stainless steel-clad fuels
6b. Experimental reactors - zirconium-clad fuels
6c. Experimental reactors - other fuel configurations

d. Spent nuclear fuel storage at this facility will cease by December 31, 2000, as part of an agreement between DOE and the State of Idaho.

Figure 2-2. Distribution of INEL SNF. The Power Burst Facility reactor was placed in operational standby in 1992. A limited amount of spent nuclear fuel from this facility remains in wet storage, in a storage pool that is in good condition, but it is small and uneconomical to use. DOE plans to remove the fuel from this facility by 1996.

DOE has used Test Area North for commercial reactor fuel research. The large Test Area North Hot Shop and Hot Cells have supported the Loss of Fluid Test and commercial nuclear fuel testing, including dry cask storage demonstration. Test Area North stores special case commercial fuel (including Three Mile Island Unit 2 core debris) and DOE experimental fuel similar to commercial nuclear fuel.

Test Reactor Area has historically operated a number of test reactors, but the Advanced Test Reactor and its associated Critical Facility are the only reactors now operating. Most spent nuclear fuel at this area is associated with the Test Reactor Area reactors, which utilized aluminum-based fuels. In addition, DOE stores small amounts of special case commercial, foreign, and Power Burst Facility spent nuclear fuel at Test Reactor Area in the Materials Test Reactor basin. All spent nuclear fuel in storage at the Test Reactor Area is in water-filled pools (DOE 1993).

2.1.3 Spent Nuclear Fuel Mission

The INEL spent nuclear fuel mission is to manage DOE-owned spent fuel cost-effectively and in a way that protects the safety of INEL workers, the public, and the environment. As the lead laboratory for the DOE Spent Nuclear Fuel Program, the INEL provides support to the Office of Spent Fuel Management and coordinates the development of an integrated program for DOE.

The main focus of near-term activities is the accurate quantification and characterization of DOE-owned spent nuclear fuel, identification of spent nuclear fuel management facilities and their conditions, identification of safe interim storage for existing and new spent nuclear fuel, and identification of technologies and requirements to place DOE spent nuclear fuel in safe interim storage.

Long-term activities include the development of final waste acceptance criteria requirements and stabilization technologies for alternate fuel disposition, construction of facilities to stabilize fuel to meet waste disposal requirements, processing of the fuel to a final waste form, and transportation of the waste form for disposition.

2.2 Regulatory Framework for Spent Nuclear Fuel Management

This section summarizes State of Idaho laws and regulations that apply to spent nuclear fuel management at the INEL. Volume 1, Section 7.2, provides summary information for Federal laws and regulations, Executive Orders, and DOE Orders. Volume 2, Chapter 2, provides information on National Environmental Policy Act reviews related to site-specific decisions that have potential environmental impacts. Volume 2, Chapter 7, provides information on regulatory permits that the INEL holds or for which it has applied.

The Idaho Environmental Protection and Health Act (Idaho Code, Title 39, Chapter 101 et seq.) establishes general provisions for the protection of the environment and public health. The Act created the Idaho Department of Health and Welfare and its Division of Environmental Quality, thereby consolidating all state public health and environmental protection activities in one department. The Act authorizes the Department to promulgate standards, rules, and regulations related to water and air quality, noise reduction, and solid waste disposal; and grants authority to issue required permits, collect fees, establish compliance schedules, and review plans for the construction of sewage and public water treatment and disposal facilities.

The Idaho Water Pollution Control Act (Idaho Code, Title 39, Chapter 36) authorizes the Department of Health and Welfare to protect the waters of Idaho. This law contains general language on the prevention of water pollution and the provision of financial assistance to municipalities.

The Idaho Department of Health and Welfare is also responsible for the enforcement and implementation of the Hazardous Waste Management Act of 1983, as amended (Idaho Code, Title 39, Chapter 44), which provides for the protection of health and the environment from the effects of improper or unsafe management of hazardous wastes and for the establishment of a tracking or manifesting system for these wastes. This program is intended to be consistent with, and not more stringent than, the Federal regulations established under the Resource Conservation and Recovery Act (RCRA). At this time, Idaho has primacy over hazardous and mixed waste regulations promulgated through July 1, 1990, by the U.S. Environmental Protection Agency. The Hazardous Waste Management Act sets forth requirements for the development of plans that address the identification of hazardous wastes; unauthorized treatment, storage, release, use, or disposal of these wastes; and permit requirements for hazardous waste facilities. Under the authority of this Act, the Idaho Department of Health and Welfare has promulgated rules and regulations on the transportation, monitoring, reporting, and record keeping of hazardous wastes.

Several INEL facilities have air quality permits from the State, and operate in compliance with permit conditions. Permit applications are currently pending with the State for proposed new or modified emission sources. In April 1991 DOE submitted an inventory of all potential INEL radioactive and criteria pollutant emission sources to the State. The inventory contains the information necessary for the State to issue the INEL a Permit to Operate.

The Idaho Department of Health and Welfare, Division of Environmental Quality, Air Quality Bureau, conducts annual inspections of the INEL to determine if the operating portions of the site are in compliance with the Rules for the Control of Air Pollution in Idaho. The most recent inspections were in January 1994. In addition, pursuant to 40 CFR Part 61.94(H), DOE submits to the State an annual report documenting compliance with National Emission Standards for Hazardous Air Pollutants at the INEL.

2.3 Spent Nuclear Fuel Management Program at the INEL

In 1992 the Secretary of Energy directed the Assistant Secretary for Environmental Restoration and Waste Management to develop an integrated, long-term spent nuclear fuel management program. In response to this request, DOE created the Office of Spent Fuel Management (EM-37). This office, which has strategic programmatic responsibilities, has designated the INEL as the program support organization for the DOE Spent Nuclear Fuel Program. In this role, the INEL provides technical support to the Office of Spent Fuel Management and develops site communication and integration for the national program.

As identified in the Spent Fuel Working Group Report on Storage of the Department's Spent Nuclear Fuel and Other Reactor Irradiated Nuclear Materials and Their Environmental, Safety and Health Vulnerabilities, Volume I (DOE 1993), some of the current storage facilities at the INEL are inadequate for extended interim storage, and additional storage facilities or modifications might be necessary. In February 1994, DOE issued, Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities, Phase I (DOE 1994a), followed by a Phase II Plan in April 1994 (DOE 1994b) and a Phase III Plan in October 1994 (DOE 1994c), which identified specific corrective actions to address the spent nuclear fuel vulnerabilities. At the INEL, many of the corrective actions have been completed or are currently underway. The spent nuclear fuel storage pools at Test Area North, Power Burst Facility, and the Underwater Fuel Storage Facility do not comply with new facility regulatory requirements. The INEL plans to move spent nuclear fuel from the CPP-603 Underwater Fuel Storage Facility by December 31, 2000. To stabilize this fuel for storage, the INEL also plans to install canning equipment in the Irradiated Fuel Storage Facility hot cell. This equipment is scheduled for operation by late 1995. To the extent of its existing capability, DOE could consolidate spent nuclear fuel at the Power Burst Facility, the Idaho Chemical Processing Plant, and the Test Area North at the Idaho Chemical Processing Plant as a result of implementing the management alternatives described in Chapter 3. These activities and other planned actions for which National Environmental Policy Act review will be completed before the Record of Decision of this EIS were analyzed under the No-Action Alternative (see Chapter 3).

Each of the specific INEL spent nuclear fuel Plan of Action projects could result in emissions, worker exposures, and other potential environmental impacts. The potential environmental impacts that could result from each project or corrective action item were not analyzed individually but were collectively enveloped by the spent nuclear fuel management activities reported and analyzed for each alternative. Successful completion of the corrective actions would significantly reduce the near-term environmental, safety, and health risks associated with spent fuel storage at INEL.

The INEL has provided support in the development of dry at-reactor storage of special case commercial spent nuclear fuel in accordance with the requirements of the Nuclear Waste Policy Act of 1982 and its 1987 amendments. Dry-storage demonstrations and research at the INEL contributed to the granting of NRC licenses to several utilities for the construction and operation of dry-storage facilities at reactor sites. Research at these facilities is demonstrating the technical feasibility and the economics of adding dry storage capacity in metal or concrete spent fuel storage casks at reactor sites.

3. SPENT NUCLEAR FUEL MANAGEMENT ALTERNATIVES

Chapter 3 describes the alternatives for spent nuclear fuel management as they relate to the Idaho National Engineering Laboratory (INEL) and summarizes and compares potential environmental consequences for each alternative. Chapter 5 contains full descriptions of the consequences of implementing the alternatives.

3.1 Description of Alternatives

DOE has identified five spent nuclear fuel management alternatives:

Alternative 1 - No Action
Alternative 2 - Decentralization (2a, 2b, and 2c)
Alternative 3 - 1992/1993 Planning Basis
Alternative 4 - Regionalization (4a and 4b)
Alternative 5 - Centralization (5a and 5b)

Table 3-1 summarizes the actions that would result from the implementation of these alternatives at the INEL. For each alternative, this table summarizes the proposed transportation, stabilization, storage, research and development, and naval-type fuel examination activities. For alternatives 2, 4, and 5, it identifies a number of options.

The analysis of each alternative considers, as appropriate, existing and projected spent nuclear fuel inventories, existing spent nuclear fuel wet and dry storage facilities, the construction of storage facilities and associated stabilization facilities to achieve interim management objectives, and the relocation of the spent nuclear fuel as appropriate to proposed interim storage facilities.

Table 2-2 lists existing spent nuclear fuel storage facilities with associated type(s) of storage and fuel. Table 3-2 lists the potential facilities and projects required for specific alternatives. DOE has based the potential environmental consequences for each alternative on the existing and proposed facilities and projects listed in Tables 2-2 and 3-2, respectively.

Table 3-1. Summary of spent nuclear fuel management alternatives at the Idaho National Engineering Laboratory. (Page 1)

Table 3-1. (Page 2) Table 3-1. (Page 3) Table 3-2. Potential spent nuclear fuel projects required for each alternative(a).

The alternatives involving the interim storage of naval spent nuclear fuel at sites other than the INEL include a transition period, which would start on June 1, 1995, and continue for approximately 3 years. During this period, approximately 80 shipments of naval spent nuclear fuel would occur to the Expended Core Facility for examination and subsequent shipment to the Idaho Chemical Processing Plant for storage. After this transition period, DOE would phase out the Expended Core Facility such that the worker total at the facility would decline to about 10 by 2001. Appendix D describes this transition period.

3.1.1 Alternative 1: No Action

Table 3-1 lists the basic actions expected under this alternative. This alternative would be restricted to the minimum actions necessary for the continued safe and secure management of spent nuclear fuel. Table 3-3 lists the existing inventory of spent nuclear fuel at the INEL. This alternative is not a status quo condition in terms of spent nuclear fuel receipts (unlike Alternative 3, under which operations would continue in accordance with the 1992/1993 planning basis). Rather, DOE would maintain spent nuclear fuel close to defueling or current storage locations with minimal facility upgrades or replacements.

DOE would continue the operation of the following existing spent nuclear fuel-related facilities: the Fuel Storage Area/Fluorinel Dissolution Process Cell; CPP-603 Underwater Fuel Storage Facility (until 2000); Irradiated Fuel Storage Facility; Underground Storage Facility; Power Burst Facility storage canal; Advanced Test Reactor canal; Advanced Reactivity Measurement Facility; Coupled Fast Reactivity Measurement Facility; Materials Test Reactor canal; Test Area North Pool and Test Pad; Argonne National Laboratory - West Hot Fuel Examination Facility, Radioactive Scrap and Waste Facility, Transient Reactor Test Facility, Zero Power Physics Reactor, and Neutron Radiography Reactor pool. Table 2-2 lists the type(s) of storage and spent nuclear fuels associated with each facility.

3.1.1.1 Transportation. Under this alternative, the INEL would neither receive nor ship spent

nuclear fuel except for naval spent fuel during a transition period. DOE would continue to transfer the Advanced Test Reactor canal spent nuclear fuel to the Idaho Chemical Processing Plant. In addition, DOE could transfer other spent nuclear fuel at the INEL site (e.g., Test Reactor Area, Test Area North Pad, Power Burst Facility storage canal, Experimental Breeder Reactor-II, and Naval Nuclear

Table 3-3. Spent nuclear fuel inventory for each alternative by 2035 (metric tons of heavy metal). ,b,c

---

a. Source: Wichmann (1995).
b. To convert metric tons to tons, multiply by 1.10. Heavy metals are uranium, plutonium, and thorium.
c. The values may not sum exactly due to rounding.
d. The No-Action Alternative represents the present inventory and projections and serves as the basis for determining the net increase or decrease for each type of spent nuclear fuel for each of the other alternatives.
e. Regionalization 4b(2), Regionalization by Geography (Elsewhere), assumes all spent nuclear fuel inventories at the INEL go to the Nevada Test Site or Hanford Site. Inventories for 4b(2) would equal those listed for Alternative 5a.
f. N/C = No change from the No-Action Alternative.

Propulsion Program prototype reactors at the Naval Reactors Facility) to the Idaho Chemical Processing Plant to the extent of its storage capability.

3.1.1.2 Stabilization. Due to the deteriorated condition of some of the fuel in the CPP-603

Underwater Fuel Storage Facility, additional canning and characterization capabilities would be necessary to stabilize this fuel for safe transport and subsequent storage. DOE has scheduled the installation and operation of new fuel canning and characterization equipment in the Irradiated Fuel Storage Facility, which could provide these capabilities, by late 1995. (The installation of such equipment would be a minor upgrade and would have a smaller extent than similar actions described under Alternatives 3, 4, and 5.) DOE could perform other required stabilization of spent nuclear fuel at the INEL in either the Remote Analytical Laboratory or the Fluorinel Dissolution Process Hot Cell.

3.1.1.3 Storage. DOE has identified the CPP-603 Underwater Fuel Storage Facility as one of

five complex-wide spent nuclear fuel storage facilities that exhibit the greatest vulnerabilities according to selected criteria and, therefore, has selected this facility for priority attention (DOE 1993b). As part of the August 9, 1993, agreement between the Secretaries of the Department of Energy and the Department of the Navy and the Governor of Idaho to phase out storage operations in the 45-year old CPP-603 facility, one goal of this and the other alternatives would be to remove spent nuclear fuel from underwater storage in the North and Middle Basins of the CPP-603 facility by the end of 1996 and from the South Basin of this facility by the end of 2000 (DOE 1993a). DOE would relocate this material to the Fuel Storage Area at the Idaho Chemical Processing Plant.

At the Argonne National Laboratory-West, the spent nuclear fuel stored at the Hot Fuel

Examination Facility and the Radioactive Scrap and Waste Facility, primarily Experimental Breeder Reactor-II fuel and blanket elements, would remain in dry storage until its potential processing in the Fuel Cycle Facility. At the Experimental Breeder Reactor-II site, DOE would use dry storage with the exception of the Neutron Radiography Reactor pool fuel. The Test Area North Pool Fuel Transfer project would continue, resulting in the relocation of Test Area North spent pool contents into dry cask storage at the Idaho Chemical Processing Plant by 1998. The dry cask storage required for this project is not related to the Dry Fuels Storage Facility.

DOE would start no new projects to increase spent nuclear fuel storage capacity because there is sufficient storage capacity to meet No-Action storage needs. The planning of spent nuclear fuel storage projects such as the Dry Fuels Storage Facility and Additional Increased Rack Capacity for the Fuel Storage Area would stop.

3.1.1.4 Research and Development. There would be only limited spent nuclear fuel

research and development. Existing spent nuclear fuel management research and development projects would continue. Existing facilities such as the Process Improvement Facility, the Remote Analytical Laboratory, and the Pilot Plant Facility would support continuing research and development work.

3.1.1.5 Naval-Type Fuel Examination. After a transition period, DOE would cease

shipments of naval spent nuclear fuel to the INEL and would phase out the Expended Core Facility. DOE would make onsite shipments of the "library fuel" (a representative sampling of different fuel types maintained for reference purposes) and the spent nuclear fuel that originated at the prototype sites at the Naval Reactors Facility to the Idaho Chemical Processing Plant.

3.1.2 Alternative 2: Decentralization

Under this alternative, DOE could transport fuel for safety or research and development activities. In addition, DOE could undertake actions for safety it deemed desirable, though not essential, and could perform spent nuclear fuel treatment and research and development. As listed in Table 3-3, the anticipated spent nuclear fuel inventory for this alternative would be slightly greater than the inventory for Alternative 1, with the increase consisting primarily of aluminum-clad and stainless-steel-clad spent nuclear fuel from university and foreign research and experimental reactors.

3.1.2.1 Transportation. This alternative assumes that the INEL would accept primarily

limited shipments of spent nuclear fuel from offsite sources into the Fuel Storage Area (e.g., DOE or university reactors) after the Record of Decision for this EIS (1995). Onsite transfers could occur from the Fuel Storage Area to the Storage Facility or the Irradiated Fuel Storage Facility. DOE would consolidate the spent nuclear fuel in the Advanced Test Reactor and in the Materials Test Reactor and Power Burst Facility canals at the Idaho Chemical Processing Plant for canning, characterization, and storage.

As in the No-Action Alternative, there would be a transition period during which the Naval Nuclear Propulsion Program would ship naval spent nuclear fuels to the Expended Core Facility for examination and subsequent shipment to the Idaho Chemical Processing Plant for storage. Section 3.1.2.5 describes the transportation of naval spent fuels that would occur after the transition period.

3.1.2.2 Stabilization. DOE would use the canning and characterization equipment identified in

Section 3.1.1.2 to stabilize spent nuclear fuel removed from the CPP-603 Underwater Fuel Storage Facility for interim underwater storage.

3.1.2.3 Storage. As in Alternative 1, DOE would transfer the spent nuclear fuel in the

CPP-603 Underwater Fuel Storage Facility to the Fuel Storage Area by 2000. DOE would continue to use the Underground Storage Facility and the Irradiated Fuel Storage Facility for existing spent nuclear fuel inventory and transfers of other spent nuclear fuel based on safety analyses. DOE would upgrade or increase fuel storage capacity at the INEL as required.

The Test Area North Pool Fuel Transfer project would result in the relocation of the contents of Test Area North spent nuclear fuel into dry storage at a pad at the Idaho Chemical Processing Plant.

3.1.2.4 Research and Development. The development of technology for the disposition of

spent nuclear fuel would continue. Research and development activities would include laboratory and pilot plant testing, continued repository performance assessments and waste acceptance criteria development, and the characterization of spent nuclear fuel. Shipments of samples or selected spent nuclear fuel assemblies to offsite DOE facilities would be necessary.

3.1.2.5 Naval-Type Fuel Examination. DOE would consider three options for naval reactor

spent nuclear fuel receipt and shipment. Under options 2a and 2b, DOE would stop shipments of naval spent nuclear fuel to the INEL and would shut down the Expended Core Facility. Option 2c would enable the continued receipt of naval-type fuel for examination at the Expended Core Facility and its return to the originating shipyards for storage in transport casks. Chapter 3 of Appendix D further describes these options. As with Alternative 1, each option would require approximately a 3-year transition period. During this period, DOE would transport spent nuclear fuel in shipping containers to the Expended Core Facility, unload the containers, and use them to support additional refuelings and defueling.

3.1.3 Alternative 3: 1992/1993 Planning Basis

This alternative is consistent with DOE plans at the INEL before the injunction that stopped spent nuclear fuel shipment to the INEL; it assumes a 40-year planning horizon for the continued transportation, receipt, stabilization, and storage of spent nuclear fuel. As with Alternative 1, DOE would continue the maintenance and operation of existing spent nuclear fuel-related facilities; however, some consolidation of INEL facilities could occur. DOE would send newly generated spent nuclear fuel to either the INEL or the Savannah River Site. DOE would assess the construction of new facilities to accommodate current and projected spent nuclear fuel management requirements.

The amount of spent nuclear fuel at the INEL under this alternative would be greater than that for either Alternative 1 or 2 (see Table 3-3) because this alternative assumes that the INEL would manage, before stabilization and disposal, its present inventory (see Alternative 1) plus additional receipts of DOE spent nuclear fuel, including the following:

- Naval-type spent nuclear fuel
- Approximately half of the aluminum-clad spent nuclear fuel from university and foreign research and experimental reactors
- All Training Reactor Isotopics General Atomics (TRIGA) spent nuclear fuels from the

Hanford Site and approximately half of that from foreign, DOE, and university reactors

- Fort St. Vrain spent nuclear fuel from Public Service of Colorado
- Special case commercial pressurized water reactor and boiling water reactor spent nuclear fuel from the DOE facility in West Valley, New York
- Miscellaneous spent nuclear fuel types from such DOE sites as Los Alamos, New Mexico, and Oak Ridge, Tennessee, and from university reactors and other locations

3.1.3.1 Transportation. DOE would consolidate the spent nuclear fuel in the Test Reactor

Area (Advanced Test Reactor canal, Materials Test Reactor canal, and Coupled Fast Reactivity Measurements Facility and Advanced Reactivity Measurement Facility canal) and the Power Burst Facility at the Idaho Chemical Processing Plant for canning and dry storage.

The INEL would receive and temporarily store new spent nuclear fuels in the Fuel Storage Area. Transfers could occur from the Fuel Storage Area to the Underground Storage Facility or the Irradiated Fuel Storage Facility or, when available, the dry storage vaults at the proposed Dry Fuels Storage Facility.

At present, DOE is transferring spent nuclear fuel from the Advanced Test Reactor Canal to the Idaho Chemical Processing Plant. DOE would maintain this canal for the storage and management of its recyclable fuel assemblies until the reactor no longer had a mission. The Experimental Breeder Reactor-II spent nuclear fuel in storage would remain at Argonne National Laboratory-West. As with Alternative 2, the Test Area North Pool Fuel Transfer project would result in the relocation of the contents of the Test Area North spent nuclear fuel pool to dry storage at a pad at the Idaho Chemical Processing Plant.

3.1.3.2 Stabilization. DOE would complete a new Canning and Characterization Facility with

appropriate inspection, stabilization, and packaging equipment to stabilize new receipts of spent nuclear fuel and to prepare fuel currently in underwater storage for dry storage. This facility would be an integral part of the Dry Fuels Storage Facility that DOE would complete under this alternative. Until the Dry Fuels Storage Facility is in service, DOE would use the canning and characterization equipment described under Alternative 1 to stabilize spent nuclear fuel removed from the CPP-603 Underwater Fuel Storage Facility for interim underwater storage.

3.1.3.3 Storage. As with Alternative 2, DOE would upgrade or increase dry fuel storage

capacity at the INEL as required. DOE would complete the Fuel Storage Area increased Rack Capacity project in 1997. Coupled with stringent fuel management and, if necessary, temporary storage of some aluminum fuel in stainless steel racks, this project would allow the Fuel Storage Area to accept all of the project spent nuclear fuel receipts until the Additional Increased Rack Capacity project would be completed in 2001. The Additional Increased Rack Capacity project would allow the Fuel Storage Area to accept the projected spent nuclear fuel receipts until the Dry Fuels Storage Facility project would become available in 2005. The INEL would receive the Fort St. Vrain spent nuclear fuel in the Irradiated Fuel Storage Facility on a space-available basis or in the new vault storage in the Dry Fuels Storage Facility. Modifications to the Irradiated Fuel Storage Facility cask handling equipment would be necessary to accept the new Fort St. Vrain shipping casks.

DOE would continue to use the Underground Storage Facility and the Irradiated Fuel Storage Facility for current inventory and for transfers of other fuel inventories based on safety analyses. Based on these safety analyses, upgrades would be limited to those required for facility safety improvements and for making transfers safely.

3.1.3.4 Research and Development. Spent nuclear fuel research and development would

continue as planned, with the construction of a Technology Development Facility. The Electrometallurgical Process Demonstration Project at Argonne National Laboratory - West Fuel Cycle Facility would continue. In addition, Argonne National Laboratory would implement the EBR-II Blanket Processing project under this alternative. The Dry Fuels Storage Facility would develop and demonstrate technology for the dry storage of selected DOE highly enriched uranium fuels.

3.1.3.5 Naval-Type Fuel Examination. The practice of transporting spent nuclear fuel from

naval reactors to the Expended Core Facility at the INEL would resume. After an examination, DOE would transfer such fuel to the Idaho Chemical Processing Plant for interim storage pending final disposition. Under this alternative, the Naval Nuclear Propulsion Program would complete the Expended Core Facility Dry Cell Construction project.

3.1.4 Alternative 4: Regionalization

This alternative assumes that DOE would base the spent nuclear fuels shipped between DOE sites and the receipt of fuels from other locations primarily on either geography or fuel type. Alternative 4 offers two options for the redistribution of existing and new spent nuclear fuel:

- Option 4a assumes that DOE would base the spent nuclear fuels shipped between DOE sites and the receipt of fuels from other locations at the INEL, Hanford Site, or the Savannah River Site primarily on fuel type.

- Option 4b assumes that DOE would base the spent nuclear fuels shipped between DOE sites and the receipt of fuels on geography. There would be a single western site at either the Hanford Site, INEL or Nevada Test Site. Option 4b(1) in which the INEL is the western regional site is essentially the same as Alternative 5b. Option 4b(2) in which INEL ships all SNF to another western regional site is the same as Alternative 5a.

3.1.4.1 Transportation. Under option 4a, the INEL would receive all Zircaloy- and

stainless-steel-clad spent nuclear fuel. This redistribution would optimize DOE spent nuclear fuel management.

The spent nuclear fuel inventory involved under option 4a would be greater than those for Alternative 1, 2, or 3 because this alternative assumes that the INEL would manage its present inventory plus the following additional spent nuclear fuels (see Table 3-3) prior to stabilization and disposal:

- Naval-type spent nuclear fuel

- All spent nuclear fuel except aluminum-clad fuel and Hanford spent nuclear fuel

- All Training Reactor Isotopics General Atomics spent nuclear fuels from the Hanford Site

- Fort St. Vrain spent nuclear fuel from Public Service of Colorado

- Special case commercial pressurized water reactor and boiling water reactor spent nuclear fuel from the DOE facility in West Valley, New York

Under option 4b(1), DOE would regionalize all western DOE SNF at the INEL. DOE would transport all spent nuclear fuel at other western sites to the INEL. Because the fuel inventory for this alternative would be within 15 percent of that for Alternative 5b, analyses for this option conservatively assume that environmental impacts would be the same as those for as Alternative 5b - Centralization at INEL.

Under option 4b(2), DOE would regionalize all western DOE SNF at either the Nevada Test Site or Hanford Site. DOE would transport spent nuclear fuel at the INEL to the selected western site. As such, this option would be the same as Alternative 5a - Centralization at Other DOE Sites.

3.1.4.2 Stabilization. DOE would stabilize the spent nuclear fuels it would retain at the INEL

as planned for Alternative 3, with the construction of such new facilities as a canning and characterization facility and the Dry Fuels Storage Facility. Options 4a and 4b(1) would require such a facility for the receipt and storage of spent nuclear fuel, while option 4b(2) would require stabilization capabilities for shipping spent nuclear fuel. For spent nuclear fuel that the INEL would ship to other regional sites, the receiving site would perform any stabilization beyond that required for transportation.

3.1.4.3 Storage. Under option 4a, DOE would increase dry storage capacity and undertake

facility upgrades similar to those described for Alternative 3, with replacements and additions as appropriate. Under option 4b(1), DOE would increase dry storage capacity and undertake facility upgrades similar to those described for Alternative 5b, with replacements and additions as appropriate.
Option 4b(2) would not require increased storage capacity and, therefore, there would be no facility upgrades.

3.1.4.4 Research and Development. As with Alternative 3, this alternative would include

the continuation of activities related to the treatment of spent nuclear fuel, including research and development (e.g., Electrometallurgical Process Demonstration Project), and the construction of the Dry Fuels Storage Facility. DOE would initiate pilot programs as needed to support future decisions on spent nuclear fuel management and disposition. DOE would use historic data on spent nuclear fuel to provide the bounding case for a determination of the impacts associated with potential pilot program activities.

3.1.4.5 Naval-Type Fuel Examination. Under options 4a and 4b(1), the transportation of

spent nuclear fuel from naval reactors to the Expended Core Facility at the INEL would resume. As with Alternative 1, under option 4b(2) DOE would phase out shipments of naval-type spent nuclear fuel to the INEL and would phase out the Expended Core Facility.

3.1.5 Alternative 5: Centralization

Under this alternative, DOE would send all current and future spent nuclear fuel inventories from both DOE and the Naval Nuclear Propulsion Program to one DOE site for interim storage until final disposition.

The two options under Alternative 5 encompass the extreme ranges of spent nuclear fuel inventories that DOE could store at the INEL (i.e., all or none of the inventory). Under option 5a, DOE would ship the INEL spent nuclear fuel inventory off the site to the Hanford Site, the Savannah River Site, the Nevada Test Site, or the Oak Ridge Reservation. Under option 5b, DOE would ship all existing spent nuclear fuel to the INEL.

This alternative would bound the maximum number of spent nuclear fuel-related actions that DOE could reasonably undertake at any site. DOE would have to build new facilities at the selected site to accommodate the increased inventories. Shipments of spent nuclear fuel to the sites not selected as the centralized destination would continue as an interim action pending the construction of necessary storage and examination facilities at the selected site. DOE would then transfer all spent nuclear fuel to the selected site, and the other sites would close their spent nuclear fuel facilities. Before DOE would ship spent nuclear fuel from the originating site, it would characterize and can all spent nuclear fuel as necessary.

The locations from which spent nuclear fuel would originate, in addition to the Hanford Site and Savannah River Site, would include Argonne National Laboratory - East, Babcock and Wilcox, Brookhaven National Laboratory, General Atomics, Los Alamos National Laboratory, Oak Ridge National Laboratory, Sandia National Laboratories, West Valley, and Fort St. Vrain. This alternative would also include fuel that might be returned to the United States following irradiation or testing.

This alternative would include activities related to the treatment of spent nuclear fuel, including research and development and pilot programs to support future decisions on its disposition. DOE would use historic data on spent nuclear fuel to provide a foundation case for determining the impacts associated with potential pilot program activities.

3.1.5.1 Alternative 5a - Centralization at Other DOE Sites.

3.1.5.1.1 Transportation - This option assumes that the INEL would consolidate and

prepare all existing and projected onsite spent nuclear fuel for shipment to another DOE facility: the Hanford Site, the Savannah River Site, the Nevada Test Site, or Oak Ridge.

3.1.5.1.2 Stabilization - The DOE would construct a canning and characterization facility

at the Idaho Chemical Processing Plant to accept the different types of INEL spent nuclear fuel in various shipping casks and storage containers, and to stabilize these fuel types before their shipment to the selected DOE facility.

3.1.5.1.3 Storage - As in Alternative 1, DOE would complete the CPP-603 Underwater

Fuel Storage Facility pool inventory transfer to existing dry storage facilities by 2000. DOE would not build the Dry Fuels Storage Facility. DOE would then close all spent nuclear fuel-related facilities at the INEL with the exception of those in direct support of operating reactors, such as the Advanced Test Reactor canal or the Argonne National Laboratory-West Hot Fuel Examination Facility and Fuel Cycle Facility. This closure would require the establishment of a major surveillance and maintenance operation until DOE determined the disposition of these facilities. The timeframe for closure would depend on the following factors:

- The time necessary to stabilize the spent nuclear fuel in the CPP-603 Underwater Fuel Storage Facility
- The time necessary for the selected DOE site to prepare facilities qualified to accept the spent nuclear fuel
- The time necessary for the procurement and licensing of shipping containers that would be compatible with the selected receiving DOE site

The spent nuclear fuel inventory that DOE would export off the INEL site for Alternative 5a is the same quantity listed for Alternative 1 (see Table 3-3).

3.1.5.1.4 Research and Development - Under this option there would be a phaseout of

all research and development activities, although the Electrometallurgical Process Demonstration Project would continue at the Argonne National Laboratory - West Fuel Cycle Facility (but would stabilize only spent nuclear fuel currently on the site).

3.1.5.1.5 Naval-Type Fuel Examination - As with Alternative 1, DOE would phase out

shipments of naval-type spent nuclear fuel to the INEL and would phase out the Expended Core Facility.

3.1.5.2 Alternative 5b - Centralization at the INEL.

3.1.5.2.1 Transportation - This option assumes that the INEL would receive all DOE and

naval-type spent nuclear fuel (see Table 3-3).

3.1.5.2.2 Stabilization - The Hanford Site, the Savannah River Site, and other DOE

facilities would stabilize as necessary, spent nuclear fuel for safe transportation to the Idaho Chemical Processing Plant. The Hanford Site, the Savannah River Site, and other DOE facilities would procure an undetermined number of additional casks and install cask handling equipment as necessary. DOE would complete an expanded Dry Fuels Storage Facility at the INEL, which would include a new Canning and Characterization Facility similar to that described for Alternative 3. This facility would, if needed, repackage the spent nuclear fuel into compatible canisters for dry storage. Other new facility projects would be the same as those described for Alternative 3. In addition, DOE would begin stabilizing for safe storage all complex-wide spent nuclear fuel, as necessary, in existing facilities at the Idaho Chemical Processing Plant. Upgrades and new facilities would be necessary to support long-term fuel stabilization for ultimate disposition; this would address criticality (unplanned and uncontrolled nuclear fission) concerns about the disposal of spent nuclear fuel in a potential Federal repository.

3.1.5.2.3 Storage - Projects and activities for storage of spent nuclear fuel would be similar

to those described for Alternative 3, except that accelerated schedules for the Increased Rack Capacity and Additional Increased Rack Capacity projects would be necessary to accommodate the increased fuel receipts. In addition, the schedule for the Dry Fuel Storage Facility project would have to be accelerated and its scope expanded. For example, the Increased Rack Capacity project may have to be completed in late 1996, the Additional Increased Rack Capacity project may have to be completed in late 1998, and the Expanded Dry Fuels Storage Facility project may have to be completed in 2002. If the Expanded Dry Fuels Storage Facility would become available even earlier, it could eliminate the need for the Additional Increased Rack Capacity project.

3.1.5.2.4 Research and Development - DOE would conduct maximum spent nuclear

fuel research and development under this option.

As with Alternative 4, the Electrometallurgical Process Demonstration Project would continue at the Argonne National Laboratory - West.

3.1.5.2.5 Naval-Type Fuel Examination - Similar to Alternative 3, the practice of

transporting spent nuclear fuel from naval reactors to the Expended Core Facility at the INEL would resume.

3.2 Comparison of Alternatives

Chapter 5 analyzes the environmental consequences of the alternatives. Tables 3-4 through 3-6 summarize and compare the potential impacts associated with each alternative from the information in Chapter 5 for construction, normal operations, and accidents, respectively.

A review of the impacts of the alternatives, as presented in Chapter 5, indicates that impacts would be minimal or negligible in most areas. Further, most areas with measurable impacts would have no appreciable differences among alternatives.

In general, the levels of potential impacts associated with Alternatives 1 through 4 (option 4a) would be similar because the amounts of spent nuclear fuel that DOE would manage at the INEL under these alternatives would be on the same order of magnitude (e.g., 300 to 450 MTHM) and activities would extend throughout the full 40-year management period. The lowest level of overall potential impact at the INEL would occur under Alternative 4b(2) - Regionalization by Geography (Elsewhere) and Alternative 5a - Centralization at Other DOE Sites because DOE would ship INEL spent nuclear fuel off the site well before the management period ended in 2035. Alternative 5b and Alternative 4b(1), under which DOE would ship all or nearly all spent nuclear fuel to the INEL, would result in the greatest potential onsite impacts.

4. AFFECTED ENVIRONMENT

4.1 Overview

Chapter 4 describes the existing environment at the Idaho National Engineering Laboratory (INEL) site and the surrounding region. It emphasizes areas that the proposed spent nuclear fuel management alternatives could affect. The information in this chapter provides the existing environmental conditions against which the Department of Energy (DOE) can measure the potential environmental effects of the alternatives. It supports the assessment of the potential environmental consequences that Chapter 5 discusses. DOE used the discussion of the Affected Environment in Volume 2 of this EIS as input for this chapter.

4.2 Land Use

The INEL site encompasses 570,914 acres (2,310.4 square kilometers) in Butte, Bingham, Jefferson, Bonneville, and Clark Counties, Idaho. This section describes existing land uses at the INEL and in the surrounding region, and land use plans and policies applicable to the surrounding area.

4.2.1 Existing and Planned Land Uses at the INEL

Categories of land use at the INEL include facility operations, grazing, general open space, and infrastructure such as roads. Facility operations include industrial and support operations associated with energy research and waste management activities (DOE also conducts such activities at its Idaho Falls facilities). In addition, DOE uses INEL land for recreation and environmental research associated with the designation of the INEL as a National Environmental Research Park.

Much of the INEL is open space that DOE has not designated for specific uses. Some of this open space serves as a buffer zone between INEL facilities and other land uses. Facilities and operations use about 2 percent of the total INEL site area (11,400 acres or 46 square kilometers). Public access to most facility areas is restricted. Approximately 6 percent of the INEL, or 32,985 acres (133.5 square kilometers), is devoted to public roads and utility rights-of-way that cross the site. Recreational uses include public tours of general facility areas and the Experimental Breeder Reactor-I (a National Historic Landmark), and controlled hunting, which is generally restricted to 0.5 mile (0.8 kilometer) inside the INEL boundary.

Cattle and sheep grazing occupies between 300,000 and 350,000 acres (1,200 and 1,400 square kilometers). The U.S. Sheep Experiment Station uses a 900-acre (3.6-square-kilometer) portion of this land, at the junction of Idaho State Highways 28 and 33, for a winter feed lot for approximately 6,500 sheep. Grazing is not allowed within 2 miles (3.2 kilometers) of any nuclear facility and, to avoid the possibility of milk contamination by long-lived radionuclides, dairy cattle are not permitted on the site. The Department of the Interior's Bureau of Land Management grants and administers rights-of-way and grazing permits. Figure 4.2-1 shows selected land uses at the INEL and in the surrounding region.

Figure 4.2-1 Selected land uses at the INEL and in the surrounding region.

The INEL site is within the Medicine Lodge Resource Area (approximately 140,415 acres or 568.3 square kilometers in the eastern and southern portions of the INEL site) and the Big Butte Resource Area (430,499 acres or 1,742 square kilometers in the central and western portions); the Bureau of Land Management administers both of these areas. Under Resource Management Plans, the Bureau manages portions of these Resource Areas for grazing and wildlife habitat. No mineral exploration or development is allowed on INEL land.

DOE land use plans and policies applicable to the INEL include the INEL Institutional Plan - Fiscal Year 1994 - 1999 (DOE-ID 1993c) and the INEL Technical Site Information Report (DOE-ID 1993a). The Institutional Plan provides a general overview of INEL facilities, outlines strategic program directions and major construction projects, and identifies specific technical programs and capital equipment needs. The Technical Site Information Report presents a 20-year master plan for development activities at the site. Under the scope of these planning documents, energy research and waste management activities would continue in existing facility areas and, in some instances, expand into currently undeveloped site areas. These documents also describe environmental restoration, waste management, and spent nuclear fuel activities. Projected land use scenarios for the next 25 to 50 years include the outgrowth of current functional areas and the possible development of waterfowl production ponds in existing grazing areas.

No onsite land use restrictions due to Native American treaty rights would exist for any of the alternatives described in this EIS. The INEL does not lie within any of the land boundaries established by the Fort Bridger Treaty, and the entire INEL site is land occupied by the U.S. Department of Energy. Therefore, the provisions in the Fort Bridger Treaty that allows the Shoshone-Bannock Indians to hunt on unoccupied lands of the United States do not apply to the INEL site.

4.2.2 Existing and Planned Land Use in Surrounding Areas

The Federal government, the State of Idaho, and private parties own the lands surrounding the INEL site. Land uses on Federally owned land consist of grazing, wildlife management, range land, mineral and energy production, and recreational uses. State-owned lands are used for grazing, wildlife management, and recreational purposes. Privately owned lands are used primarily for grazing, crop production, and range land.

Small communities and towns near the INEL boundaries include Mud Lake to the east; Arco, Butte City, and Howe to the west; and Atomic City to the south. The larger communities of Idaho Falls, Rexburg, Blackfoot, and Pocatello and Chubbock are to the east and southeast of the INEL site. The Fort Hall Indian Reservation is to the southeast of the INEL. Recreation and tourist attractions in the region around the INEL include the Craters of the Moon National Monument, Hell's Half Acre Wilderness Study Area, Black Canyon Wilderness Study Area, Camas National Wildlife Refuge, Market Lake State Wildlife Management Area, North Lake State Wildlife Management Area, Yellowstone National Park, Grand Teton National Park, Jackson Hole Recreation Complex, Targhee and Challis National Forests, and the Snake River.

Lands surrounding the INEL site are subject to Federal and state planning laws and regulations. Federal rules and regulations that require public involvement in their implementation govern planning for and use of Federal lands and their resources. Land use planning in the State of Idaho is derived from the Local Planning Act of 1975 (State of Idaho Code 1975). Because the State currently has no land use planning agency, the Idaho legislature requires each county to adopt its own land use planning and zoning guidelines. County plans that are applicable to lands bordering the INEL site include the Clark County Planning and Zoning Ordinance and Interim Land Use Plan (Clark County 1994); Bonneville County Comprehensive Plan (Bonneville County 1976); Bingham County Zoning Ordinance and Planning Handbook (Bingham County 1986); Jefferson County Comprehensive Plan (Jefferson County 1988); and Butte County Comprehensive Plan (Butte County 1992). Land use planning for INEL facilities within the Idaho Falls city limits is subject to Idaho Falls planning and zoning restrictions (City of Idaho Falls 1989, 1992).

All county plans and policies accept development adjacent to previously developed areas to minimize the need to extend infrastructure improvements and to avoid urban sprawl. Because the INEL is remote from most developed areas, INEL lands and adjacent areas are not likely to experience residential and commercial development; no new development is planned near the INEL site. However, DOE expects recreational and agricultural uses to increase in the surrounding area in response to greater demand for recreational areas and the conversion of range land to crop land.

4.3 Socioeconomics

This section presents a brief overview of current socioeconomic conditions within a region of influence where approximately 97 percent of the INEL workforce lived in 1991 (DOE-ID 1991). The INEL region of influence is a seven-county area comprised of Bingham, Bonneville, Butte, Clark, Jefferson, Bannock, and Madison Counties. The region of influence also includes the Fort Hall Indian Reservation and Trust Lands (home of the Shoshone-Bannock Tribes) in Bannock, Bingham, Caribou, and Power Counties.

4.3.1 Employment

Historically, the regional economy has relied predominantly on natural resource use and extraction. Today, farming, ranching, and mining remain important components of the regional economy. Idaho Falls is the retail and service center for the region of influence, and Pocatello has evolved into an important processing and distribution center and site of higher education institutions.

4.3.1.1 Region. The labor force in the region of influence increased from 92,159 in 1980 to

104,654 in 1991, an average annual growth rate of approximately 1.2 percent. In 1991 the region of influence accounted for approximately 18 percent of the total state labor force of 504,000 (ISDE 1992). As listed in Table 4.3-1, the projected labor force in the region of influence will reach 108,667 by 1995.

Unemployment rates varied considerably among the counties of the region of influence in 1991, ranging from 2.6 percent in Clark County to 6.3 percent in Bannock and Bingham Counties. Since 1980 the average annual unemployment rate for the region has ranged from 5.3 percent in 1989 to 8.3 percent in 1983. In 1991 the average annual unemployment rate for the region of influence was 5.5 percent compared to the statewide average of 6.2 percent (ISDE 1992).

Employment in the region of influence increased from 86,261 in 1980 to 98,898 in 1991, an average annual growth rate of approximately 1.3 percent. As listed in Table 4.3-1, employment is projected to increase to 101,450 by 1995.

Table 4.3-1. Projected labor force, employment, and population for the INEL region of influence, 1995-2004.

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Labor Force	108,667	109,607	110,547	111,487	112,427	113,367	114,308	115,248	116,188	117,128
Employment	101,450	102,328	103,205	104,083	104,960	105,838	106,716	107,593	108,471	109,348
Population	247,990	251,518	255,096	258,726	262,406	266,140	268,667	271,219	273,795	276,395

Source: ISDE (1992); SAIC (1994); ISDE (1991); ISDE (1986).

4.3.1.2 Idaho National Engineering Laboratory. INEL plays a substantial role in the

regional economy. During Fiscal Year 1990, INEL directly employed approximately 11,100 personnel, accounting for almost 12 percent of total regional employment. The estimated population directly supported by INEL employment was approximately 38,000 persons, or 17 percent of the total regional population. The major employers at INEL are DOE-ID, DOE-ID contractors, Argonne National Laboratory-West, and the Naval Reactors Facility (see Figure 4.3-1). In 1992, the total direct INEL employment was approximately 11,600 jobs (DOE-ID 1994). Projections as of January 1995 indicate that the total number of jobs at INEL will decrease to approximately 8,620 in Fiscal Year 1995 and to approximately 7,250 in Fiscal Year 2004 (Tellez 1995). Projected decreases in INEL employment are primarily related to contractor consolidation, which accounts for 64 percent of the projected losses between Fiscal Year 1994 and Fiscal Year 2004, and to reduced activities at the Naval Reactors Facility, which accounts for 33 percent of the projected job losses. Contract changes at DOE-ID resulted in the consolidation of several contracts under one contract. The consolidation eliminated redundant administrative activities previously performed by each individual contractor and offered early retirement or other options to impacted INEL contractor employees.

4.3.2 Population and Housing

4.3.2.1 Population. From 1960 to 1990, population growth in the region of influence

mirrored statewide growth. During this period, the region's population increased at an average annual rate of approximately 1.3 percent, while the growth rate for the State was 1.4 percent. Between 1980 and 1990, population growth in the region of influence approximately equaled that of the State with an average growth rate of 0.6 percent per year. The region of influence had a 1990 population of 219,713, which comprised 22 percent of the total State population of 1,006,749. Based on population and employment trends, the population in the region of influence will reach approximately 248,000 persons by 1995 (Table 4.3-1).

Figure 4.3-1. Historic and projected employment at the Idaho National Engineering Laboratory, 1990- 2004.

In 1990, the most populous counties were Bannock and Bonneville, which together contained over 60 percent of the seven-county total (Figure 4.3-2). Butte and Clark were the least populous of the counties in the region of influence. The largest cities in the region of influence are Pocatello and Idaho Falls, with 1990 populations of approximately 46,000 and 44,000, respectively. In 1990, the Fort Hall Indian Reservation and Trust Lands contained 5,113 residents, most of whom (52 percent) resided in Bingham County.

4.3.2.2 Housing. Bonneville and Bannock Counties (which respectively include the cities of Idaho Falls and Pocatello) provided 67 percent of the 73,230 year-round housing units in the region of influence in 1990 (see Table 4.3-2). Of this number, approximately 70 percent were single-family units, 17 percent were multifamily units, and 13 percent were mobile homes. Most of the multifamily units (75 percent) were in Bonneville and Bannock Counties. About 29 percent of the occupied housing units in the region were rental units and 71 percent were homeowner units (USBC 1992).

The median value of owner-occupied housing units ranged from $37,300 in Clark County to $68,700 in Madison County, and median monthly rents ranged from $243 in Butte County to $366 in Bonneville County. In 1990, there were 1,510 occupied housing units on the Fort Hall Indian Reservation and Trust Lands (USBC 1992) and a vacancy rate of 14 percent.

4.3.3 Community Services

This assessment considers the following selected community services in the region of influence: public schools, law enforcement, fire protection, hospital services, and solid waste disposal. Table 4.3-3 summarizes pertinent characteristics of these services for the region of influence.

Seventeen public school districts and three nonpublic schools provide educational services for **about 58,000 children in the region of influence.** Of these students, about 6,500 were dependents of INEL-related employees. During the 1990-1991 academic year, most public school districts spent an average of $3,000 to $4,000 per student annually. Higher education in the region is provided by the University of Idaho, Idaho State University, Brigham Young University, Ricks College, and the Eastern Idaho Technical College.

Seven county sheriff's offices, 12 city police departments, and the Idaho State Police provide law enforcement services in the region. There was a total of 479 sworn officers and 100 other law enforcement personnel in 1991, more than 59 percent of whom served Bannock and Bonneville Counties.

Figure 4.3-2. Historic and projected total population for the counties of the region of influence, 1940 through 2004.

Table 4.3-2. Number of housing units, vacancy rates, median house value, and median monthly rent by county and region of influence.

County	Homeowner housing units Number of units	Vacancy rates	Median value ($)	Rental units Number of units	Vacancy rates	Median monthly rent ($)
Bannock	16,447	2.4	53,300	7,467	10.3	294
Bingham	9,010	2.0	50,700	2,955	9.2	284
Bonneville	17,707	1.9	63,700	7,375	6.2	366
Butte	780	4.6	41,400	302	16.2	243

a. Source: USBC (1992).

Eighteen fire districts in the region of influence operate 30 fire stations staffed by 180 paid and approximately 300 volunteer firefighters. Bingham, Bonneville, Butte, Clark, and Jefferson Counties, which surround the INEL, have developed emergency plans to be implemented in the event of a radiological or hazardous materials emergency. Each emergency plan identifies facilities with extremely hazardous substances and defines transportation routes for these substances. The emergency plans also include procedures for notification and response, listings of emergency equipment and facilities, evacuation routes, and training programs.

Eight hospitals serve the region of influence with more than 900 licensed beds and a capacity of nearly 128,000 patient-days per year. Occupancy rates range from 22.0 to 61.7 percent in the region (IDHW 1990). County governments and the Blackfoot, Dubois, Idaho Falls, and Pocatello fire departments provide regional ambulance services. A private ambulance company serves residents in Butte County. Four quick-response units, two medical helicopters, and two clinics specializing in emergency medical services also serve the region of influence (Hardinger 1990; U.S. West Directories 1992).

Table 4.3-3. Summary of public services available in the region of influence.

Public Service	County Bannock	Bingham	Bonneville	Butte	Clark	Jefferson	Madison
Schools							
Number of public school districts	2	5	3	1	1	3	2
Total enrollment	15,455	11,311	17,896	765	166	5,339	5,967
Number of INEL-related students (excluding military)	485	1,532	4,040	301	5	134	47
Health Care Delivery							
Number of hospitals	3	2	1	1	0	0	1
Number of licensed beds	309	238	311	4	-	-	52
Law Enforcement							
Number of sworn law enforcement officers	151	65	143	4	2	18	43
Total personnel per 1000 population	2.5	2.0	2.2	1.3	6.3	1.6	1.9
Fire Protection

Number of firefighters	166	96	121	15	7	63	24
Number of firefighting vehicles	37	25	24	3	1	11	6
Municipal Solid Waste Disposal							
Number of landfills meeting EPA[b] regulations	1[c]	3[d]	1[e]	2	0[f]	1	0[f]
Expected lifespan in years	30	3-6	50	30	-	2	-

a. Source: IDE (1991); IDHW (1990); IDLE (1991); Kouris (1992a); and Kouris (1992b).
b. EPA = U.S. Environmental Protection Agency.
c. Fort Hall Mine Landfill is being redesigned to meet EPA standards.
d. Aberdeen Landfill may close due to noncompliance with EPA standards.
e. A new landfill is replacing Bonneville County Landfill.
f. Madison and Clark Counties are evaluating a regional landfill for use after 1993.

Municipal solid waste generated in the region of influence is transported to county landfills. In 1992, twelve landfills served the region of influence. Four landfills (one each in Bannock, Clark, Jefferson, and Madison Counties) will close without replacement before reaching their planned capacity due to noncompliance with new Environmental Protection Agency standards (CFR 1991a).

4.3.4 Public Finance

In Fiscal Year 1991, total county revenues for the region of influence amounted to approximately $90 million (see Table 4.3-4). County governments receive most of their revenues from taxes and intergovernmental transfers. In 1991 the total assessed value of taxable property in the region of influence was about $4.5 billion. In addition to property tax revenues, local governments (cities and counties) also receive revenue from sales tax disbursements and revenue-sharing programs. These two sources provide approximately 60 to 85 percent of the total revenues received by each county.

Table 4.3-4. Total revenues and expenditures by county, Fiscal Year 1991.

County	Total revenues ($)	Total expenditures ($)
Bannock	16,232,274	14,216,708
Bingham	11,434,200	10,708,011
Bonneville[b]	50,186,650	51,850,100
Butte	1,417,684	1,397,012

Clark	1,236,849	1,086,379
Jefferson	4,408,236	4,566,074
Madison	5,249,432	5,662,080
Seven-county region	90,165,325	89,486,364

a. Sources: Ghan (1992); Bingham County (circa 1992); McFadden (circa 1992); Swager & Swager (1992a); Swager & Swager (1992b); Draney, Searle, and Associates (1992); Schwendiman & Sutton (1992).

b. Bonneville County's financial statements and total revenue data include special accounts for schools, cities, cemeteries, fire districts, ambulance districts, and other special accounts not found in other county budgets. The majority of intergovernmental revenue is used to fund these accounts.

Although DOE as a Federal agency is exempt from paying state or local taxes, INEL employees and contractors are not. In 1992, INEL employees paid an estimated $60 million in Federal withholding tax and $24 million in state withholding tax.

In 1991 the major categories of county government expenditures were general government services, 27 percent; road maintenance, 18 percent; public safety, 16 percent; health and welfare programs, 16 percent; sanitation and public works, 9 percent; debt service, 3 percent; trust remittances, 2 percent; and other expenditures, 9 percent.

4.4 Cultural Resources

This section discusses cultural resources at the INEL, including prehistoric and historic archeological sites and historic sites and structures, and traditional resources that are of cultural or religious importance to local Native Americans. It also discusses paleontological localities on the INEL site.

4.4.1 Archeological Sites and Historic Structures

As summarized in the INEL Draft Management Plan for Cultural Resources (Miller 1992), the INEL contains a rich and varied inventory of cultural resources. This includes fossil localities that provide an important paleontological context for the region and the many prehistoric archeological sites that are preserved within it. These latter sites, including campsites, lithic workshops, cairns, and hunting blinds, among others, are also an important part of the INEL inventory because they provide information about the activities of aboriginal hunting and gathering groups who inhabited the area for approximately 12,000 years. In addition, archeological sites, pictographs, caves, and many other features of the INEL landscape are also important to contemporary Native American groups for historic, religious, and traditional reasons. Historic sites, including the abandoned town of Powell/Pioneer, a northern spur of the Oregon Trail known as Goodale's Cutoff, many small homesteads, irrigation canals, sheep and cattle camps, and stage and wagon trails, document the use of the area during the late 1800s and early 1900s. Finally, the many scientific and technical facilities inside the INEL boundaries have preserved important information on the historic development of nuclear science in America.

To date, more than 100 cultural resource surveys have been conducted over approximately 4 percent of the area on the INEL site. These surveys, most of which have occurred near major facility areas, have identified 1,506 archeological resources, including 688 prehistoric sites, 38 historic sites, 753 prehistoric isolates, and 27 historic isolates (Miller 1992; Gilbert and Ringe 1993). These numbers do not include architectural properties associated with the creation and operation of the INEL. Until formal significance evaluations (archeological testing and historic records searches) have been completed, all cultural sites in this inventory are considered to be potentially eligible for nomination to the National Register of Historic Places. However, all the isolates have been categorized as unlikely to meet eligibility requirements (Yohe 1993).

Due to the relatively high density of prehistoric sites on the INEL and the need to consider these resources during Federal undertakings, DOE has sponsored a preliminary study, which resulted in the development of a predictive model, to identify areas where densities of sites are highest and where the potential impacts to significant archeological resources, as well as costs of compliance, would increase correspondingly (Ringe 1993). This information provides guidance for INEL project managers in the selection of appropriate areas for new construction. However, it does not take the place of inventories that are required by the National Historic Preservation Act before ground-disturbing projects can start (NHPA 1966 as amended).

The predictive model, constructed using a multivariate statistical technique on environmental variables associated with areas with and without sites, indicates that prehistoric cultural resources appear to be concentrated in association with certain definable physical features of the land. In this context, very high densities of resources are likely to occur along the Big Lost River and Birch Creek, atop buttes, and within craters and caves. The Lemhi Mountains, the Lake Terreton basin, and a 1.75-mile- (2,800-meter-) wide zone along the edge of local lava fields probably contain a fairly high density of sites. Within the extensive flows of basaltic lava and along the low foothills of the Lemhi Mountains, site density is classified as moderate, and the lowest density of prehistoric resources probably occurs in the floodplain of the Big Lost River and the alluvial fans emerging from the Birch Creek Valley, in the sinks, and in the recent Cerro Grande lava flow. However, a classification of low or medium density does not eliminate the possibility that significant resources exist in those areas. Although the predictive model has not been tested, it is useful as a planning guide for defining areas most likely to contain archeological resources based on past surveys.

Although there has been no systematic inventory of historically significant facilities associated with the creation and operation of the INEL, a preliminary study indicated that all INEL facilities will require evaluation (Braun et al. 1993). The Experimental Breeder Reactor-I is a National Historic Landmark listed in the National Register of Historic Places. To date, however, few of the other properties have been formally evaluated for eligibility to the National Register. Memoranda of Agreement between DOE, the Idaho State Historic Preservation Office, and the National Advisory Council on Historic Preservation establish that certain structures at Test Area North (DOE 1993b) and Auxiliary Reactor Area (DOE 1993a) are eligible for nomination, and outline specific techniques for preserving the historic value of the areas in conformance with the requirements of the Historic American Building Survey and the Historic American Engineering Record. Other facilities on the INEL site are likely to require similar efforts if DOE schedules them for major modification, demolition, or abandonment.

4.4.2 Native American Cultural Resources

Because Native American people believe the land is sacred, the entire INEL reserve is culturally important to them. Cultural resources, to the Shoshone-Bannock peoples, include all forms of traditional lifeways and usage of all natural resources. This includes not only prehistoric archeological sites, which are important in a religious or cultural heritage context, but also features of the natural landscape, air, plant, water, or animal resources that might have special significance. These resources may be affected by changes in the visual environment (construction, ground disturbance, or introduction of a foreign element into the setting), dust particles, or by contamination. Geographically, the INEL is included within a large territory once inhabited by and still of importance to the Shoshone-Bannock Tribes. Plant resources used by the Shoshone-Bannock Tribes that are located on or near the INEL site are listed in Table 4.4-1. Areas significant to the tribes would include the buttes, wetlands, sinks, grasslands, juniper woodlands, Birch Creek, and the Big Lost River.

Five Federal laws prompt consultation between Federal agencies and Indian Tribes: the National Environmental Policy Act (NEPA 1969), the National Historic Preservation Act (NHPA 1966 as amended), the American Indian Religious Freedom Act (AIRFA 1978), the Archeological Resources Protection Act (ARPA 1979), and the Native American Graves Protection and Repatriation Act (NAGPRA 1990). In accordance with these directives and in consideration of its Native American Policy (DOE 1990a and DOE 1992a), DOE is developing procedures at the INEL for consultation and coordination with the Shoshone-Bannock Tribes of the Fort Hall Reservation. DOE has committed to additional interaction and exchange of information with the Shoshone-Bannock Tribes, and has outlined this relationship in a formal Working Agreement with these tribes (DOE 1992c). In addition, the Cultural Resources Management Plan for the INEL (Miller 1992) and the curation agreement for permanent storage of archaeological materials will be completed by June 1996. The Cultural Resources Management Plan will define procedures for involving the tribes during the planning stages of project development and the curation agreement will provide for the repatriation of burial goods in accordance with NAGPRA.

4.4.3 Paleontological Resources

There are 31 known fossil localities at the INEL site. Available information suggests that the region has relatively abundant and varied paleontological resources. Preliminary analyses suggest that these materials are most likely to occur in association with archeological sites; in areas of basalt flows;

Table 4.4-1. Plants used by the Shoshone-Bannock tribes that are located on or near the INEL.

Plant Family	Type of Use	Location	Abundance
Desert Parsley	medicine, food	scattered over site	common
Milkweed	food, tools	roadsides	scattered, uncommon
Sagebrush	medicine, tools	throughout the site	common, abundant
Balsamroot	food, medicine	around buttes	common but scattered
Thistle	food	scattered throughout site	common but scattered
Gumweed	medicine	disturbed areas	common
Sunflower	medicine, food	roadside	common
Dandelion	food, medicine	throughout site	common
Beggar's Ticks	food	disturbed areas throughout site	common, abundant
Tansymustard	food, medicine	disturbed areas	common
Cactus	food	throughout the site	common, abundant
Honeysuckle	food, tools	Big Southern Butte	common on butte
Goosefoot	food	throughout site	common, abundant
Russian Thistle	food	disturbed areas throughout site	common, abundant
Dogwood	food, medicine, tools	Webb Springs, Birch Creek	common where found
Juniper	medicine, food, tools	throughout site	common to abundant
Gooseberry	food	scattered throughout site	common
Mentha arvensis	medicine	Big Lost River	uncommon
Wild onion	food, medicine, dye	throughout site	common
Caloehortus spp.	food	buttes	common
Fireweed	food	throughout site	common
Pine	food, tools, medicine	Big Southern Butte	common on butte
Douglas Fir	medicine	Big Southern Butte	common on butte
Plantain	medicine, food	throughout site	uncommon
Wildrye	food, tools	throughout site	common, abundant
Indian Ricegrass	food	throughout site	common, abundant
Bluegrass	food, medicine	throughout site	common, abundant
Serviceberry	food, tools, medicine	buttes	common where found
Chokeberry	food, medicine, tools, fuel	buttes	common where found
Wood's Rose	food, smoking, medicine, ritual	Big Lost River, Big Southern Butte	common, abundant
Red Raspberry	food, medicine	Big Southern Butte	uncommon
Willow	medicine	throughout site in moist areas	common
Coyote Tobacco	smoking, medicine	Big Lost River, Webb Springs	uncommon
Cattail	food, tools	sinks, outflow from facilities	uncommon

Source: Andersen et al. (1995).

in deposits of the Big Lost River, Little Lost River, and Birch Creek; in deposits of Lake Terreton and playas; in some wind and sand deposits; and in sedimentary interbeds or lava tubes within local lava flows (Miller 1992).

4.5 Aesthetic and Scenic Resources

4.5.1 Visual Character of the INEL Site

The Bitterroot, Lemhi, and Lost River mountain ranges border the INEL site on the north and west. Persons can see volcanic buttes near the southern boundary of the INEL from most locations on the site and from the Fort Hall Reservation. Most of the INEL site consists of open undeveloped land, covered predominantly by large sagebrush and grasslands (see Section 4.9). Pasture and irrigated farmland border much of the INEL site (see Section 4.2).

Although the INEL has a master plan, it has not established specific visual resource standards. The nine facility areas on the INEL site are generally of low density, look like commercial or industrial complexes, and are spread across the site. Structures in the facility areas range in height from 10 feet to approximately 100 feet (3 to 30 meters). About 90 miles (145 kilometers) of paved public highway run through the INEL site (see Section 4.11). Although many INEL facilities are visible from these highways, most facilities are located more than 0.5 mile (0.8 kilometer) from public roads.

4.5.2 Scenic Areas

The Craters of the Moon National Monument is about 15 miles (24 kilometers) southwest of the INEL site's western boundary. The Monument is located in a designated Wilderness Area, which must maintain Class I (very high) air quality standards or minimal degradation, as defined by the Clean Air Act (CAA 1990; CFR 1990; CFR 1991b). Under Section 169a of the Clean Air Act, air quality includes visibility and scenic view considerations.

Lands adjacent to the INEL under Bureau of Land Management jurisdiction are Visual Resource Management Class II areas (BLM 1984; BLM 1986), which urge preservation and retention of the existing character of the landscape. Lands inside the INEL boundaries are Class III and IV areas, the most lenient classes in terms of modification. The Bureau of Land Management is considering the Black Canyon Wilderness Study Area, which is adjacent to the INEL, for a Wilderness Area designation (BLM 1986); if approved, this would result in an upgrade from Visual Resource Management Class II to a Class I.

Features of the natural landscape have special significance to the Shoshone-Bannock tribes. The visual environment of the INEL site is within the visual range of Fort Hall Reservation.

4.6 Geology

This section describes the geology of the INEL and the surrounding area. Section 4.6.1 characterizes the general geology, while section 4.6.2 describes the natural resources of the area. Sections 4.6.3 and 4.6.4 describe seismic and volcanic hazards, respectively.

4.6.1 General Geology

The site is on the Eastern Snake River Plain (Figure 4.6-1). The Plain forms a broad northeast-trending, crescent-shaped trough with low relief composed primarily of surface basaltic lava flows formed 1.2 million to 2,100 years ago. The Plain features thin, discontinuous, and interbedded deposits of wind-blown loess and sand; water-borne alluvial fan, lacustrine, and floodplain alluvial sediments; and rhyolitic domes formed 1,200,000 to 300,000 years ago (Kuntz et al. 1990)

(Figure 4.6-2). Mountains and valleys of the Basin and Range Province, which trend north to northwest and consist of folded and faulted rocks that are more than 70 million years old, bound the Plain on the north and south. The Yellowstone Plateau bounds the Plain on the northeast. The major episode of Basin and Range faulting began 20 to 30 million years ago and continues today, most recently associated with the October 28, 1983, Borah Peak earthquake [moment magnitude 6.9, magnitude 7.3 on the Richter scale with a resulting peak ground acceleration of 0.022 to 0.078 at the INEL (Jackson 1985)], which occurred along the Lost River fault, approximately 100 kilometers (62 miles) from site facilities and the 1959 Hebgen Lake Earthquake, moment magnitude 7.5, approximately 150 kilometers (93 miles) from the INEL (Figure 4.6-1).

The northeast-trending volcanic terrain of the Plain has a markedly different geologic history and tectonic pattern than the folded and faulted terrain of the northwest-trending Basin and Range. The Basin and Range faults have not been observed on or across the Plain. Four northwest-trending volcanic rift zones, attributed to basaltic eruptions that occurred 4 million to 2,100 years ago, lie across the Plain at the INEL (Bowman 1995; Hackett and Smith 1992; Kuntz et al. 1990).

The seismic characteristics of the Eastern Snake River Plain and the adjacent Basin and Range Province are also different. Earthquakes and active faulting are associated with the Basin and Range tectonic activity. The Plain has historically experienced few and small earthquakes (King et al. 1987; Pelton et al. 1990; WCC 1992; Jackson et al. 1993).

Figure 4.6-1. Location of INEL in context of regional geologic features. **Figure 4.6-2. Lithologic logs of deep drill holes in the INEL area.**

4.6.2 Natural Resources

In 1979 the INEL drilled a geothermal exploration well to 3,159 meters (10,365 feet). Researchers measured a temperature of 142yC (288yF) but identified no commercial quantities of geothermal fluids (IDWR 1980). Mineral resources include several quarries or pits inside the INEL boundary that supply sand, gravel, pumice, silt, clay, and aggregate for road construction and maintenance, new facility construction and maintenance, waste burial activities, and ornamental landscaping cinders. During excavations, DOE might study the gravel pits to characterize the local surficial geology of the site. Outside the site boundary, mineral resources include sand, gravel, pumice, phosphate, and base and precious metals (Strowd et al. 1981; Mitchell et al. 1981). The geologic history of the Plain makes the potential for petroleum production at the INEL very low.

4.6.3 Seismic Hazards

The distribution of earthquakes at and near the INEL from 1884 to 1989 clearly shows that the Plain has a remarkably low rate of seismicity, whereas the surrounding Basin and Range has a fairly high rate (Figure 4.6-3, WCC 1992). The mechanism for faulting and generation of earthquakes in the Basin and Range is attributed to northeast-southwest directed crustal extension.

Several investigators have suggested hypotheses for the low rate of seismic activity within the Plain compared to the activity in both the Centennial Tectonic Belt and the Intermountain Seismic Belt:

- Smith and Sbar (1974) and Brott et al. (1981) suggest that high crustal temperatures beneath the Plain and adjacent region inside the seismic parabola (Figure 4.6-1) result in ductile deformation (aseismic creep), in contrast to the brittle deformation (rock fracture) that occurs in the Basin and Range.
- Anders et al. (1989) suggest that the Plain and the adjacent region inside the seismic parabola (Figure 4.6-1) have increased integrated lithospheric strength. They propose that the presence of mid-crustal basic intrusive rock strengthens the crust so that it is too strong to fracture (see also Smith and Arabasz 1991).

Figure 4.6-3. Earthquakes with magnitudes greater than 2.5 from 1884 to 1989.

- Parsons and Thompson (1991) propose that magma dike injection suppresses normal faulting and associated seismicity by altering the local tectonic stress field. As dikes are injected in volcanic rift zones, they push apart the surrounding rocks and decrease differential stress, thereby preventing earthquakes from occurring.

- Anders and Sleep (1992) propose that the introduction of mantle-derived magma into the midcrust beneath the Plain has decreased faulting and earthquakes by lowering the rate of deformation.

The markedly different tectonic and seismic histories of the Plain and Basin and Range provinces reflect the dissimilar deformational processes acting in each region. Both regions are subjected to the same extensional stress field (Weaver et al. 1979; Zoback and Zoback 1989; Pierce and Morgan 1992; Jackson et al. 1993); however, crustal deformation occurs through dike injection in the Plain and through large-scale normal faulting in the Basin and Range (Rodgers et al. 1990; Parsons and Thompson 1991; Hackett and Smith 1992).

Major seismic hazards include the effects from ground shaking and surface deformation (faulting, tilting). Other potential seismic hazards (e.g., avalanches, landslides, mudslides, soil settlement, and soil liquefaction) are not likely to occur at the INEL because the local geologic conditions are not conducive to them. Based on the seismic history and the geologic conditions, earthquakes greater than moment magnitude 5.5 (and associated strong ground shaking and surface fault rupture) are not likely to occur in the Plain. However, moderate to strong ground shaking from earthquakes in the Basin and Range can affect the INEL. Researchers use patterns of seismicity and locations of mapped faults to assess potential sources of future earthquakes and to estimate levels of ground motion at the site.

The sources and maximum magnitudes of earthquakes that could produce the maximum levels of ground motions at all INEL facilities include the following (WCC 1990; WCC 1992):

- A moment magnitude 7.0 earthquake at the southern end of the Lemhi fault along the Howe and Fallert Springs segments
- A moment magnitude 7.0 earthquake at the southern end of the Lost River fault along the Arco segment
- A moment magnitude 5.5 earthquake associated with dike injection in either the Arco or Lava Ridge-Hell's Half Acre Volcanic Rift Zone and the Axial Volcanic Zone
- A "random" moment magnitude 5.5 earthquake occurring in the Eastern Snake River Plain

Figure 4.6-4 shows a facility-specific example of the relationship of the peak ground acceleration on the INEL to the annual frequency of occurrence of seismic events on various seismic sources in the region, including the four events described above (WCFS 1993). The curves refer specifically to the site of the Idaho Chemical Processing Plant in the south-central INEL and might not apply directly to other INEL areas. Ground motion contributions from seismic sources not shown on Figure 4.6-4 (i.e., Intermountain seismic belt and Yellowstone Region) are significantly smaller because of their distant locations or lower estimated maximum magnitudes. The INEL Natural Phenomena Committee determines INEL seismic design-basis events based on studies such as those performed by Woodward Clyde Consultants (1990) and Woodward Clyde Federal Services (1993).

A maximum horizontal ground surface acceleration of 0.24g at the Idaho National Engineering Laboratory is estimated to result from an earthquake that could occur once every 2,000 years (DOE 1994). The seismic hazard information presented in this EIS is for general seismic hazard comparisons across DOE sites. Potential seismic hazards for existing and new facilities should be evaluated on a facility-specific basis, consistent with DOE orders, standards, and site-specific procedures. Section 5.15 describes the potential impacts of postulated seismic events.

4.6.4 Volcanic Hazards

Volcanic hazards at the INEL can come from sources inside or outside Plain boundaries. These hazards include the effects of lava flows, ground deformation (fissures, uplift, subsidence), volcanic earthquakes (associated with magmatic processes as distinct from earthquakes associated with tectonics), and ash flows or airborne ash deposits (Bowman 1995). Most of the basalt volcanic activity occurred from 4 million to 2,100 years ago in the INEL area. The most recent and closest volcanic eruption occurred 2,100 years ago at the Craters of the Moon, 25 kilometers (15 miles) southwest of the INEL (Kuntz et al. 1992). The rhyolite domes along the Axial Volcanic Zone formed between 1.2 million and 300,000 years ago and have a recurrence interval of about 200,000 years. Therefore, the probability of future dome formation affecting INEL facilities is very low.

Figure 4.6-4. Contribution of the seismic sources to the mean peak acceleration at the Idaho Chemical Processing Plant.

Catastrophic Yellowstone eruptions have occurred three times in the past 2 million years, but the

INEL is more than 160 kilometers (70 miles) from the Yellowstone Caldera rim and high-altitude winds would not disperse Yellowstone ash in the direction of INEL. Due to the infrequency, great distance, and unfavorable dispersal, pyroclastic flows or ash fallout from future Yellowstone eruptions should not impact the INEL.

Basaltic lava flows and eruptions from fissures or vents might occur. Based on a probability analysis of the volcanic history in the Big Southern Butte area (Volcanism Working Group 1990), the conditional probability that basaltic volcanism would affect a south-central INEL location is less than 2.5 y 10-5 per year (once per 40,000 years or longer), where the risk associated with Axial Volcanic Zone volcanism is greatest. The estimated probability of volcanic impact on INEL facilities farther north, where both silicic and basaltic volcanism have been older and less frequent, is less than 10-6 per year (once every million years or longer). The statistics of 116 measured INEL-area lava flow lengths and areas were used to define the two lava flow hazard zones (Figure 4.6-5). The hazard for a particular site within or near a volcanic zone is much lower, typically by an order of magnitude or more, and must be assessed on a site-specific basis (Bowman 1995).

Figure 4.6-5. Map of the INEL showing locations of volcanic rift zones and lava flow hazard zones. 4.7 Air Quality

This section describes the air resources of the INEL site and the surrounding area. The discussion includes the climatology and meteorology of the region, descriptions of nonradiological and radiological air contaminant emissions, and a characterization of existing and projected levels of air pollutants. The analysis includes both existing facilities and those that were expected (at the time the analysis was performed) to be operational before June 1, 1995. Additional detail and background information on the material presented in this section is presented in Appendix F, Section F-3, of Volume 2.

4.7.1 Climatology and Meteorology

The Eastern Snake River Plain climate exhibits low relative humidity, wide daily temperature swings, and large variations in annual precipitation. Average seasonal temperatures measured on the INEL site range from -7.3yC (18.8yF) in winter to 18.2yC (64.8yF) in summer, with an annual average temperature of about 5.6yC (42yF). Temperature extremes range from a summertime maximum of 39.4yC (103yF) to a wintertime minimum of -45yC (-49yF). The annual average relative humidity is 50 percent, with monthly average maximum values ranging from 59 percent in July to 89 percent in February and December, and with monthly average minimum values ranging from 16 percent in June and July to 47 percent in January (Clawson et al. 1989).

Annual precipitation is light, averaging 221.2 millimeters (8.71 inches), with monthly extremes of zero to 127 millimeters (5 inches). The maximum 24-hour precipitation rate is 46 millimeters (1.8 inches). The greatest short-term precipitation rates are attributable primarily to thunderstorms, which occur approximately two or three days per month during the summer. The average annual snowfall is 701 millimeters (27.6 inches), with a maximum of 1,516 millimeters (59.7 inches) and a minimum of 173 millimeters (6.8 inches) (Clawson et al. 1989).

The INEL site is in the belt of prevailing westerlies; however, the mountain ranges bordering the Eastern Snake River Plain normally channel these winds into a southwest wind. Most offsite locations experience the predominant southwest-northeast wind flow of the Eastern Snake River Plain, although subtle terrain features near some locations cause considerable variations from this flow regime. The annual average wind speed measured at the 6.1-meter (20-foot) level at the Central Facilities Area Weather Station is 3.4 meters per second (7.5 miles per hour). Monthly average values range from 2.3 meters per second (5.1 miles per hour) in December to 4.2 meters per second (9.3 miles per hour) in April and May (Clawson et al. 1989). The highest hourly average near-ground wind speed measured onsite is 22.8 meters per second (51 miles per hour) from the west-southwest, with a maximum instantaneous gust of 34.9 meters per second (78 miles per hour) (Clawson et al. 1989). Figure 4.7-1 presents the frequency of wind speed and wind direction at three meteorological monitoring sites on the INEL site from 1988 to 1992. The wind directions presented in the figure are the direction from which the wind blows. The three wind-roses demonstrate the effects of terrain on predominant wind directions and wind speed. The winds at the Test Area North monitoring station are predominantly from the north-northwest, whereas the winds from the other stations are predominantly from the southwest.

Air pollutant dispersion is a result of the processes of transport and diffusion of airborne contaminants in the atmosphere. Transport is the movement of a pollutant in the wind field, while diffusion refers to the process whereby turbulent eddies dilute a pollutant plume. The temperature gradient of the atmosphere (i.e., the change in temperature with altitude) can restrict or enhance the vertical diffusion of pollutants. Lapse rate conditions, which tend to enhance vertical diffusion, occur slightly less than 50 percent of the time. Conversely, thermal stratification or inversion conditions, which inhibit vertical diffusion, occur slightly more than 50 percent of the time. The height to which the pollutants can freely diffuse is the mixing depth, while the layer of air from the ground to the mixing depth is the mixed layer. Estimates of the monthly average depth of the mixed layer range from 400 meters (1,312 feet) in December to 3,000 meters (9,843 feet) in July. With calm winds and mostly clear skies, nocturnal inversions begin forming after sunset and dissipate about 1 to 2 hours after sunrise. These inversions are often ground-based, meaning the atmospheric temperature increases with height from the ground (Clawson et al. 1989).

Other than thunderstorms, severe weather is uncommon. Five funnel clouds (tornadoes not touching the ground) and no tornadoes were reported on the site between 1950 and 1988. Visibility in the region is good because of the low moisture content of the air and minimal sources of visibility-reducing pollutants. From Craters of the Moon National Monument, the seasonal visual range is from 130 to 155 kilometers (81 to 97 miles) (Notar 1993).

4.7.2 Air Quality

4.7.2.1 Nonradiological Air Quality.

The INEL is in the Eastern Idaho Intrastate Air Quality Control Region (AQCR 61). Neither the INEL nor any of the surrounding counties is designated as a nonattainment area (CFR 1992b) for the National Ambient Air Quality Standards (CFR 1991b). Ambient air quality data monitored in the vicinity of the INEL indicate that the site is in compliance with applicable air quality standards (DOE 1991a).

Figure 4.7-1. Depiction of annual average wind direction and speed at INEL meteorological monitoring stations.

The Clean Air Act (CAA 1990) contains requirements to prevent the deterioration of air quality in areas designated to be in attainment with the ambient air quality standards. These requirements are administered through a program that limits the increase in specific air pollutants above the levels that existed in what has been termed a baseline (or starting) year, which is 1977. The requirements specify maximum allowable ambient pollutant concentration increases or increments. They specify increment limits for pollutant level increases for the nation as a whole (Class II areas) and prescribe more stringent increment limits (as well as ceilings) for designated national resources, such as national forests, parks, and monuments (Class I areas). Three areas in the INEL vicinity are Prevention of Significant Deterioration Class I ambient air quality areas: Craters of the Moon Wilderness Area, approximately 53 kilometers (33 miles) to the west-southwest; Yellowstone National Park, approximately 143 kilometers (89 miles) to the northeast; and Grand Teton National Park, approximately 145 kilometers (90 miles) to the east-northeast.

DOE evaluates proposed new and modified sources of emissions at INEL to determine the net emissions increase of all pollutants. The INEL is considered a major source, because facility-wide emissions of specific regulated air contaminants exceed 227 metric tons (250 tons) per year. Therefore, a Prevention of Significant Deterioration analysis must be performed for all significant emission increases of specified regulated pollutants. Levels of significance for net emission increases range from very small quantities (less than 1 pound) for beryllium up to 91 metric tons (100 tons) per year for carbon monoxide. Their significance is dependent on the toxicity of the substance. For radionuclides, significance means any increase in emissions that would result in an offsite dose of 0.1 millirem per year or greater.

Ambient air quality standards for Idaho are the same as the National Ambient Air Quality Standards but include total suspended particulates and fluorides. The Idaho Department of Health and Welfare (IDHW) also has ambient concentration limits for hazardous and toxic air pollutants. Table 4.7-1 lists emission rates of criteria and hazardous and toxic air pollutants.

The types and amounts of nonradiological emissions from INEL facilities and activities are **similar to those from other industrial complexes that are the same sizes as the INEL.** Combustion sources such as boilers and emergency generators emit both criteria and toxic pollutants. Other sources include chemical processing operations, transportation, waste management activities, and research laboratories.

Table 4.7-1. Baseline annual average and maximum hourly emission rates of nonradiological air pollutants at the INEL.

Pollutant	Annual average (kg/yr)[b,c]	Maximum hourly (kg/hr)[b]
Criteria pollutants		
Carbon monoxide (CO)	301,000	177
Lead (Pb)	11	0.085
Nitrogen dioxide (NO_2)	744,000	545
Particulate matter (PM_{10})[d]	302,000	230
Sulfur dioxide (SO_2)	202,000	136
Hazardous/toxic air pollutants[e]		
Acetaldehyde	31	0.39
Ammonia	1,600	3.4
Arsenic	4.2	9.0 y 10-4
Benzene	370	16
1,3-Butadiene	220	0.8
Carbon tetrachloride	28	0.08
Chloroform	1.9	5.5 y 10-3
Chromium - trivalent	3.1	2.5 y 10-3
Chromium - hexavalent	0.4	6.2 y 10-4
Cyclopentane	350	0.58
Dichloromethane	620	0.29
Formaldehyde	960	8.9
Hydrazine	8.3	9.5 y 10-4
Hydrochloric acid	1,500	0.34
Mercury	200	0.023
Napthalene	16	2.2
Nickel	270	0.057
Nitric acid	1,500	1.7
Phosphorous	56	0.024
Potassium hydroxide	990	0.24
Propionaldehyde	62	0.24
Styrene	4.7	0.74
Tetrachlorethylene	980	0.11
Toluene	580	56
Trichloroethylene	4.7	0.013
Trimethylbenzene	87	12

a. Source: Volume 2, Table 4.7-2.
b. To convert kilograms to pounds, multiply by 2.2.
c. Annual average values include actual emissions plus projected increases from facilities that will become opertional after the baseline year.
d. It is conservatively assumed that all particulate matter is PM10 (less than 10 microns in diameter).
e. Hazardous/toxic air pollutants that are listed in State of Idaho regulations and are emitted in levels that exceed screening criteria.

Table 4.7-2 compares the INEL contribution to air quality to applicable standards and guidelines. This assessment modelled the INEL air emissions inventory for 1990 using the methodology approved by the U.S. Environmental Protection Agency to predict the maximum ground-level concentration that would occur at or beyond the site boundary for each regulated pollutant (EPA 1993b). The Industrial Source Complex-2 model primarily assessed criteria pollutants, and the SCREEN model assessed toxic air pollutants. The SCREEN model incorporates meteorological data that tend to overestimate impacts, and is useful for identifying cases that require additional, more refined assessments. The baseline concentrations listed in Table 4.7-2 are the sums of the following factors: the concentrations resulting from potential impacts from current operations and the concentrations resulting from the construction or operation of planned upgrades or modifications before the implementation of the proposed actions described in Section 5.7. Background concentrations have not been included because (a) reliable data on background levels in the INEL environs are not available for most pollutants and (b) background levels are low and are more than offset by the use of the maximum (as opposed to actual) baseline. The baseline concentrations represent the maximum calculated concentration occurring at public access locations (site boundary, public roads, and Craters of the Moon Wilderness Area). A comparison of the baseline concentrations to applicable Federal and state criteria pollutant and hazardous/toxic air pollutant guidelines and regulations shows that air quality at INEL is in compliance with those guidelines and regulations. The 24-hour total suspended particulate background concentration is listed as 40 micrograms per cubic meter, which is the same as the annual geometric mean value. The annual sources include chemical processing operations, transportation, waste management activities, and research laboratories.

4.7.2.2 Radiological Air Quality. The major source of radiation exposure in the Eastern Snake River Plain is from natural background radiation sources such as cosmic rays; radioactivity naturally present in soil, rocks, and the human body; and airborne radionuclides of natural origin (such as radon). Sources of radioactivity related to INEL operations include research and training reactors, spent nuclear fuel testing and stabilization, irradiated material and fuel examination, nuclear waste treatment and storage, and depleted uranium armor production.

Radioactive emissions from INEL facilities include the noble gases (argon, krypton, and xenon) and iodine; particulate fission products such as rubidium, strontium, and cesium; radionuclides formed

Table 4.7-2. Comparison of baseline ambient air concentrations with most stringent applicable regulations and guidelines at the INEL.

Pollutant	Averaging time	Most stringent regulation or guideline (-g/m3)a,b,c	Maximum baseline concentration (-g/m3)	Percent of standard

by neutron activation such as tritium (hydrogen-3), carbon-14, and cobalt-60; and very small quantities (less than 6 y 10-4 curies per year) of heavy elements such as uranium, thorium, plutonium, and their decay products. Historically, the radionuclide with the highest emission rate is the noble gas krypton-85, which is released primarily by the chemical reprocessing of spent nuclear fuel at the Idaho Chemical Processing Plant. Fuel reprocessing also releases small amounts (less than 0.1 curie per year) of iodine-129, which is of concern because of its long half-life (16 million years) and biological properties (iodine isotopes tend to accumulate in the human thyroid). Reactor operations release noble gas isotopes with short half-lives, including argon-41 and isotopes of xenon (primarily xenon-133, -135, and -138). Other activities at the INEL, including waste management operations, result in very low levels of airborne radionuclide emissions (less than 1 y 10-4 curie per year). Table 4.7-3 summarizes airborne radionuclide emissions from INEL facility areas, plus estimated emissions from projects expected, at the time of the analysis was performed, to become operational before June 1, 1995.

Radioactivity released to the atmosphere can result in human exposure through a number of pathways, including inhalation, external exposure, and ingestion. DOE conducts physical

Table 4.7-3. Summary of airborne radionuclide emissions from INEL facility areas (curies per year).

Facility	Tritium/ carbon-14	Iodines	Noble gases	Mixed fission and activation productsb	U/Th/TRUc

a. With the exception of the Idaho Chemical Processing Plant, emissions estimates are based on 1991 operations. Idaho Chemical Processing Plant emissions are based on 1993 emissions but are scaled upward to reflect operation of the New Waste Calcining Facility at maximum permitted levels. Anticipated projects in the baseline include the Waste Experimental Reduction Facility (compacting and sizing operations but not incineration), Argonne National Laboratory-West Fuel Cycle Facility, and Portable Water Treatment Unit, as described in Appendix F of Volume 2.

b. Mixed fission and activation products that are primarily particulate in nature (for example, cobalt-60, strontium-90, and cesium-137).

c. U/Th/TRU = Radioisotopes of uranium, thorium, or transuranic elements such as plutonium, americium, and neptunium.

d. A dash (-) indicates that the emissions for this group are negligibly small or zero.

Source: Volume 2, Table 4.7-1.

measurements (ambient air monitoring) and uses calculation techniques (atmospheric dispersion modeling) to assess existing levels of radiation (both cosmic and manmade) in and near the site, and to assess doses to workers and the surrounding population.

The offsite population can receive a radiation dose as a result of radiological conditions directly attributable to existing INEL operations. DOE assesses such a dose for a maximally exposed individual and for the population as a whole. The maximally exposed individual is a hypothetical person whose habits and proximity to the site are such that the person would receive the highest dose projected to result from sitewide radioactive emissions. The calculated annual dose to this individual as a result of current and anticipated sitewide emissions is 0.05 millirem (Section 4.7 to Volume 2). This value is a small fraction of both the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year (CFR 1992a) and the dose received from natural background sources of 351 millirem per year (Section 4.7 to Volume 2). Figure 4.7-2 compares these dose rates.

The collective annual dose to the surrounding population, determined using 1990 U.S. Census Bureau data for the total population residing within an 80-kilometer (50-mile) radius from each facility on the site, is about 0.3 person-rem (Section 4.7 to Volume 2). This value is small in comparison to the annual dose received by the same population from background sources, which is more than 40,000 person-rem (Section 4.7 to Volume 2).

Workers at each major INEL facility can receive radiation exposures. DOE has based its assessment of the dose to these workers on contributions from sources at each facility and those expected to become operational before June 1, 1995. The results of this assessment indicate that the maximum dose received by a worker at any onsite area is about 4.3 millirem per year (Section 4.7 to Volume 2), well below the National Emissions Standard for Hazardous Air Pollutants dose limit of 10 millirem per year. The standard applies to the highest exposed member of the public, and is not applicable to workers. However, it is the most restrictive limit for airborne releases and provides a useful comparison. This dose value of 4.3 millirem per year includes the maximum projected operation of the Portable Water Treatment Unit at the Power Burst Facility Area. However, that operation would be temporary (1 to 2 years) and is not representative of a permanent increase in the baseline. If this facility were not included, the baseline dose to the worker would be about 0.2 millirem per year.

Figure 4.7-2. Comparison of dose to maximally exposed individual (MEI) to the National Emission Standard for Hazardous Air Pollutants (NESHAP) dose limit and the dose from background sources.

4.8 Water Resources

This section describes existing regional and site hydrologic conditions and discusses the quality of surface and subsurface water and water use and rights. The subsurface water section also describes the vadose zone (or unsaturated zone and perched water bodies) located between the land surface and the water table.

4.8.1 Surface Water

Other than surface-water bodies formed from accumulated runoff during snowmelt or heavy precipitation and manmade infiltration and evaporation ponds, there is little surface water at the site.

The following sections discuss regional drainage conditions, local runoff, floodplains, and surface-water quality. Figure 4,8-1 supports discussions in this section.

4.8.1.1 Regional Drainage. The INEL is in the Pioneer Basin, a closed drainage basin that

includes three main surface-water bodies--the Big and Little Lost Rivers and Birch Creek. These water bodies drain mountain watersheds directly west and north of the site. However, most of the surface-water flow is diverted for irrigation before it reaches site boundaries (Barraclough et al. 1981), resulting in little or no flow for several years inside the site boundaries (Pittman et al. 1988).

The Big Lost River drains approximately 3,755 square kilometers (1,450 square miles) of land before reaching the site. Approximately 48 kilometers (30 miles) upstream of Arco, Idaho, Mackay Dam controls and regulates the flow of the river, which continues southeast past the towns of Moore and Arco and onto the Eastern Snake River Plain. The river channel then crosses the southwestern boundary of the site, where the INEL Diversion Dam controls surface-water flow. During heavy runoff events, the dam diverts surface water to a series of natural depressions, designated as spreading areas. The Big Lost River continues northeasterly across the site to an area of natural infiltration basins (playas or sinks) near Test Area North. In dry years, surface water does not usually reach the western boundary of the site, and because the INEL is located in a closed drainage basin, surface water never flows off the site.

Birch Creek drains an area of approximately 1,943 square kilometers (750 square miles). In the summer, upstream of the site, surface water from Birch Creek is diverted to provide irrigation and

Figure 4.8-1. Selected facilities and predicted inundation map for probable maximum flood-induced overtopping failure of Mackay Dam at INEL.

to produce hydropower. In the winter, water flow crosses the northwest corner of the site, entering a manmade channel 6.4 kilometers (4 miles) north of Test Area North, where it then infiltrates into channel gravels.

The Little Lost River drains an area of approximately 1,826 square kilometers (705 square miles). Strearnflow is diverted for irrigation north of Howe, Idaho. Surface water from the Little Lost River has not reached the site in recent years; however, during high stream flow years, water will reach the site and infiltrate into the subsurface (E(3&G 1984).

4.8.1.2 Local Runoff. Surface water generated from local precipitation will flow into

topographic depressions (lower elevations than the surrounding terrain) on the site. This surface water either evaporates or infiltrates into the ground, increasing subsurface saturation and enhancing subsurface migration (Wilhelmson et al. 1993).

Localized flooding can occur at the site when the ground is frozen and melting snow combines with heavy spring rains. Test Area North was flooded in 1969 (Koslow and Van Haaften 1986), In 1969 extensive flooding caused by snowmelt occurred in the lower Birch Creek Valley (Koslow 1984) Studies have shown that both the 25- and 100-year, 24-hour rainfall/snowmelt storm event could cause flooding within the Radioactive Waste Management Complex (Dames & Moore 1992). The drainage system, including dikes and erosion prevention features designed to mitigate potential surface water flooding, are being upgraded.

4.8.1.3 Floodplains. Intermittent surface-water flow and the INEL Diversion Dam (built in

1958 and enlarged in 1984) have effectively prevented flooding from the Big Lost River onto the site. However, onsite flooding from the river could occur if high water in the Mackay Dam or the Big Lost River were coupled with a darn failure. Koslow and Van Haaften (1986) examined the consequences of structural failure of the Mackay Dam due to a seismic event, coupled with a probable maximum flood (the largest flood assumed possible in an area), This scenario predicts flood waters overtopping the INEL Diversion Dam and spreading at the Idaho Chemical Processing Plant, Naval Reactors Facility, and the Test Area North Loss-of-Fluid Test Facility (Figure 4.8-1). In the event of a combined Mackay Dam failure and a 100-year flood (flood that occurs on an average of every

100 years), flooding along the Big Lost River would also occur, with low velocities and water depths on the INEL (Koslow and Van Haaften 1986). The area inundated under the Mackay Dam failure scenarios probably would use more than the 100- or 500-year floodplains for the Big Lost River at the INEL. A 100-year floodplain study for the INEL is in progress.

4.8.1.4 Surface-Water Ouality, Water quality in the Big and Little Lost Rivers and Birch

Creek is similar and has not varied a great deal over the period of record. Measured physical, chemical, and radioactive parameters have not exceeded applicable drinking water quality standards. Chemical composition is determined primarily by the mineral composition of the rocks in the mountain ranges northwest of the site and by the chemical composition of irrigation water in contact with the surface water (Robertson et al. 1974; Bennett 1990).

Site activities do not directly affect the quality of surface water outside the site because discharges from site facilities are to manmade seepage and evaporation basins or stormwater injection wells. Effluents are not discharged to natural surface waters. In addition, surface water does not flow directly off the site (Hoff et al. 1990). However, water from the Big Lost River, as well as seepage from evaporation basins and stormwater injection wells, does infiltrate the Snake River Plain Aquifer (Robertson et al. 1974; Wood and Low 1988; Bennett 1990). These areas are inspected, monitored, and sampled as stipulated in the INEL Stormwater Pollution Prevention Program (DOE-ID 1 993b).

4.8.2 Subsurface Water

Subsurface water at the site occurs in the Snake River Plain Aquifer and the vadose zone. This section describes regional and local hydrogeologic conditions, vadose zone hydrology, perched water, and subsurface-water quality. Generally, the term "groundwater" refers to usable quantities of water that enter freely into wells under confined and unconfined conditions within an aquifer (Driscoll 1989).

4.8.2. 1 Regional Hydrogeology. The INEL overlies the Snake River Plain Aquifer, the

largest aquifer in Idaho (Figure 4.8-2). This aquifer underlies the Eastern Snake River Plain and covers an area of approximately 24,900 square kilometers (9,611 square miles). Groundwater in the aquifer generally flows south and southwestward across the Snake River Plain. The estimated water storage in the aquifer is 2.5 x 1012 cubic meters (2 billion acre-feet, which is about the same as the volume of water contained in Lake Erie) (Robertson et al. 1974). A typical irrigation well can yield as much as 13.9 x 106 cubic meters (3.7 x 10(9) gallons) per year of water if pumped every day (Garabedian 1989). The Snake River Plain Aquifer is among the most productive aquifers in the nation.

The drainage basin recharging the Snake River Plain Aquifer covers an area of approximately 90,643 square kilometers (35,000 square miles). The aquifer is recharged by infiltration of irrigation

Figure 4.8-2. Location of the INEL, Snake River Plain, and generalized groundwater flow direction of the Snake River Plain Aquifer.

water, seepage from stream channels and canals, underflow from tributary stream valleys extending into the watershed, and direct infiltration from precipitation (Garabedian 1989). Most recharge occurs in surface water-irrigated areas and along the northeastern margins of the plain. Groundwater discharges primarily from the aquifer through springs that flow into the Snake River and from pumping for irrigation. Major springs and seepages that flow from the aquifer are located near the American Falls Reservoir (southwest of Pocatello) and the Thousand Springs area between Milner Dam and King Hill (near Twin Falls).

4.8.2.2 Local Hydrogeology. The INEL site covers 2,305 square kilometers (890 square

miles) of the north-central portion of the Snake River Plain Aquifer. Depth to groundwater from the land surface at the site ranges from approximately 61 meters (200 feet) in the north to over 274 meters (900 feet) in the south (Pittman et al. 1988) (see Figure 4.8-3). Groundwater flow is generally toward the south-southwest, and the upper surface is primarily unconfined (not overlain by impermeable soil or bedrock). However, the aquifer behaves as if it were partially confined because of localized geologic conditions. The occurrence and movement of groundwater in the aquifer depends on the geologic setting and the recharge and discharge of water within that setting. Most of the aquifer consists primarily of numerous relatively thin, basaltic lava flows with interbedded sediments extending to depths of 1,067 meters (3,500 feet) below the land surface (Irving 1993). Most of the groundwater migrates horizontally through fractured, basaltic interflow zones (broken and rubble zones) that occur at various depths. Water also migrates vertically along joints and the interfingering edges of interflow zones (Garabedian 1986). Sedimentary interbeds restrict the vertical movement of groundwater. The variability in how the aquifer stores and transmits water increases the difficulty in aquifer investigations and modeling.

The rate at which water moves through the ground depends on the hydraulic gradient (change in elevation and pressure with distance in a given direction) of the aquifer, the effective porosity (percentage of void spaces), and hydraulic conductivity (capacity of a porous media to transport water) of the soil and bedrock. Because aquifer porosity and hydraulic conductivity decrease with depth, most of the water in the aquifer moves through the upper 61 to 152 meters (200 to 500 feet) of the basalts. Estimated flow rates within the aquifer range from 1.5 to 6.1 meters (5 to 20 feet) per day (Barraclough et al. 1981).

The aquifer's ability to transmit water (transmissivity), and its ability to store water (storativity) are important physical properties of the aquifer. In general, the hydraulic characteristics of the aquifer enable the easy transmission of water, particularly in the upper portions.

Figure 4.8-3. Hydrostratigraphy scross the INEL and water table surface.

Recharge to the aquifer originates off the site from precipitation in the mountains to the west and north. Most of the inflow to the aquifer results from the underflow of groundwater along alluvial-filled valleys adjacent to the Eastern Snake River Plain and adjacent surface-water drainages (i.e., Big and Little Lost Rivers and Birch Creek). In addition, recharge at the site is related to the amount of precipitation, particularly snowfall, for a given year (Barraclough et al. 1981).

4.8.2.3 Vadose Zone Hydrology The vadose (unsaturated) zone extends from the land

surface down to the water table. Within the vadose zone, water and air occupy openings in the geologic materials. Subsurface water in the vadose zone is referred to as vadose water. At the site this complex zone consists of surface sediments (primarily clay and silt, with some sand and gravel) and many relatively thin basaltic lava flows, with some sedimentary interbeds. Thick surficial deposits occur in the northern part of the site, which thin to the south where basalt is exposed at the surface.

The vadose zone protects the groundwater by filtering many contaminants through adsorption, buffering dissolved chemical wastes, and slowing the transport of contaminated liquids to the aquifer. The vadose zone also protects the aquifer by storing large volumes of liquid or dissolved contaminants released to the environment through spills or migration from disposal pits or ponds, allowing natural decay processes to occur.

Travel times for water through the vadose zone are important for an understanding of contaminant movement. The flow rates in the vadose zone depend directly on the extent of fracturing, the percentage of sediments versus basalt, and the moisture content of vadose zone material. Flow increases under wetter conditions and slows under dryer conditions.

4.8.2.4 Perched Water. Locally, saturated conditions that exist above the water table are

called perched water. Perched water occurs when water migrates vertically and laterally from the surface until it reaches an impermeable layer (Irving 1993). As perched water spreads laterally, sometimes for hundreds of meters, it moves over the edges of the impermeable layer and continues downward. Several perched water bodies can form between the land surface and the water table.

In general, perched water bodies slow the downward migration of fluids that infiltrate into the vadose zone from the surface because the downward flow is not continuous. The occurrence of perched water at the site is related to the presence of disposal ponds or other surface-water bodies, which studies have detected at the Idaho Chemical Processing Plant, Test Reactor Area, and Test Area North. For example, a 1986 field study at the Idaho Chemical Processing Plant showed that perched water occurs in three areas at possibly three depth zones, ranging from approximately 9 meters (30 feet) to 98 meters (322 feet) below the ground surface and extending laterally as much as 1 ,097 meters (3,600 feet). In general, the chemical concentrations, shape, and size of these bodies have fluctuated over time in response to the volume of water discharged to the infiltration ponds (Irving 1993).

4.8.2.5 Subsurface Water Quality. Natural water chemistry and contaminants originating at

the site affect subsurface water quality. The INEL Groundwater Protection Management Program conducts monitoring programs. This program collects samples from surface water, perched water, and aquifer wells to identify contaminants and contaminant migration to and within the aquifer.

4.8.2,5.1 Natural Water Chemistry - Several factors determine the natural groundwater

chemistry of the Snake River Plain Aquifer beneath the site. These factors include the weathering reactions that occur as water interacts with minerals in the aquifer and the chemical composition of (1) groundwater originating outside the site; (2) precipitation falling directly on the land surface; and (3) streams, rivers, and runoff infiltrating the aquifer (Wood and Low 1986, 1988). The chemistry of the groundwater is different, depending on the source areas. For example, groundwater from the northwest contains calcium, magnesium, and bicarbonate leached from sedimentary rocks, and groundwater from the east contains sodium, fluorine, and silicate resulting from contact with volcanic rocks (Robertson et al. 1974).

Although the natural chemical composition of groundwater beneath the site does not exceed the Environmental Protection Agency drinking water standards for any component, the natural chemistry affects the mobility of contaminants introduced into the subsurface from INEL activities. Many dissolved contaminants adsorb (or attach) to the surface of rocks and minerals in the subsurface, thereby retarding the movement of contaminants in the aquifer and inhibiting further migration of contamination. However, many naturally occurring chemicals compete with contaminants for adsorption sites on the rocks and minerals or react with contaminants to reduce their attraction to rock and mineral surfaces.

4.8.2.5.2 Groundwater Quality - Previous waste discharges to unlined ponds and deep

wells have introduced radionuclides, nonradioactive metals, inorganic salts, and organic compounds to the subsurface.

Table 4.8-1 summarizes the highest detected concentrations of contaminants observed in the aquifer between 1987 and 1992, concentrations near the site boundary, Environmental Protection **Agency maximum contaminant levels, and DOE Derived Concentration Guides.** The following paragraphs discuss each category of contaminants and comparisons of observed concentrations to maximum contaminant levels.

Table 4.8-1. Highest dtected contaminant concentrations in groundwater at the Idaho National Engineering Laboratory (1987 to 1992).

Radionuclides - In general, radionuclide concentrations in the Snake River Plain Aquifer beneath the site have decreased since the mid-1980s because of changes in disposal practices, radioactive decay, adsorption of radionuclides to rocks and minerals, and dilution by natural surface water and groundwater entering the aquifer (Pittman et al. 1988; Orr and Cecil 1991; Bargelt et al. 1992). Radionuclides released and observed in the soil and groundwater include tritium, strontium-90, iodine-129, cobalt-60, cesium-137, plutonium-238, plutonium-239/240, and americium-241 (Golder Associates 1994). Most of these radionuclides have been observed at the Idaho Chemical Processing

Plant and Test Reactor Area facility areas. However, radionuclides have also been observed in the Test Area North disposal well.

Concentrations of radionuclides in the aquifer have decreased over time. This decrease is attributed to reduced discharges, adsorption, radioactive decay, and improved waste management practices. As of 1992, concentrations of iodine-l29, cobalt-60, tritium, strontiurn-90, and cesium-137 had exceeded the EPA maximum contaminant levels for radionuclides in drinking water in localized areas inside the INEL boundary. Currently, there are no individual maximum contaminant levels for plutonium-238, plutonium-239, plutonium-240, and americium-24 1. However, these radionuclides have not been detected above the established limits for gross radioactivity or the proposed adjusted gross alpha activity maximum contaminant level for drinking water (Golder Associates 1994; Mann et al. 1988; Orr and Cecil 1991).

Extremely low concentrations of iodine- 129 and tritium have migrated outside site boundaries. In 1992, iodine- 129 concentrations were well below the maximum contaminant levels in two wells approximately 6 and 13 kilometers (4 and 8 miles) south of the site boundary (Mann 1994). Tritium concentrations were much below maximum contaminant levels just south of the site boundary in 1985. By 1988 the tritium plume encompassed by the 500 picocurie per liter contour was back inside the site boundary, and its size has continued to decrease (Pittman et al. 1988; Otr and Cecil 1991; Orr et al. 1991). Cobalt-60, strontium-90, cesium-i 3?, plutonium-238, plutonium-240!241, and americium-241 have not been detected outside the site boundaries.

Nonradioactive Metals - The INEL has released sodium, chromium, lead, and mercury on the site and into the subsurface through unlined ponds and deep wells. Of these metals, the INEL released sodium in the greatest quantity from waste treatment processes; however, sodium is not toxic and does not have an established maximum contaminant level. In 1988 chromium concentrations exceeding the maximum contaminant level were measured near the Test Reactor Area. Lead and mercury have occurred at concentrations below the maximum contaminant level near the Idaho Chemical Processing Plant (Orr and Cecil 1991).

Inorganic Salts - Human activities at the site have released chloride, sulfate, and nitrate into the subsurface. Although chloride and sulfate releases have occurred, only nitrate has exceeded maximum contaminant levels (near the Idaho Chemical Processing Plant in 1981). Disposal of nitrates to the injection well and infiltration ponds at the Idaho Chemical Processing Plant account for the elevated nitrate levels in the central portion of the site. By 1988 the levels of nitrate decreased to below the maximum contaminant level. Irrigation in the Mud Lake area might be causing these contaminants to enter the northeastern portion of the site in concentrations comparable to those in nearby irrigated areas (Orr et al. 1991; Robertson et al. 1974; Edwards et al. 1990).

Organic Compounds - Concentrations of volatile organic compounds have been detected in the aquifer beneath the site. However, many of these compounds were detected at amounts below the detection limit (0.002 milligram per liter), or two parts per billion, which is the lowest concentration at which a specific analytical method can detect a contaminant. However, concentrations of the following compounds exceeding the maximum contaminant levels have occurred in and near the Test Area North disposal well: carbon tetrachloride, chloroform, l,2-cis-dichloroethylene, 1,1 -dichloroethylene, 1 ,2-trans-dichloroethylene, trichloroethylene, tetrachloroethylene, and vinyl chloride (Leenheer and Bagby 1982; Mann and Knobel 1987; Mann 1990; Liszewski and Mann 1992).

4.8.2.5.3 Perched Water Quality - Wastewater discharges from INEL operations have

infiltrated into the vadose zone and created most of the perched water beneath the site. Studies have detected elevated concentrations of the following contaminants in samples: tritium, cesium-l37, cobalt-60, chromium, and sulfate concentrations in deep perched water near the Test Reactor Area, and strontium-90 in perched water near the Idaho Chemical Processing Plant and at Test Area North (Irving 1993; Schafer-Perini 1993). DOE has not yet measured potential concentrations of contaminants in all INEL perched water bodies. In general, the chemical concentrations, shape, and size of these bodies have fluctuated over time in response to the volume of water discharged to the infiltration ponds.

4.8.3 Water Use and Rights

The INEL does not withdraw or use surface water for site operations, nor does it discharge effluents to natural surface water. However, the three surface-water bodies at or near the site (Big and Little Lost Rivers and Birch Creek) have the following designated uses: agricultural water supply, cold-water biota, salmonid spawning, and primary and secondary contact recreation. In addition, waters in the Big Lost River and Birch Creek have been designated for domestic water supply and as special resource waters.

Groundwater use on the Snake River Plain includes irrigation, food processing and aquaculture, and domestic, rural, public, and livestock supply. Water use for the upper Snake River drainage basin and the Snake River Plain Aquifer was 16.4 billion cubic meters (4.3 trillion gallons) per year in 1985, which was more than 50 percent of the water used in Idaho and approximately 7 percent of agricultural withdrawals in the nation. Most of the water withdrawn from the Eastern Snake River Plain [1.8 billion cubic meters (0.47 trillion gallons) per year] is for agriculture. The aquifer is the source of all water used at the INEL. Site activities withdraw water at an average rate of 7.4 million cubic meters (1.9 billion gallons) per year (DOE-ID 1993e). However, the baseline annual withdrawal rate dropped to 6.5 million cubic meters (1.7 billion gallons) in 1995. The average annual withdrawal is equal to approximately 0.4 percent of the water consumed from the Eastern Snake River Plain Aquifer, or 53 percent of the maximum annual yield of a typical irrigation well. Of the quantity of water pumped from the aquifer, a substantial portion is discharged to the surface or subsurface and eventually returned to it (DOE-ID l993d,e).

A sole-source aquifer, as designated by the Safe Drinking Water Act (SDWA 1974) is one that supplies 50 percent of the drinking water consumed in the area overlying the aquifer. Sole-source aquifer areas have no alternative source or combination of sources that could physically, legally, and economically supply all those who obtain their drinking water from the aquifer. Because groundwater supplies 100 percent of the drinking water consumed within the Eastern Snake River Plain (Gaia Northwest 1988) and an alternative drinking water source or combination of sources is not available, the Environmental Protection Agency designated the Snake River Plain Aquifer a sole-source aquifer in 1991 (FR 1991b).

DOE holds a Federal Reserved Water Right for the INEL, which permits a water pumping capacity of 2.3 cubic meters (80 cubic feet) per second and a maximum water consumption of 43 million cubic meters (11.4 billion gallons) per year for drinking, process water, and noncontact cooling. Because it is a Federal Water Right, the site's priority on water rights dates back to the establishment of the INEL.

4.9 Ecological Resources

This section describes the biotic resources - flora, fauna, threatened and endangered species, and wetlands - on the INEL site, which are typical of the Great Basin and Columbia Plateau. Because the proposed actions are most likely to affect areas near existing major facilities, this section emphasizes the biotic resources in those areas. However, because the proposed actions could affect other resources outside such areas (e.g., more mobile species like pronghorn, Antilocapra americana), it also describes biotic resources for the entire INEL site.

4.9.1 Flora

Vegetation on the INEL site is primarily of the shrub-steppe type and is a small fraction of the 45,000 square kilometers (111.2 million acres) of this vegetation type in the Intermountain West. The 15 vegetation associations on the INEL site range from primarily shadscale-steppe vegetation at lower altitudes through sagebrush- and grass-dominated communities to juniper woodlands along the foothills of the nearby mountains and buttes (Rope et al. 1993; Kramber et al. 1992; Anderson 1991). These associations can be grouped into six basic types: juniper woodland, grassland, shrub-steppe (which consists of "sagebrush-steppe" and "salt desert shrubs"), lava, bareground-disturbed, and wetland vegetation. Shrub-steppe vegetation, which is dominated by big sagebrush (Artemisia tridentata), saltbush (Atriplex spp.), and rabbitbrush (Chrysothamnus spp.) covers more than 90 percent of the INEL. Grasses include cheatgrass (Bromus tectorum), Indian ricegrass (Oryzopsis hymenoides), wheatgrasses, (Agropyron spp.), and squirreltail (Sitanion hysterix). Herbaceous plants include phlox (Phlox spp.), wild onion (Allium spp.), milkvetch (Astragalus spp.), Russian thistle (Salsola kali), and various mustards. Work being conducted by Idaho State University will provide additional information on INEL plant communities and the status of sensitive plant species.

Facility and human-disturbed (grazing not included) areas cover only about 2 percent of the INEL. Introduced annuals, including Russian thistle and cheatgrass, frequently dominate disturbed areas. These species usually are less desirable to wildlife as food and cover, and compete with more desirable perennial native species. These disturbed areas serve as a seed source, increasing the potential for the establishment of Russian thistle and cheatgrass in surrounding less-disturbed areas.
Vegetation inside facility boundaries is generally disturbed or landscaped. Species richness on the INEL is comparable to that of like-sized areas with similar terrain in other parts of the Intermountain West. Plant diversity is typically lower in disturbed and modified areas.

4.9.2 Fauna

The INEL site supports animal communities characteristic of shrub-steppe vegetation and habitats. More than 270 vertebrate species occur, including 46 mammal, 204 bird, 10 reptile, 2 amphibian, and 9 fish species (Arthur et al. 1984; Reynolds et al. 1986). Common small-mammal genera include mice (Reithrodontomys spp. and Peromyscus spp.), chipmunks (Tamias spp.), jackrabbits (Lepus spp.), and cottontails (Sylvilagus spp.).

Songbirds and passerines commonly observed at the INEL include the American robin (Turdus migratorius), horned lark (Eremophila alpestris), black-billed magpie (Pica pica), sage thrasher (Oreoscoptes montanus), Brewer's sparrow (Spizella breweri), sage sparrow (S. belli), and western meadowlark (Sturnella neglecta), while resident upland gamebirds include the sage grouse (Centrocercus urophasianus), chukar (Alectoris chukar), and grey partridge (Perdix perdix). Common migratory bird species, which use the INEL for part of the year, include a variety of waterfowl [e.g., mallard (Anas platyrhynchos), northern pintail (Anas acuta), and Canada goose (Branta canadensis)] and raptors [e.g., Swainson's hawk (Buteo swainsoni), rough-legged hawk (B. lagopus), and American kestrel (Falco sparverius)].

The most abundant big-game species that occurs on the INEL is the pronghorn, but mule deer (Odocoileus hermonius), moose (Alces alces), and elk (Cervus elaphus) are present in small numbers as transients. Other large mammals observed on the INEL include the coyote (Canis latrans), which is common across the site, and the badger (Taxidea taxus) and bobcat (Felis rufus), both of which are present across the site but are much less abundant. Fish, including kokanee salmon (Oncorhynchos nerka), rainbow trout (Oncorhynchos mykiss), and mountain whitefish (Prosopium williamsoni), occur on the INEL only when the Big Lost River flows onto the site (as a result of heavy rain- or snowfall in the mountains to the northwest); they are not full-time residents.

A number of researchers have studied effects of radiation exposure from contaminated areas at INEL on small mammals and birds, and have concluded that subtle sublethal effects (e.g., reduced growth rates and life expectancies) can occur in individual animals as a result of radiation exposure.
However, they can attribute no population or community-level impacts to such exposures (Halford and Markham 1978; Evenson 1981; Arthur et al. 1986; Millard et. al 1990).

The monitoring of radionuclide levels outside the boundaries of the various INEL facilities and off the INEL site has detected radionuclide concentrations above background levels in individual plants and animals (Markham 1974; Craig et al. 1979; Markham et al. 1982; Morris 1993), but these limited data suggest that populations of exposed animals (e.g., mice and rabbits) as well as animals that feed on these exposed animals (e.g., eagles and hawks) are not at risk.

4.9.3 Threatened, Endangered, and Sensitive Species

State and Federal regulatory agency lists (Lobdell 1992, 1995), the Idaho Department of Fish and Game Conservation Data Center list, and information from site surveys provided the information to identify Federal- and state-protected, candidate, and sensitive species that potentially occur on the INEL. This information identified two Federal endangered (bald eagle, and peregrine falcon) and nine Federal Category 2 candidate (white-faced ibis, northern goshawk, ferruginous hawk, burrowing owl, long-eared myotis, small-footed myotis, pygmy rabbit, Townsend's western big-eared bat, and Idaho pointheaded grasshopper) species as animals that potentially occur on the INEL site (Table 4.9-1). Five animal species listed by the state as Species of Special Concern occur on the site. No frequent observations of the Federal- or state-listed animal species have occurred near any of the facilities where proposed actions would occur. This analysis did not identify any Federal- or state-listed plant species as potentially occurring on the INEL site. Eight plant species identified by other Federal agencies and the Idaho Native Plant Society as sensitive, rare, or unique occur on the site (Chowlewa and Henderson 1984).

4.9.4 Wetlands

The U.S. Fish and Wildlife Service National Wetlands Inventory has identified more than 130 areas inside the boundaries of the INEL that might possess some wetlands characteristics. Surveys conducted in the fall of 1992 indicate that these possible wetlands cover about 1.4 percent (33 square kilometers or 8,206 acres) of the INEL site (Hampton et al. 1993). Approximately 70 percent of these possible wetlands areas occur near the Big Lost River and its spreading areas and playas, near the Birch Creek Playa, and in an area north of and in the general vicinity of Argonne National Laboratory-West. Limited riparian (riverbank) communities with mature trees along the Big Lost River (Reynolds 1993) reflect the intermittent flow in the river (1986 and 1993 were the last two years with flow reported on the site). The remainder of the possible wetlands are scattered throughout the INEL site. In 1994, INEL began evaluating these potential wetlands to determine if they meet the Corps of Engineers definition of jurisdictional wetlands (COE 1987). Approximately 20 wetlands are near facilities and are mostly manmade (e.g., industrial waste and sewage treatment ponds, borrow pits, and gravel pits).

Table 4.9-1. Threatened and endangered species, special species of concern, and sensitive species that may be found on the INEL.

	Name	Status[a]	Comments
BIRDS	Northern goshawk (Accipiter gentilis)	C2, SSC, FS, BLM	The ferruginous hawk nests on and migrates through the INEL. This species is found throughout the INEL but is observed more frequently in juniper woodlands. The peregrine falcon has been observed rarely in winter, but has not been observed during other seasons. The last sighting was in 1993 (Morris 1993). It is not known to nest on the INEL and is not commonly observed near facilities (Reynolds 1993a). The bald eagle is a winter resident and is locally common in the far north end and on the western edge of the INEL near Howe (Reynolds 1993a). It is not known to nest on the INEL and is not commonly observed near facilities (Reynolds 1993). The white-faced ibis, which uses aquatic and riparian habitats, is an uncommon migrant at the INEL. The
	Burrowing owl (Athene cunicularia)	C2, BLM	
	Ferruginous hawk (Buteo regalis)	C2, SSC, BLM	
	Swainson's hawk (Buteo swainsoni)	BLM	
	Great egret (Casmerodius albus)	SSC	
	Merlin (Falco columbarius)	SSC, BLM	
	Peregrine falcon (Falco peregrinus)	E	
	Gyrfalcon (Falco rusticolus)	BLM	
	Common loon (Gavia immer)	SSC, FS	
	Bald eagle (Haliaeetus leucocephalus)	E	
	Long-billed curlew (Numenius americanus)	SPS, BLM	
	American white pelican (Pelecanus erythrorhynchos)	SSC	

			long-billed curlew is known to nest on the north end of
	White-faced ibis (Plegadis chihi)	C2	the INEL near agricultural lands. The northern goshawk is a casual migrant through the INEL.
MAMMALS	Merriam's shrew (Sorex merriami)	SPS	The pygmy rabbit is common on the INEL, but its distribution is
	Pygmy rabbit (Brachylagus (Sylvilagus) idahoensis)	C2, BLM, SSC	patchy (Reynolds et al. 1986). Roosts and hibernation caves for
	California myotis (Myotis californicus)	SSC	Townsend's western big-eared bat occur on the INEL. All are over
	Fringed myotis (Myotis thysanodes)	SSC	7 kilometers (3 miles) from facilities. Brood caves might exist on the
	Western pipistrelle (Pipistrellus hesperus)	SSC, BLM	site but have not been located.
	Townsend's western big-eared bat (Plecotus townsendii)	C2, SSC, FS, BLM	
	Long-eared myotis (Myotis evotis)	C2	
	Small-footed myotis (Myotis subulatus)	CS	
PLANTS	Lemhi milkvetch (Astragalus aquilonius)	BLM, FS, INPS	The 8 plant species identified as sensitive, rare, or unique that are
	Painted milkvetch (Astragalus ceramicus var. apus)	3c, INPS-M	known to occur on the INEL occur primarily at a distance from INEL
	Winged-seed evening primrose (Camissonia pterosperma)	BLM, INPS-S	facilities and are uncommon on the INEL because they require unique
	Nipple cactus (Coryphantha missouriensis)	INPS-M	microhabitat conditions.
	Spreading gilia (Ipomopsis (Gilia) polycladon)	BLM, INPS-2	
	King's bladderpod (Lesquerella kingii var. cobrensis)	INPS-M	
	Tree-like oxytheca (Oxytheca dendroidea)	INPS-S	
	Sepal-tooth dodder (Cuscuta denticulata)	INPS-1	
INSECTS	Idaho pointheaded grasshopper (Acrolophitus pulchellus)	C2, BLM	Occurs just north of the INEL.

a. Key: C2 = Federal Category 2 species. BLM = Bureau of Land Management monitored. INPS-S = Idaho Native Plant Society sensitive.
3c = No longer considered for Federal listing. FS = U.S. Forest Service monitored. INPS-M = Idaho Native Plant.
E = Federal and state endangered species. INEL = Idaho National Engineering Laboratory. INPS-1 = Idaho Native Plant Society State Priority 1.
SSC= State species of special concern. SPS = State protected species. INPS-2 = Idaho Native Plant Society State Priority 2.

4.10 Noise

The major noise sources at the INEL occur primarily in developed operational areas. These sources include facilities; equipment and machines (e.g., cooling towers, transformers, engines, pumps, boilers, steam vents, paging systems, construction equipment, and materials-handling equipment); aircraft; and bus, car, truck, and railroad traffic. At the INEL boundary, which is more than 3 kilometers (2 miles) from any facility, noise from most sources is barely distinguishable from background noise levels. Some disturbance of wildlife activities could occur at the INEL as a result of noise from operational and construction activities. The State of Idaho and the counties in which the INEL is located have not established any regulations that specify acceptable community noise levels, with the exception of prohibitions on nuisance noise.

Existing INEL-related noises of public significance are from the transportation of people and materials to and from the site and in-town facilities via buses, trucks, private vehicles, helicopters, and freight trains. During the normal workweek, most of the 4,000 to 5,000 employees who work on the site (as opposed to those working in Idaho Falls) travel daily by buses from surrounding communities (see Section 4.3). In addition, 300 to 500 private vehicles travel to the INEL site from surrounding communities each day (see Section 4.11). Noise measurements along U.S. Highway 20 about 15 meters (50 feet) from the roadway indicate that the sound level from traffic ranges from 64 to 86 decibels, A-weighted (dBA) (Abbott et al. 1990), and that the primary source is buses (71 to 81 dBA). While few people reside within 15 meters (50 feet) of the roadway, the results indicate that INEL traffic noise might be objectionable to members of the public residing near principal highways or busy bus routes. The acoustic environment along the INEL site boundary in rural areas and at nearby areas away from traffic noise is typical of a rural location, with the day-night sound level (DNL) in the range of 35 to 50 dBA (EPA 1974).

Public exposure to aircraft noise is due in part to INEL-related activities. Air cargo and business travel of INEL personnel via commercial air transport is a significant fraction of all such travel in and out of regional airports. Onsite INEL security patrol and surveillance flights do not adversely affect individuals off the site because of the INEL's remoteness. For INEL helicopter flights that originate or terminate in Idaho Falls, members of the public are exposed to the unique noises produced by these aircraft. Because the number of flights per day is limited and most flights occur during nonsleeping hours, public exposure to aircraft nuisance noise is not great.

Normally only one train per day serves the INEL, via the Scoville spur. Noise sources related to rail transport include those from diesel engines, wheel-track contact, and whistle warnings at rail crossings. Even with only one or two exposures to these sources per day, individuals residing near the railroad tracks might find the noises mildly objectionable.

4.11 Traffic and Transportation

Roads are the primary access to and from the INEL site. Commercial shipments are transported via truck and plane, some bulk materials are transported via rail, and waste is transported by road and rail. This section discusses the existing traffic volumes, transportation routes, transportation accidents, and waste and materials transportation, including baseline radiological exposures from waste and materials transportation. This section summarizes the information in Lehto (1993).

4.11.1 Roadways

4.11.1.1 Infrastructure Regional and Site Systems. Figure 4.11 - 1 shows the existing

regional highway system. Two interstate highways serve the regional area. Interstate 15 (1-15), a north-south route that connects several cities along the Snake River, is approximately 40 kilometers (25 miles) east of the INEL site. 1-86 intersects 1-15 approximately 64 kilometers (40 miles) south of the INEL site, and provides a primary linkage from I-li to points west. 1-15 and US 91 are the primary access routes to the Shoshone-Bannock reservation. US 20 and US 26 are the main access routes to the southern portion of the INEL site. Idaho State Routes 22, 28, and 33 pass through the northern portion of the INEL; State Route 33 provides access to the northern INEL site facilities.

Table 4.11-1 lists the baseline (1991) traffic for several of these access routes. The level of service of these segments is currently designated "free flow," which is defined as "operation of vehicles is virtually unaffected by the presence of other vehicles."

The INEL has developed an onsite road system of approximately 140 kilometers (87 miles) of paved surface, including about 29 kilometers (18 miles) of service roads that are closed to the public.

Most of the roads are adequate for the current level of normal transportation activity and could handle some increased traffic volume. DOE plans to reconstruct several deteriorating INEL roads built in the 1950s that have been and will continue to be used to transport heavier-than-normal loads.

4.11.1.2 Infrastructure Idaho Falls. Approximately 4,000 DOE and contractor personnel

administer and support INEL work at offices in Idaho Falls. DOE shuttle vans provide hourly transport between in-town facilities. One of the busiest intersections is Science Center Drive and Fremont Avenue, which serves Willow Creek Building, Engineering Research Office Building, INEL Electronic Technology Center, and DOE Office Buildings. This intersection is congested during peak

Figure 4.11-1. Transportation routes in the vicinity of the INEL. (not available in electronic copy).

Table 4.11-1. Baseline traffic for selected highway segments.

weekday hours, but it is designed for the current traffic.

4.11.1.3 Transit Modes. Four major modes of transit use the regional highways, community

streets, and INEL site roads to transport people and commodities: DOE buses and shunle vans, DOE motor pool vehicles, commercial trucks, and personal vehicles. Table 4.11-2 summarizes the baseline miles for INEL-related traffic.

Table 4.11-2. Baseline annual vehicle miles traveled for Idaho National Engineering Laboratory-related traffic. a

4.11.2 Railroads

Figure 4.11-1 shows the Union Pacific Railroad lines in southeastern Idaho. Idaho Falls receives railroad freight service from Butte, Montana, to the north, and from Pocatello and Salt Lake City to the south, The Union Pacific Railroad's Blackfoot-to-Arco branch, which crosses the southern portion of the INEL, provides rail service to the site for the shipment of spent nuclear fuel and other waste, bulk commodities, and radioactive materials. This branch connects with a DOE-owned spur line at Scoville Siding, then links with developed INEL areas. Table 4.11-3 lists rail shipments for Fiscal Years 1988 through 1992.

Table 4.11-3. Loaded rail shipments to and from the Idaho National Engineering Laboratory (1988-1992)a.

4.11.3 Airports and Air Traffic

Commercial airlines provide Idaho Falls with jet aircraft passenger and cargo service, as well as commuter service to both the Idaho Falls and Pocatello airports. In addition, local charter service is available in Idaho Falls, and private aircraft use the major airport and many other fields in the area. Total landings at the Idaho Falls airport for 1991 and 1992 were 5,367 and 5,598, respectively. The Idaho Falls and Pocatello airports collectively record nearly 7,500 landings annually.

Non-DOE air traffic over the INEL site is limited to altitudes greater than 305 meters (1,000 feet) over buildings and populated areas, and non-DOE aircraft are not permitted to use the site. The primary air traffic at the INEL site is DOE helicopters, which are used for security and emergency purposes. These helicopters have specific operations stations and duties.

4.11.4 Accidents

From 1987 through 1992, the average motor vehicle accident rate was 0.94 accident per million kilometers (1.5 accidents per million miles) for INEL vehicles, which compares with an accident rate of 1.5 accidents per million kilometers (2.4 accidents per million miles) for all DOE complex vehicles and 8 accidents per million kilometers (12.8 accidents per million miles) nationwide for all motor vehicles (Lehto 1993). There are no recorded rail or air accidents associated with the INEL and, to date, no fatal air traffic accidents have involved flights through either the Idaho Falls or Pocatello airports.

4.11.5 Transportation of Waste, Materials, and Spent Nuclear Fuel

Hazardous, radioactive, industrial commercial, and recyclable wastes are transported oYl the INEL site. Federal and State regulations and requirements govern the transportation of hazardous and radioactive materials (Lehto 1993). Hazardous materials include commercial chemical products and hazardous wastes that are nonradioactive; they are regulated and controlled based on their chemical toxicity. Onsite spent nuclear fuel comes from Argonne National Laboratory - West, the Naval Reactors Facility, and the Advanced Test Reactor; it is transported by truck to various onsite storage and research and development facilities.

This assessment used six years of data (1987 through 1992) to establish a baseline of radiological doses from incident-free, onsite total nonnaval spent nuclear fuel transportation at the INEL. **Table 4.11-4 lists the results in terms of cumulative doses (1995-2035) and health effects.** These doses do not include onsite naval shipments, which are assessed in Attachment A to Appendix D of Volume 1 of this ElS. The baseline includes no offsite shipments, which are addressed in Appendixes D and I.

Table 4.11-4. Cumulative dose and cancer fatalities from incident-free onsite shipment of nonnaval spent nuclear fuel at the Idaho National Engineering Laboratory for 1995 through 2035. (a,b)

4.12 Occupational and Public Health and Safety

4.12.1 Radiological Health and Safety

DOE Order 5480.11, "Radiation Protection for Occupational Workers" (DOE 1992b), limits the radiation dose that INEL workers can receive to 5 rem per year; administrative controls further limit a worker dose to 2 rem per year, except under unusual circumstances. In addition, DOE has established a comprehensive program, known as ALARA (As Low As Reasonably Achievable), to ensure the reduction of occupational doses to the extent practicable.

The largest fraction of the occupational dose received by INEL workers is from external radiation. Internal radiation doses constitute a small fraction of the occupational dose. Personnel who could receive annual external radiation exposures with measured doses greater than 0.1 rem receive a thermoluminescent dosimeter that they must wear at all times during work on the site. DOE used recorded doses for 1987 to 1991 as a baseline for routine site operations for this EIS. During this period, the INEL monitored about 6,000 workers annually for radiation exposure. About 32 percent of those individuals received measurable radiation doses. Monitoring reports indicate that, from 1987 to 1991, 20 individuals (most of whom were maintenance and construction workers employed by M-K Ferguson at the Idaho Chemical Processing Plant) received annual doses larger than 2 rem (4 individuals in 1987, 1 in 1989, and 15 in 1990).

From 1987 to 1991, the average occupational dose to individuals who had received measurable doses was 0.156 rem per year, resulting in an average collective dose (the number of monitored workers receiving measurable doses was about 32 percent or 1,920) of about 300 person-rem. The resulting number of expected excess latent cancer fatalities would be less than 1 for each year of operation.

This analysis based the doses to the maximally exposed individual and offsite population on baseline radioactive concentrations associated with normal operations. The baseline dose to the maximally exposed individual is 5.6 y 10-2 millirem, which corresponds to a latent fatal cancer probability of 2.8 y 10-8. The baseline population dose is 7.0 y 10-2 person-rem which, corresponds to a latent fatal cancer incidence of less than 1 (4 y 10-5) annually and less than 1 (1 y 10-3) over 40 years.

4.12.2 Nonradiological Exposure and Health Effects

DOE used the air quality data in Table 4.7-2 to evaluate health impacts associated with potential exposure to two compound classes: criteria pollutant and toxic. This analysis has based health effects on air emissions only, and not water pathways, because none of the alternatives would involve the discharge of pollutants to surface waters or the subsurface. Table 4.7-2 lists 5 criteria pollutant and 26 toxic compounds. The classification of two of the toxic compounds (benzene and formaldehyde) as carcinogens was consistent with EPA designations published in the Integrated Risk Information System (IRIS) data base (DOE 1991b). However, this data base does not include sufficient data to perform a quantitative inhalation cancer risk assessment.

To obtain a hazard index, this analysis evaluated toxic and criteria pollutant compound health effects by adding hazard quotients for each compound. The EPA Risk Assessment Guidance for Superfund (EPA 1989) describes this approach. The hazard quotient is the ratio of compound concentration or dose to a Reference Concentration (RfC) or Dose (RfD). For compounds without listed Reference Concentration or Dose values, the analysis used appropriate State of Idaho standards.

The use of the noncancer hazard index assumes a level of exposure (standard) below which adverse health effects would be unlikely. The hazard index is not a statistical probability; therefore, it cannot be interpreted as such.

This analysis based toxic and criteria pollutant compound hazard index values for the maximally exposed individual on the maximum concentrations for the compounds at the INEL site boundary, public access roads inside the INEL site boundary, and the Craters of the Moon Wilderness Area. Because the hazard index for criteria pollutants is less than 1, no adverse health effects would be likely from routine operations for either workers or the maximally exposed individual. Because the hazard index for toxic pollutants exceeds 1, the potential for carcinogenic health risks could exist. However, varying spacial and temporal distributions of the concentrations of individual air pollutants make it unlikely that any individual would be exposed to all the pollutants all the time. Since individual hazard indices for the toxic compounds are less than 1, adverse health effects are not expected.

4.12.3 Occupational Health and Safety

Total injury and illness incidence rates at the INEL varied from an annual average of 1.8 to 4.9 per 200,000 work hours from 1987 to 1991. During this time, total lost workday cases ranged from a low of 1 per 200,000 work hours in 1988 and 1989 to a high of 2.6 per 200,000 work hours in 1991. The rates appear higher for 1991 because of a 1990 change in reporting requirements for injuries and illnesses. INEL rates for 1987 to 1989 are below overall DOE rates (2.9 total injury and illness incidence and 1.4 total lost workday cases per 200,000 work hours) and Bureau of Labor Statistics rates (8.5 total injury and illness incidence and 4.0 total lost workday cases per 200,000 work hours). For 1990 and 1991, INEL rates are slightly above overall DOE rates, but below Bureau of Labor Statistics rate.

There were 1,337 total recordable injury and illness cases at the INEL from 1987 to 1991, for an average of 8,385 employees working 79,654,000 hours. Of these cases, 114 (8.5 percent) were occupational illnesses, of which 48 percent were repeated trauma disorders and 30 percent were classified as skin diseases or disorders. One fatality occurred at the INEL between 1987 and 1991 when an employee was struck and killed by a forklift.

4.13 Idaho National Engineering Laboratory Services

This section discusses water, electricity, fuel capacities and consumption, wastewater disposal, and security and emergency protection at INEL facilities.

4.13.1 Water Consumption

A system of about 30 wells, with pumps and storage tanks, provides the water supply for the INEL site. Because of the distance between site facility areas, the water supply system for each facility is independent. The site uses no natural surface water. The City of Idaho Falls water supply system, which includes about 16 wells, provides water to DOE and contractor facilities in the city.

A Water Rights Agreement between DOE and the State of Idaho regulates groundwater use at the INEL site. Under this agreement, INEL has claim to 2,300 liters per second (36,000 gallons per minute) of groundwater, not to exceed 43 billion liters (11 billion gallons) per year (Teel 1993). DOE has not measured the total pumping rate from the aquifer, which would depend on the number of pumps operating. There is a slight possibility that the site could exceed the regulated pumping rate for very short periods, such as during recovery from an extended power outage when many pumps would run to refill depleted storage tanks.

The average INEL site water consumption from 1987 through 1991 was 7.4 billion liters (1.9 billion gallons) per year, based on the cumulative volumes of water withdrawn from the wells (Teel 1993). The projected baseline usage for 1995 will be about 6.5 billion liters (1.7 billion gallons). The estimated average water consumption of Idaho Falls facilities is 300 million liters (80 million gallons) per year.

4.13.2 Electricity Consumption

The Antelope substation supplies commercial electric power to the INEL site through two feeders to the Federally owned Scoville substation. The Scoville substation supplies electric power directly to the INEL electric power distribution system (Teel 1993). The contract with Idaho Power Company to supply electric power to the INEL site provides "up to 45,000 kilowatts monthly" at 13.8 kilovolts (IPC/DOE 1986). Hydroelectric generators along the Snake River in southern Idaho and the Bridger and Valmy coal-fired thermal electric generation plants in southwestern Wyoming and northern Nevada, respectively, generate the electric power supplied by Idaho Power. The Experimental Breeder Reactor-II can also provide approximately 12 to 15 megavolt-amperes of capacity for the electric power loop (Teel 1993).

The rated capacity of the INEL site power transmission loop line is 124 megavolt-amperes. The peak demand on the system from 1990 through 1993 was about 40 megavolt-amperes, and the average usage was slightly less than 217,000 megawatt-hours per year (Teel 1993). This usage rate should decrease by about 4 percent by 1995.

The INEL facilities in Idaho Falls receive electric power from the City of Idaho Falls, which operates four hydroelectric power generation plants on the Snake River along with substation and distribution facilities. The Bonneville Power Administration, which operates hydroelectric plants on the Columbia River system, supplies supplemental power to the City of Idaho Falls. In 1993, Idaho Falls facilities used 31,500 megawatt-hours of electricity (Teel 1993).

4.13.3 Fuel Consumption

Fuels consumed at the INEL site include several liquid petroleum fuels, coal, and propane. All fuels are transported to the site for storage and use. Natural gas is the only reported fuel consumed at the INEL Idaho Falls facilities; the Intermountain Gas Company provides this fuel through a system of underground lines (Teel 1993).

The average annual fuel consumption at the INEL site from 1990 through 1993 was as follows: fuel oil, 10,578,000 liters (2,795,000 gallons); diesel fuel, 5,690,000 liters (1,500,000 gallons); and propane gas, 568,000 liters (150,000 gallons). The INEL also uses about 8,200 metric tons (9,000 tons) of coal. Fuel storage is provided at each facility and inventories are restocked as necessary. No fossil fuel shortage has ever occurred at the INEL site (Teel 1993).

4.13.4 Wastewater Disposal

Sanitary wastewater systems at the smaller onsite facility areas consist primarily of septic tanks and drain fields. The larger areas, such as Central Facilities Area, Idaho Chemical Processing Plant, and Test Reactor Area, have wastewater treatment facilities. The City of Idaho Falls wastewater treatment system serves the Idaho Falls facilities (Teel 1993).

The average annual wastewater discharge volume at the INEL site from 1989 through 1991 was 537 million liters (142 million gallons). The wastewater from DOE and contractor-operated facilities

in Idaho Falls is not metered but is estimated to be 300 million liters (80 million gallons) per year.
The primary causes of the difference between water pumped and estimated wastewater discharge are evaporation from ponds and cooling towers, irrigation of landscaped areas, and discharge of unmetered wastewater (Teel 1993). Some industrial wastewater, such as steam condensate, is also discharged to evaporation ponds and injection wells.

4.13.5 Security and Emergency Protection

This section describes the fire protection and prevention, security, and emergency preparedness resources for the INEL site and the surrounding areas. This discussion includes the INEL Fire Department, DOE and INEL Emergency Preparedness, and DOE and INEL Security. DOE established an Emergency Management System that incorporates all applicable requirements for emergency planning, preparedness, and response at the INEL. Each INEL facility must prepare an Emergency Plan that contains detailed contingency plans and emergency procedures.

4.13.5.1 DOE Fire Department. The contractor-operated Fire Department staffs and operates

three fire stations on the INEL that support the entire site. Each station has the equipment and expertise to respond to explosions, fires, spills, and medical emergencies. These stations are on the north end at Test Area North, at Argonne National Laboratory-West, and at the Central Facilities Area.
Each station has a minimum of one engine company capable of supporting any fire emergency in its assigned area. The Fire Department has a staff of 44 firefighters and 11 support personnel and operates with a minimum critical staff of 7 firefighters at any time. In addition to providing firefighting services, the Fire Department provides the INEL ambulance, emergency medical technician (EMT), and hazardous material response services. The Fire Department has mutual aid agreements with other firefighting organizations, such as the Bureau of Land Management and the Cities of Idaho Falls, Blackfoot, and Arco. Through these agreements, the Idaho Falls Fire Department serves DOE facilities in the City of Idaho Falls.

4.13.5.2 DOE and INEL Emergency Preparedness. Each DOE INEL contractor

administers and staffs its own emergency preparedness program under the direction and supervision of DOE. All contractor programs for emergency control and response are compatible. The Warning Communication Center is in the DOE Headquarters building and staffed by the INEL prime contractor with DOE oversight; it is the communication and overall control center for support to onscene commanders in charge of an emergency response. The DOE emergency preparedness system includes mutual aid agreements with all regional county and major city fire departments, police, and medical facilities. Through the agreements, the Idaho Falls emergency preparedness organizations serve DOE facilities in the City of Idaho Falls.

4.13.5.3 DOE and INEL Security. DOE has oversight responsibility for safeguards and

security at the INEL. The security program has three categories: security operations, personnel security, and safeguards. The security operations division provides asset protection (classified matter, special nuclear material, facilities, and personnel) and technical security (computer and information).
Under this category, DOE administers the INEL protective force, which is supplied by contract. The personnel security staff processes personnel security clearances. The safeguards department is responsible for the management and accountability of special nuclear materials. The INEL protective force, consisting of 200 armed guards and 350 support personnel, provides the onsite personnel who administer the programs. Each INEL contractor has a safeguards and security staff, divided in a similar manner, to manage the security associated with its facilities. Contractor safeguards and security staffs range from about 5 to 60 persons, depending on the size and complexity of the

associated facilities. Each staff works with the INEL protective forces.

4.14 Materials and Waste Management

This section summarizes the management of materials and wastes (high-level, transuranic, mixed low-level, low-level, hazardous, industrial and commercial solid wastes and hazardous materials) at the INEL and Idaho Falls facilities, and presents an overview of the current status of the various waste types generated, stored, and disposed at the INEL.

The total amount of waste generated and disposed has been reduced through waste minimization and treatment. The INEL attains waste minimization by reducing or eliminating waste generation, by recycling, and by reducing the volume, toxicity, or mobility of waste before storage or disposal. In addition, the site has achieved volume reduction of radioactive wastes through more intensive surveying, waste segregation, and use of administrative and engineering controls.

The quantitative data presented in this section are from Volume 2 of this EIS, unless otherwise noted.

4.14.1 High-Level Waste

At present, about 11,900 cubic meters (4,970 cubic yards calcine solid and 2,140,000 gallons liquid) of high-level waste are in storage at the INEL Idaho Chemical Processing Plant (see Figure 2-1 for locations of major waste management facilities). This facility blends liquid waste, consisting of aluminum and zirconium wastes from past spent nuclear fuel reprocessing, and sodium-bearing wastes, and processes them through calcination to produce a granular calcine solid. Because of the termination of reprocessing, the site no longer generates liquid high-level waste, with the exception of high-level waste residues. Liquid high-level wastes generated by prior reprocessing activities are solidified at the site. At present, the site generates liquid waste that is not directly the result of reprocessing. The site manages this liquid as high-level waste. The site will calcine the liquid high-level waste that does not contain sodium, and as much sodium-bearing high-level waste as practicable by January 1, 1998, in accordance with the Amended Order Modifying Order of June 28, 1993, United States District Court for the District of Idaho, December 22, 1993. The projected 1995 baseline for high-level waste generation is 750 cubic meters (980 cubic yards) annually (EG&G 1993).

4.14.2 Transuranic Waste

About 65,000 cubic meters (85,000 cubic yards) of transuranic and alpha-contaminated low-level wastes are retrievably stored and 62,000 cubic meters (81,000 cubic yards) of transuranic waste (Morton and Hendrickson 1995) have been buried at the Radioactive Waste Management Complex at the INEL. At present, no facilities can dispose of transuranic waste; however, DOE ultimately intends to retrieve, repackage, certify, and ship stored transuranic wastes at the INEL to a potential Federal repository for final disposition. DOE has not determined the disposition of alpha-contaminated low-level waste and buried waste. Since the October 1988 ban by the State of Idaho prohibiting shipments of transuranic waste to the INEL, DOE has shipped only minor amounts of transuranic waste generated on the site to the INEL Radioactive Waste Management Complex for interim storage. At present, there are no treatment facilities for transuranic wastes at the INEL. The projected 1995 baseline for transuranic waste generation is 6 cubic meters (8 cubic yards) annually (EG&G 1993).

4.14.3 Mixed Low-Level Waste

At present, DOE accepts only mixed low-level waste generated at the INEL for treatment and disposal at the INEL. DOE stores mixed low-level waste generated at the INEL at interim storage facilities until treatment systems become available or operational. A total of 1,800 cubic meters (2,400 cubic yards) of mixed low-level waste interim storage capacity is available at the INEL. Current mixed low-level waste interim storage is approximately 1,100 cubic meters (1,400 cubic yards). Treatment technologies exist for much of the mixed low-level waste generated at the INEL, and waste minimization eliminates potential sources of mixed low-level waste before generation. The projected 1995 baseline for mixed low-level waste is 525 cubic meters (687 cubic yards) annually (EG&G 1993).

4.14.4 Low-Level Waste

Through 1991, DOE disposed of 145,000 cubic meters (190,000 cubic yards) of low-level waste at the Radioactive Waste Management Complex. In 1991, the total available low-level waste disposal capacity at the complex was 37,000 cubic meters (48,000 cubic yards). DOE has curtailed low-level waste treatment since 1991 while waiting for updated safety documentation and an environmental impact assessment for the Waste Experimental Reduction Facility. The INEL stores low-level waste awaiting treatment on asphalt or concrete pads at the Waste Experimental Reduction Facility and in radioactive waste storage containers at the generating facilities. The projected 1995 baseline for low-level waste generation is 4,270 cubic meters (5,585 cubic yards) annually (EG&G 1993).

4.14.5 Hazardous Waste

DOE collects hazardous waste generated at the INEL and stores it temporarily at the Hazardous Waste Storage Facility before shipping it off the site. The Hazardous Waste Storage Facility has adequate storage capacity [approximately 64 cubic meters (84 cubic yards)] to manage the quantities of hazardous waste generated at the INEL. The site recycles, reuses, or reprocesses such waste if possible, and might replace some hazardous substances with nonhazardous substances.

4.14.6 Industrial/Commercial Solid Waste

DOE disposes of the industrial and commercial solid waste generated at the site in the INEL Landfill Complex at the Central Facilities Area. The Landfill Complex has approximately 910,000 square meters (225 acres) of land available for solid waste disposal, including the remaining area at Landfill III, which is currently in use. The estimated capacity of the INEL Landfill Complex will be sufficient to dispose of INEL waste for 30 to 50 years; however, capacity of the current excavations will be filled by 1998. DOE has proposed expanding the excavation. Volume 2 of this EIS describes the landfill expansion project. The industrial and commercial solid waste landfill currently in use is in a 48,000-square-meter (12-acre) gravel pit area north of Disposal Area II. DOE does not expect to store solid waste intended for disposal. Waste segregation occurs at each INEL facility so recyclable materials do not enter the solid waste stream. The average annual volume of waste disposed at the Central Facilities Area landfill from 1988 through 1992 was approximately 52,000 cubic meters (68,000 cubic yards) (also the projected 1995 baseline) (EG&G 1993).

4.14.7 Hazardous Materials

The INEL 1993 chemical inventory lists 774 hazardous chemicals. The number and the total weight of hazardous chemicals used on the site and at individual facilities change daily in response to use. The annual Superfund Amendments and Reauthorization Act reports for the INEL facilities include year-to-year inventories.

5. ENVIRONMENTAL CONSEQUENCES

5.1 Overview

This chapter discusses the potential environmental consequences for each spent nuclear fuel management alternative described in Chapter 3. The U.S. Department of Energy (DOE) used the environmental consequence analyses of nonnaval spent nuclear fuel management from Volume 2 as input for this chapter; however, DOE made necessary adjustments to accommodate the differences between Volume 1 and Volume 2 alternatives. In addition, DOE adjusted the 10-year planning horizon for Volume 2 alternatives to 40 years for Volume 1.

As described in Chapter 1, this chapter analyzes only nonnaval DOE actions; however, Section 5.16, "Cumulative Impacts and Impacts from Connected or Similar Actions," includes impacts from the Naval Nuclear Propulsion Program and nonnaval DOE impacts that are cumulative. The Appendix B restriction of analysis to nonnaval actions results in Alternative 2 (options 2a, 2b, and 2c) becoming a single alternative.

Chapter 5 addresses potential impacts from construction and normal operations for each element of the affected environment described in Chapter 4. In addition, it provides potential consequences from accidents and several types of summary information. In cases where the consequence analysis does not result in a distinction among the alternatives, this chapter describes the consequences without division by alternative to avoid needless repetition. Tables 3-4 through 3-6 in Section 3.2 summarize and compare the potential impacts associated with each alternative.

5.2 Land Use

Alternatives 1, 2, 4b(2), and 5a [No Action, Decentralization, Regionalization by Geography (Elsewhere), and Centralization at other DOE sites] would have the least impact on land use, affecting 0.8 acre (0.003 square kilometer); Alternatives 4b(1) [Regionalization by Geography (INEL)] and 5b (Centralization at the INEL) would result in the greatest changes, impacting nearly 31 acres (0.12 square kilometer).

Overall environmental impacts on land use by any of the alternatives would be small because DOE would build new facilities in developed areas that it has already dedicated to industrial use and that previous activities have disturbed. Under all the alternatives, proposed activities would be consistent with the existing land use plans discussed in Section 4.2 and would be similar to uses in existing developed areas on the site. None of the proposed activities would involve land outside the INEL boundaries, and no effects on surrounding land uses or local land use plans should occur.

No onsite land use restrictions due to Native American treaty rights would exist for any of the alternatives described in this EIS. Potential impacts on Native American and other cultural resources are discussed in Section 5.4 (Cultural Resources) and in Appendix L (Environmental Justice).

5.3 Socioeconomics

This section describes the potential effects of the spent nuclear fuel alternatives on the socioeconomic resources of the region of influence described in Section 4.3. Tables 5.3-1 and 5.3-2 list proposed changes in the INEL-related workforce and population. Figure 5.3-1 shows these proposed changes.

5.3.1 Methodology

This section addresses socioeconomic impacts in terms of both direct and secondary employment and population effects. Direct effects are changes in INEL employment that DOE expects to occur under each alternative and include construction and operations phase impacts. Secondary effects include indirect and induced impacts. Indirect effects are impacts to regional businesses and employment resulting from changes in DOE regional purchases or nonpayroll expenditures. Induced effects are impacts to regional businesses and employment that result from changes in payroll spending by affected INEL employees. The total economic impact to the region is the sum of direct and secondary effects.

The bases for the estimated direct impacts in this section are project summary data that DOE developed in cooperation with INEL contractors. Employment impacts represent actual changes in INEL staffing; they do not include changes in staffing due to a reassignment of the existing INEL workforce. The projected decline in baseline INEL activity is not part of any alternative and therefore, a comprehensive analysis of potential impacts was not included. Projected declines in baseline site employment are presented in Figure 5.3-1 in order to provide the reader with a framework for evaluating potential employment and population impacts. This assessment used RIMS II to estimate total employment impacts with multipliers that the U.S. Bureau of Economic Analysis developed specifically for the INEL region of influence. A comprehensive discussion of the methodology is provided in Appendix F-1 of Volume 2. Cumulative impacts on socioeconomic resources in the region are discussed in Section 5.16.

Table 5.3-1. Estimated changes in employment and population for Alternatives 3, 4a, 4b(1) and 5b, 1995 - 2004.

Factor	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004
Direct employment	0	0	0	0	250	250	375	375	375	375
Secondary employment	0	0	0	0	352	352	528	528	528	528

b. ROI = region of influence.

5.3.2 Alternatives 1 and 2 - No Action and Decentralization

Activities associated with Alternatives 1 and 2 would not result in any additional construction or operations jobs at the INEL; therefore, implementation of either of these alternatives would have no impact on socioeconomic resources in the region of influence.

5.3.3 Alternatives 3, 4a, 4b(1), and 5b - 1992/1993 Planning Basis, Regionalization by Fuel Type, Regionalization by Geography (INEL), and Centralization at the INEL

5.3.3.1 Construction. As listed in Table 5.3-1, construction employment under these alternatives would peak during the period from 2001 to 2004 with approximately 375 additional direct jobs per year. When added to the estimated 528 indirect jobs, the total employment impact in the region would be an addition of approximately 903 jobs. Employment would decline to zero by 2008.

Based on historic data, approximately 97 percent of the new employees who would fill these jobs would live in the seven-county region of influence. As listed in Table 5.3-1, if all new jobs (903) were filled by in-migrants to the region, there would be a 0.8-percent increase in the regional labor force and in regional employment during the peak years. These changes would be minimal and would have no adverse impacts on socioeconomic resources in the region. In fact, although the implementation of any of these alternatives would result in an increase over projected employment levels, as shown in Figure 5.3-1, there would be an overall decline in employment from projected 1995 levels.

Assuming each new employee represented one household and 3.47 persons per household, there would be a corresponding increase in regional population levels of 1.1 percent (approximately 3,000 people). Given this minor change in population, DOE expects potential impacts on the demand for community resources and services such as housing, schools, police, health care, and fire protection to be negligible.

5.3.3.2 Operations. Activities associated with Alternatives 3, 4a, 4b(1), and 5b would not

require any additional operations jobs at the INEL. Therefore, the implementation of either of these alternatives would have no impact on socioeconomic resources in the region of influence.

5.3.4 Alternatives 4b(2) and 5a - Regionalization by Geography (Elsewhere) and Centralization at Other

DOE Sites

5.3.4.1 Construction. As listed in Table 5.3-2, construction employment under these

alternatives would peak during the period from 1995 to 1996 with approximately 50 additional direct jobs per year. When added to the estimated 70 indirect jobs, the total employment impact in the region would be approximately 120 jobs. Employment after 1996 would drop to zero.

Figure 5.3-1. INEL employment by SNF alternative relative to site employment projections. (not available in electronic copy)

Based on historic data, approximately 97 percent of the new employees who would fill these jobs would live in the seven-county region of influence. As listed in Table 5.3-2, if all new jobs (120) were filled by in-migrants to the region, there would be a 0.1-percent increase in the regional labor force and in regional employment levels during the peak years. These changes would be minimal and would have no adverse impacts on socioeconomic resources in the region. In fact, although the implementation of any of these alternatives would be an increase over projected employment levels from 1995 to 1996, as shown in Figure 5.3-1, there would be an overall decline in employment from projected 1995 levels.

Assuming each new employee represented one household and 3.47 persons per household, there would be a corresponding increase in regional population levels of 0.2 percent (approximately 400 people). Given this minor change in population, DOE expects potential impacts on the demand for community resources and services such as housing, schools, police, health care, and fire protection to be negligible.

5.3.4.2 Operations. Activities associated with Alternatives 4b(2) and 5a would not result in

any additional operations jobs at the INEL. Therefore, the implementation of either of these alternatives would have no impact on socioeconomic resources in the region of influence.

5.4 Cultural Resources

This section summarizes the potential impacts of spent nuclear fuel management activities on cultural resources at the INEL site.

This assessment evaluated both direct and indirect impacts due to the proposed alternatives. At the INEL, direct impacts to archaeological resources usually would be those associated with ground disturbance from construction activities. Direct impacts to existing historic structures could result from demolition, modification, deterioration, isolation from or alteration of the character of the property's setting; or introduction of visual, audible, or atmospheric elements out of character or that alter the property's setting. In addition, indirect impacts to archaeological resources could occur due to an overall increase in activity at the INEL, which could bring a larger workforce closer to significant sites. Direct impacts to traditional resources could occur through land disturbance, vandalism, or changes to the environmental settings of traditional use and sacred areas. Impacts could result from pollution, noise, and contamination that could affect the traditional hunting and gathering areas or the visual or audible settings of sacred areas.

The potential for adverse impacts on cultural resources would be the least under Alternatives 1, 2, 4b(2), and 5a, which would disturb approximately 0.8 acres (0.003 square kilometer). Impacts would be minor because surveys of the area to be disturbed found no eligible cultural resources (Reed et al. 1986; DOE 1993a).

The potential for adverse impacts on cultural resources would be similar under Alternatives 3, 4a, 4b(1), and 5b with the greatest potential under Alternatives 4b(1) and 5b [Regionalization by Geography (INEL) and Centralization at the INEL], which would involve the disturbance of nearly 31 acres (0.12 square kilometer). Again, impacts would be minimal because surveys of the previously disturbed area found no eligible cultural resources (Reed et al. 1986). Under these alternatives, proposed modifications at the Idaho Chemical Processing Plant facilities could adversely affect historically significant structures and could require consultation with the Idaho State Historic Preservation Office (Braun et al. 1993).

The Shoshone-Bannock Tribes are also concerned with the potential impact to important Native American resources from changes in the visual setting, noise, air quality, or water quality. Because activities associated with spent nuclear fuel management would take place within existing facility areas currently engaged in similar activities, DOE does not expect any impacts to important Native American resources from alteration of the visual setting or noise associated with implementation of any of the alternatives. There could be temporary, minor impacts on air quality from fugitive dust associated with construction activities. Emissions of radionuclides to the air under normal operations would be minor and would be well below applicable standards and guidelines. Under normal operating conditions, radioactive discharges to the soil or directly to the aquifer would not occur.

DOE would minimize the potential for direct and indirect adverse impacts on traditional use resources from pollution, noise, and contamination through compliance with applicable local, state, and Federal laws and regulations. Impact avoidance and other mitigation measures for cultural resources are described in Section 5.20.2.

5.5 Aesthetic and Scenic Resources

None of the alternatives for spent nuclear fuel management at the INEL would have adverse consequences on scenic resources or aesthetics because DOE would confine the proposed projects to developed areas. Although the construction of the proposed facilities would produce fugitive dust that could temporarily affect visibility, the INEL would follow standard construction practices to minimize both erosion and dust generation. Facility operations under each alternative would not produce emissions to the atmosphere that would impact visibility.

5.6 Geology

This section discusses the potential effects of the spent nuclear fuel management alternatives on geologic resources at the INEL site.

Proposed INEL spent nuclear fuel management activities would only have minor localized impacts on the geology of the site for all the alternatives. Direct impacts to geologic resources at the site would be associated with the disturbance or extraction of surface deposits to construct new facilities. These impacts could include excavations into the soil and rock of the site, soil mounding and banking, and the extraction of aggregate materials from gravel and borrow pits on the site. Table 5.6-1 lists estimated extractions of aggregate from site gravel pits for all INEL spent nuclear **fuel, environmental restoration, and waste management projects.** These values serve to bound the spent nuclear fuel project usage.

A secondary impact to geological resources from construction activities would be the potential for increased soil erosion. DOE would minimize any potential soil erosion by the use of Best Management Practices designed to control stormwater runoff and slope stability.

Table 5.6-1. Estimated INEL gravel/borrow use (cubic meters). ,b

Alternative	Estimated Gravel/Borrow Use
1. No Action	158,000
2. Decentralization	158,000
3. 1992/1993 Planning Basis	392,000
4a. Regionalization by Fuel Type	392,000
4b(1) Regionalization by Geography (INEL)	1,772,000
4b(2) Regionalization by Geography (Elsewhere)	296,000

b. To convert cubic meters to cubic yards, multiply by 1.31.

5.7 Air Quality and Related Consequences

This section describes the potential nonradiological and radiological impacts to air quality associated with each alternative. The term "baseline concentrations" is defined as the sum of the concentrations resulting from potential emissions from current operations and those resulting from planned upgrades or modifications that DOE would construct or operate prior to any of the proposed actions described in this EIS. Additional information is provided in Section 5.7 and Appendix F-3 of Volume 2.

5.7.1 Alternative 1 - No Action

5.7.1.1 Nonradiological Air Quality. Construction activities associated with this alternative

would be limited to upgrading an existing facility. Potential impacts to air quality from construction activities would include fugitive dust and exhaust emissions from support equipment. DOE assessed the impacts from construction using the EPA Fugitive Dust Model (FDM) (Winges 1992). The modeling results showed that the expected construction-related air quality impacts should be temporary and highly localized.

Minimal spent nuclear fuel activities would occur under this alternative. Therefore, DOE expects that the ambient concentrations levels from normal operations would be similar to those from baseline. **Table 4.7-1 lists nonradioactive emissions from normal operations.** Tables 5.7-1 and 5.7-2 list the maximum potential concentrations for the proposed alternatives; they are all below applicable standards and guidelines. Ambient concentrations from Alternative 1 activities will be below applicable standards and guidelines.

5.7.1.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

No additional facilities that would be in operation for this alternative would produce radionuclide emissions. Therefore, for normal operations, doses to the maximally exposed individual, the population, and workers would be equivalent to baseline doses, as listed in Table 5.7-3. Table 5.7-4 lists associated emission rates.

Table 5.7-1. Maximum impacts to nonradiological air quality from spent nuclear fuel - criteria pollutants. ,b

Pollutant	Averaging time	Applicable standard (-g/m3)	Maximum baseline concentration (-g/m3)	Baseline plus maximum alternativec (-g/m3)	Percent of standard
Carbon monoxide	1-hr	40,000	610	610	1.5
	8-hr	10,000	280	280	2.8
Nitrogen dioxide	Annual	100	4	4	4

4b(2). Regionalization by Geography (Elsewhere)	7.0y10-5	3.9y10-3	8.3y10-2
5a. Centralization at Other DOE Sites	7.0y10-5	3.9y10-3	8.3y10-2
5b. Centralization at the INEL	4.2y10-3	4.8y10-2	3.9y10-1

a. Source: Section 5.7 of Volume 2 of this EIS.
b. Population dose is calculated based on the projected population in 2000 or 2010 whichever is higher.
c. Baseline worker dose includes the maximum projected operation of the portable water treatment unit at the Power Burst Facility area. However, the operation would be temporary (1 to 2 years) and is not representative of a permanent increase in the baseline. If this facility were not included, the baseline dose to

the worker would be about 0.2 millirem per year.

d. Alternative 4b(1) doses are slightly less than Alternative 5b doses.

5.7.2 Alternative 2 - Decentralization

5.7.2.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that the expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operations under this alternative would include baseline emissions and those resulting from the startup of the proposed facilities. Emission rates associated with startup would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum concentrations predicted for the proposed alternatives. Ambient concentrations from Alternative 2 activities would be below applicable standards and guidelines.

5.7.2.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operations under this alternative would include the baseline emissions and those resulting from the startup of the proposed facilities. Table 5.7-4 lists emission rates for the spent nuclear fuel alternatives, including Decentralization. Table 5.7-3 lists the resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.7.3 Alternative 3 - 1992/1993 Planning Basis

5.7.3.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operations under this alternative would include baseline emissions and those resulting from the proposed facilities. Emission rates associated with startup would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum potential concentrations for the proposed alternatives. Ambient concentrations from Alternative 3 activities would be below applicable standards and guidelines.

5.7.3.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operations under this alternative would include baseline emissions and those resulting from the startup of the proposed facilities. Table 5.7-4 lists emission rates for the spent nuclear fuel alternatives. Table 5.7-3 lists the resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.7.4 Alternative 4a - Regionalization by Fuel Type

5.7.4.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that the expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the startup of the proposed facilities. Emission rates associated with startup would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum potential concentrations for the proposed alternatives. Ambient concentrations from Alternative 4 activities would be below applicable standards and guidelines.

5.7.4.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the proposed facilities. Table 5.7-4 lists emission rates for spent nuclear fuel alternatives including Regionalization. Table 5.7-3 lists the resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.7.5 Alternative 4b(1) - Regionalization by Geography (INEL)

5.7.5.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that the expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the startup of the proposed facilities. Emission rates associated with startup would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum potential concentrations from the proposed alternatives. Ambient concentrations from Alternative 4b(1) activities would be below applicable standards and guidelines.

5.7.5.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the proposed facilities. Table 5.7-4 lists associated emission rates for spent nuclear fuel alternatives including Regionalization by Geography (INEL). Table 5.7-3 lists resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.7.6 Alternative 4b(2) - Regionalization by Geography (Elsewhere)

5.7.6.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that the expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the startup of the proposed facilities. Emission rates associated with startup would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum potential concentrations from the proposed alternatives. Ambient concentrations from Alternative 4b(2) activities would be below applicable standards and guidelines.

5.7.6.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the proposed facilities. Table 5.7-4 lists associated emission rates for spent nuclear fuel alternatives including Regionalization by Geography (Elsewhere). Table 5.7-3 lists resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of

10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.7.7 Alternative 5a - Centralization at Other DOE Sites

5.7.7.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that the expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the startup of the proposed facilities. Emission rates associated with startup would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum potential concentrations from the proposed alternatives. Ambient concentrations from Alternative 5a activities would be below applicable standards and guidelines.

5.7.7.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the proposed facilities. Table 5.7-4 lists associated emission rates for spent nuclear fuel alternatives including Centralization at other DOE sites. Table 5.7-3 lists resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.7.8 Alternative 5b - Centralization at the INEL

5.7.8.1 Nonradiological Air Quality. Potential impacts to air quality from construction

activities would include fugitive dust and exhaust emissions from support equipment. The modeling assessment showed that the expected construction-related air quality impacts should be temporary and highly localized.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from the proposed facilities. Emission rates associated with the startup of the proposed facilities would be less than 1 percent of those from normal operations. Tables 5.7-1 and 5.7-2 list the maximum potential concentrations from the proposed alternatives. Ambient concentrations from Alternative 5b activities would be below applicable standards and guidelines.

5.7.8.2 Radiological Air Quality. No radiological impacts to the environment would result

from construction activities.

Emissions resulting from normal operation under this alternative would include baseline emissions and those resulting from startup of the proposed facilities. Table 5.7-4 lists associated emission rates for spent nuclear fuel alternatives including Centralization at the INEL. Table 5.7-3 lists resulting doses to the maximally exposed individual, the population, and workers. These values are small in comparison to the National Emission Standards for Hazardous Air Pollutants dose limit of 10 millirem per year, the dose limit received from background sources of 351 millirem per year, and the population dose from background sources of 40,000 person-rem.

5.8 Water Resources and Related Consequences

This section discusses potential environmental consequences to water resources under the five spent nuclear fuel management alternatives. DOE evaluated each alternative with respect to its impacts on water quality (both surface and subsurface water), water use, and human health.

Any liquid effluents from facilities proposed for the spent nuclear fuel alternatives would be in tanks or lined evaporation basins. Under normal operating conditions, radioactive discharges to the soil or directly to the aquifer would not occur. Creed (1994) presents spent nuclear fuel water quality data for the analysis of the potential impacts resulting from a hypothetical leak of 20 liters (5 gallons) per day from secondary containment around the SNF storage pools during operations. Arnett (1994) addresses the effects that this leak could have on the quality of subsurface water resources. Preliminary results indicate that there will be no contaminants above maximum contaminant levels at the INEL boundary resulting from the postulated operational leak. Some storage pools have had leakage in the past. However, based on the bounding accident scenario for high-level waste tank failure, leakage during the implementation of the selected spent nuclear fuel management alternative would cause negligible impacts to water resources (Bowman 1994). None of the proposed alternatives for the management of spent nuclear fuel would result in any renewed discharges to infiltration ponds. Section 5.15 discusses potential releases of hazardous or radioactive liquids as a result of accidents.

With respect to water usage, Alternative 4b(l) [Regionalization by Geography (INEL)] and Alternative Sb (Centralization at the INEL) would consume the largest volume of water- 1.5 million cubic meters (400 million gallons) over 40 years. The greatest water consumption rate for these alternatives would be 50,000 cubic meters (13 million gallons) per year (Hendrickson 1995). This incremental usage would represent approximately a 0.7 percent increase over the total average withdrawal rate at the INEL of 7.4 million cubic meters (1.9 billion gallons) per year. The INEL's consumptive use water right is 43 million cubic meters (11.4 billion gallons) per year. Therefore, Alternatives 4b(I) and Sb would have negligible impact on the quantity of water in the Eastern Snake River Plain Aquifer.

5.9 Ecology

DOE expects that construction impacts, which would include the loss of some wildlife habitat due to land clearing and facility development, would be greatest under Alternative 4b(1) [Regionalization by Geography (INEL)] and Alternative 5b (Centralization at the INEL). Because this construction activity would take place either within the boundaries of heavily developed areas or adjacent to those areas, it would have minimal impact on ecological resources. However, construction activities could provide opportunities for the spread of exotic plant species (e.g., cheatgrass and Russian thistle).

There would be no construction impacts to wetlands, which would be excluded from development, and impacts to threatened and endangered species would be unlikely, given the location (previously-developed areas) and the maximum size [approximately 31 acres (0.125 square kilometers)] of the affected area. Construction activities at the INEL probably would not affect either of the endangered species identified in Section 4.9.3 (the bald eagle and peregrine falcon). Both of these birds of prey are associated with riparian areas, wetlands, and larger bodies of water (e.g., reservoirs) and inhabit dry upland areas only temporarily when migrating (National Geographic Society 1987). Disturbance to other sensitive (but not Federally-listed) species identified in Section 4.9.3 (e.g., the burrowing owl, northern goshawk, ferruginous hawk, Swainson's hawk, gyrfalcon, Townsend's western big-eared bat, and pygmy rabbit) would be possible but unlikely, given the scale of the planned construction. Any impacts would be negligible and short lived, lasting only as long as the construction activities.

Representative impacts from operations would include the disturbance and displacement of animals (such as the pronghorn) caused by the movement and noise of personnel, equipment, and vehicles. Such impacts would be greatest under Alternative 4b(1) [Regionalization by Geography (INEL)] and Alternative 5b (Centralization at INEL), which would involve a generally higher level of operational activity; however, these impacts would be minor under all the proposed alternatives.

5.10 Noise

As discussed in Section 4.10, noises generated on the INEL do not travel off the site at levels that affect the general population. Therefore, INEL noise impacts for each alternative would be limited to those resulting from the transportation of personnel and materials to and from the site that would affect nearby communities, and from onsite sources that could affect wildlife near those sources.

Transportation noises would be a function of the size of the workforce (e.g., an increased workforce would result in increased employee traffic and corresponding increases in deliveries by truck and rail; a decreased workforce would result in decreased employee traffic and corresponding decreases in deliveries). This analysis of traffic noise considered railroad noise and noise from major roadways that provide access to the INEL. DOE does not expect the number of freight trains per day in the region and through the site to change as a result of any of the alternatives. Rail shipments of spent nuclear fuel, regardless of the alternative, would be a small fraction of the rail traffic on the Blackfoot-to-Arco Branch of the Union Pacific System line that crosses the INEL. The vehicles that transport employees and personnel on roads would be the principal source of community noise impacts near the INEL.

This analysis used the day-night average sound level to assess community noise, as suggested by the EPA (EPA 1974, 1982) and the Federal Interagency Committee on Noise (FICON 1992). The analysis based its estimate of the change in day-night average sound level from the baseline noise level for each alternative on projected changes in employment and traffic levels. The analysis also considers the combination of construction and operation employment. The baseline noise level is comparable to that for the No-Action alternative. Section 4.10 discusses levels representative of the No-Action alternative. The traffic noise analysis considered U.S. Highway 20, which employees use to access the INEL from Idaho Falls. Changes in noise level below 3 decibels probably would not result in a change in community reaction (FICON 1992).

The new employment associated with each alternative is a small percentage of the total onsite workforce. The maximum new employment of about 375 INEL onsite jobs would occur with Alternatives 3, 4a, 4b(1), and 5b during the peak construction period beginning in 2001 (see Section 5.3, Socioeconomics). No new operations employment is projected for any of the alternatives except Alternatives 4b(1) and 5b for which there would be 25 new jobs beginning in 2007. The cumulative onsite workforce under each alternative would be greatest in 1995 and would decrease thereafter. The peak cumulative onsite workforce for Alternatives 4b(2) and 5a would increase in 1995 by less than 1 percent compared to the No-Action baseline. There would be a corresponding increase in private vehicle and truck trips to the site. The day-night sound level (DNL) at 15 meters (50 feet) from the roads that provide access to the INEL probably would increase by less than 1 decibel. The peak cumulative onsite workforce for Alternative 2 in 1995 would be the same as that for the No-Action baseline.

For any of the alternatives, truck activity would consist of a few trips per day to and from the site carrying spent nuclear fuel. This increase in truck trips would not result in a perceptible increase in traffic noise levels along the routes to the INEL. The day-night average sound level along U.S. Highway 20 and other access routes probably would decrease slightly as a result of the anticipated overall decrease in employment levels at the INEL. DOE expects no change in the community reaction to noise along this route and other access routes. No mitigation efforts would be required.

5.11 Traffic and Transportation

5.11.1 Introduction

Spent nuclear fuel management activities involve the transportation of spent nuclear fuel inside the boundaries of the INEL (onsite) and on highways and rail systems outside the boundaries of the INEL (offsite). This section summarizes the methods of analysis used to determine the environmental consequences of onsite transportation of nonnaval spent nuclear fuel under normal conditions (incident-free) and of transportation accidents. The impacts include doses and health effects. Appendices D and I of Volume 1 address consequences of shipments to or from the INEL that involve other DOE sites and spent nuclear fuel-related locations.

5.11.2 Methodology

5.11.2.1 Incident-Free Transpodation. Radiological impacts were determined for two groups of people during normal incident-free transportation: (1) crewmen (drivers) and (2) members of the public. Members of the public are persons sharing the transport link (on-link). On-link doses were determined for Onsite shipments because members of the public have access to the majority of the roads on the INEL. Radiological impacts were calculated using the RADTRAN 4 (Neuhauser and Kanipe 1992) and RISKIND (Yuan et al. 1993) computer codes.

The magnitude of the incident-free dose depends mainly on the Transport Index of the shipment and the on-link vehicle densities. The Transport Index is defined as the dose rate at 1 meter (3.28 feet) from the surface of a radioactive package; it is measured in millirem per hour. Spent nuclear fuel was assigned a dose rate of 14 millirem per hour at 1 meter from the shipping container. This dose rate yielded a dose rate of 10 millirem per hour at 2 meters (6.56 feet) from the edge of the transport vehicle, which is the regulatory limit for an exclusive use vehicle (see Madsen et al. 1986).

Radiological doses were converted to cancer fatalities using risk conversion factors of 5.0 x lO~ fatal cancer per person-rem for members of the public and 4.0 x 10A fatal cancers per person-rem for workers. These risk conversion factors are from Publication 60 of the International Commission on Radiological Protection (ICRP 1991).

Because the onsite transportation of spent nuclear fuel at the INEL is considered rural, no incident-free nonradiological risk (from exhaust emissions and dust resuspension) was calculated.

5.11.2.2 Accidents. The doses of the maximum reasonably foreseeable onsite spent nuclear fuel transportation accident were calculated using the RISKIND computer code. Doses were analyzed for generic rural and suburban population densities, assuming 6 persons per square kilometer for rural areas and 719 persons per square kilometer for suburban areas. Areas within 80 kilometers (50 miles) of INEL have population densities between rural and suburban but are closer to the generic rural population density. Doses were also assessed under both neutral and stable atmospheric conditions. Radiation doses calculated were used to estimate the potential for fatal cancers in the exposed population using risk factors developed by the International Commission on Radiological Protection (ICRP 1991).

The probability of the maximum reasonably foreseeable onsite spent nuclear fuel transportation accident was estimated taking into account spent nuclear fuel handling procedures within the Advanced Test Reactor facility as well as factors related to transportation of the spent nuclear fuel. For this accident to occur, errors must occur in loading the wrong spent nuclear fuel into the shipping cask, radiation surveys of the loaded cask fail to detect abnormally high radiation levels, the transport vehicle must breakdown or rollover during the short transit between the Advanced Test Reactor and the Idaho Chemical Processing Plant, and operators fail to ensure that adequate cooling water is maintained inside the cask. The estimated probability of this accident is no greater than once in a million years.

The risk of the onsite spent nuclear fuel transportation accident was estimated by multiplying the accident doses by the accident probability, taking into account the probability of the atmospheric conditions used. The resulting risk value gives a bounding estimate of the annual probability of fatal cancers occurring in the local population due to onsite spent nuclear fuel transportation accidents.

5.11.3 Onsite Spent Nuclear Fuel Shipments

For each spent nuclear fuel management alternative, a small number of onsite DOE spent nuclear fuel shipments would be likely each year as a result of continuing reactor operations at the Advanced Test Reactor and the Experimental Breeder Reactor-li. The alternatives would not affect the operation of these two facilities, thus the shipments be'tween these facilities and the Idaho Chemical Processing Plant, integrated over 40 years, would be the same for each spent nuclear fuel management alternative.

Spent nuclear fuel shipments to the Idaho Chemical Processing Plant from four locations on the INEL (including the Test Reactor Area, Argonne National Laboratory-West, Test Area North, and Power Burst Facility) were evaluated. The number of shipments would not change with alternatives because DOE plans to ship all spent nuclear fuel to the Idaho Chemical Processing Plant. Alternatives that would ship spent nuclear fuel off the site under Regionalization [Alternatives 4a, 4b(1) and 4b(2)] and Centralization (Alterntives Sa and Sb) would ship it first to the Idaho Chemical Processing Plant for canning or other stabilization prior to shipment. DOE estimated the total projected number of shipments over 40 years of operation (1995-2035) from each facility from either historic records or current inventories. DOE based the projected number of shipments for Test Reactor Area and Argonne National Laboratory-West to the Idaho Chemical Processing Plant on historic records for 1987 through 1992, and the doses reflect shipments for 1995 through 2035. The projected number of shipments from Test Area North would include Three Mile Island canisters, Loss of Fluid Test fuel, special case commercial fuel, and non-fuel-bearing components stored in the Test Area North pool. The projected number of shipments from the Power Burst Facility includes all spent nuclear fuel stored at that facility.

Onsite shipments would include those that originated and ended on the INEL site. Shipments that originate or terminate at non-INEL facilities are offsite shipments. Appendixes D and I describe the consequences of naval and DOE offsite spent fuel shipments, respectively. Movements of spent nuclear fuel inside (INEL) facility fences (e.g., from the CPP-603 Underwater Storage Facility to the Fuel Storage Area) are operational transfers, not onsite shipments; therefore, this section does not consider such shipments

5.11.4 Incident-Free Impacts

The occupational and general population collective doses from onsite spent nuclear fuel shipments and the resulting incidence of latent cancer fatalities were calculated. The results are the same regardless of alternative. Occupational radiation exposure would potentially be 3.4 person-rem, resulting in 0.0014 latent cancer fatalities. General population exposure would potentially be 0.088 person-rem, resulting in 0.000044 latent cancer fatalities.

In addition to collective radiation exposure, the maximally exposed individual doses due to INEL onsite SNF shipments were calculated for a driver (occupational exposure), a person following a single shipment, and a person standing beside the road as a single shipment passes by (general member of the public). The calculated dose to a driver would be 1.7 rem, assuming that person drove all shipments over 40 years. The calculated maximally exposed individual dose to a person following a single shipment covering the longest distance from Test Area North to the Idaho Chemical Processing Plant would be 0.015 millirem, and to a person exposed to passing shipment at a distance of 1 meter (3.28 feet), the dose would be 0.0014 millirem (Maheras 1995).

Traffic impacts for the spent nuclear fuel shipments were estimated from data in Heiselmann (1994). The maximum number of spent nuclear fuel shipments of 691 per year would occur with Alternative Sb, Centralization at the INEL. A maximum 23-percent increase in traffic volume per day would occur with this alternative, based on the estimates of the number of trips required for the transport of construction equipment, material, spent nuclear fuel, other wastes, and workers to and from the INEL. Even if this average daily traffic volume were to occur for 1 hour, the maximum traffic volume would increase to 145 vehicles per hour for US 20, US 26, Routes 33 and 22; this would not change the baseline level of service, which is designated as "free flow."

5.11.5 Accident Impacts

An onsite spent nuclear fuel transportation accident involving the inadvertent shipment of a short-cooled fuel element from the Advanced Test Reactor to the Idaho Chemical Processing Plant was considered to be the maximum reasonably foreseeable accident. The melted spent nuclear fuel has potential to relocate into a critical configuration. However, the probability of a criticality accident is much less than 1 x l0(-7) per year and would be considered to be not reasonably foreseeable. Table 5.11-1 lists the calculated maximally exposed individual dose and collective dose to general population in the maximally impacted sector and corresponding risk of fatal cancers. The dose to the maximally exposed individual is considered an occupational exposure.

As listed in Table 5.11-1, the total number of fatal cancers expected in the suburban population affected by the transportation for neutral and stable meteorological conditions would be 11 and 85, respectively. For the neutral case, this would represent a 0.01-percent increase from the number of fatal cancers that would be likely from normal incidence in the affected population. For the stable case, this would represent a 0.20-percent increase from the number of fatal cancers that would be likely from normal incidence in the affected population.

The total number of fatal cancers expected in the rural population affected by the transportation for neutral and stable meteorological conditions would be 0.75 and 6.0, respectively. For the neutral

Table 5.11-1. Impacts from maximum reasonably foreseeable spent nuclear fuel transportation accident on INELa (using generic rural and suburban population densities).

Population density categoryb	Meteorologyc	Accident frequencyd (events/yr)	Dose to MEIe (rem)	Offsite population dose (person-rem)	Risk of fatal cancer per yearf
Rural	Neutral	1.0y10-6	7.6y101	1.5y103	7.5y10-7 (7.5y10-1)
Rural	Stable	1.0y10-7	2.5y102	1.2y104	6.0y10-7 (6.0y100)
Suburban	Neutral	1.0y10-6	7.6y101	2.1y104	1.1y10-5 (1.1y101)
Suburban	Stable	1.0y10-7	2.5y102	1.7y105	8.5y10-6 (8.5y101)

a. Source: Enyeart (1994).

b. Results are for generic rural and suburban population densities. The generic rural population density has an average population of 6 persons per square kilometer; the generic suburban population density has an average population of 719 persons per square kilometer. For comparison, the sector with the highest population density within 80 kilometers (50 miles) is due east of the Idaho Chemical Processing Plant and Test Reactor Area at the INEL with an average population density of 53 persons/km2.

c. Neutral meteorology is characterized by Stability Class D, 4 meters-per-second wind speed, and occuring approximately 50 percent of the time. Stable meteorology is characterized by Stability Class F, 1 meter-per-second wind speed, and occuring approximately 5 percent of the time.

d. Accident frequency includes both the event frequency and the frequency of the meteorology. The frequency of stable meteorology is approximately one-tenth the frequency of neutral meteorology.

e. Maximally exposed individual located at the point of maximum exposure to the airborne release approximately 160 to 390 meters (525 to 1,280 feet) downwind, depending on meteorology. For onsite accidents the maximally exposed individual is assumed to be an INEL worker.

f. Fatal cancer risk = dose times accident frequency times (ICRP 60 risk factor for fatal cancers). The ICRP 60 risk factor is 5.0 y 10-4 fatal cancer per rem for public, 4.0 y 10-4 fatal cancer per rem for workers. For doses of 20 rem or more, the ICRP 60 conversion factor is doubled. Numbers in parentheses indicate the total number of fatal cancers in the population if the accident occurs. The maximally exposed individual dose is considered an occupational exposure.

case, this would represent a 0.09-percent increase from the number of fatal cancers that would be likely from normal incidences in the affected population. For the stable case, this would represent a 1.7-percent increase from the number of fatal cancers that would he likely from normal incidence in the affected population.

The estimated maximum nonradiological occupational and general population traffic fatalities over 40 years due to any of the spent nuclear fuel management alternatives would be 7.1 x 10(-4) and 2.5 x 10(-3), respectively. These estimated fatalities were based on fatality risk factors for spent fuel shipments (Cashwell et. al 1986).

5.11.6 Onsite Mitigative and Preventative Measures

All onsite shipments would be in compliance with DOE ID Directive 5480.3, "Hazardous Materials Packaging and Transportation Safety Requirements." These requirements provide assurance that, under normal conditions, the INEL would meet as-low-as-reasonably-achievable conditions, reasonably foreseeable accident situations (those with a probability of occurrence greater than 1 x 10(-7) per year) would not result in a loss of shielding or containment or a criticality, and an unintentional release of radioactive maSerial would generate a timely response.

DOE would approve the type packages used for onsite shipments or would obtain a Nuclear Regulatory Commission or DOE certificate of compliance. If the Type B onsite package did not have Nuclear Regulatory Commission or DOE certification, the user of the package would have to establish how administrative controls and site-mitigating circumstances would ensure that the package would maintain containment and shielding integrity. The administrative and emergency response considerations would provide sufficient control so that accidents would not result in loss of containment or shielding, in criticality, or in an uncontrolled release of radioactive material that would create a hazard to the health and safety of the public or workers.

In the event of an accident, each DOE site has an established emergency management program. This program incorporates activities associated with emergency planning, preparedness, and response. Participating government agencies with plans that are interrelated with the INEL Emergency Plan for Action include the State of Idaho, Bingham County, Bonneville County, Butte County, Clark County, Jefferson County, the Bureau of Indian Affairs, and Fort Hall Indian Reservation. When an emergency condition exists at a facility, the Emergency Action Director is responsible for recognition, classification, notification, and protective action recommendations. At INEL emergency preparedness resources include fire protection, radiological and hazardous chemical material response, emergency control center, the INEL Warning Communication Center, the INEL Site Emergency Operational Center, and medical facilities.

5.12 Occupational and Public Health and Safety

This section presents DOE's estimates of the health effects from spent nuclear fuel-related activities at the INEL for the following human receptor groups:

- Involved Workers - workers at the facilities involved with spent nuclear fuel alternatives, including existing workers and new hires for selected alternative
- Maximally Exposed Individual (MEI) - person residing at the INEL site boundary
- Population - the general offsite population in the INEL region
- Construction Worker - labor force associated with construction activities
- Nonconstruction Worker - DOE labor force associated with nonconstruction activities

Radiological, chemical, and industrial safety hazards were considered in the estimates.

5.12.1 Radiological Exposure and Health Effects

The measure of impact used for evaluation of potential radiation exposures is risk of fatal cancers. Worker and maximally exposed individual effects are reported as individual radiation dose (in rem) and the estimated lifetime probability of fatal cancer. Population effects are reported as collective radiation dose (in person-rem) and the estimated number of fatal cancers in the affected population. Tables 5.12-1, 5.12-2, 5.12-3, and 5.12-4 summarize the radiological health effects calculations for each alternative.

Activities that workers would perform under each of the alternatives would be similar to those currently performed at the INEL. Therefore, the potential hazards encountered in the workplace would be similar to those that currently exist at the INEL. Further, DOE would mitigate these hazards with occupational and radiological safety programs operating under the same regulatory standards and limits that currently apply at the INEL. For these reasons, DOE anticipates that the average radiation dose

and the number of reportable cases of injury and illness would be proportional to the number of workers at the INEL under each alternative.

Table 5.12-1 lists involved worker doses based on an historic annual average dose of 27 mrem determined from thermoluminescent dosimeter data of workers involved in various INEL radiological work over the period 1987 to 1991 (see Appendix F of Volume 2). As mentioned above, the hazards associated with spent nuclear fuel activities are the same as the hazards associated with other INEL activities. Table 5.12-2 lists the exposure summaries for the maximally exposed individual and offsite population, based on radioactive emissions from normal operations and those resulting from startup of proposed facilities for the various alternatives. Note that population collective dose is higher than worker collective dose only under alternatives 1 and 2. For the alternatives, there is only 1 SNF worker averaged over 40 years. The nonoccupational population has more people to be exposed. When the worker population increases under Alternatives 3, 4, and 5, the worker dose becomes higher than the population dose. Section 5.7 presents the exposure information. Dose calculations are based on air emissions only, and not water pathways because none of the alternatives would involve the discharge of pollutants to surface waters or to the subsurface. Section 5.8 summarizes water quality.

Table 5.12-3 summarizes the fatal cancer incidence and probability for workers, maximally exposed individuals, and the offsite population based on the risk factors consistent with those recommended by the International Commission on Radiological Protection (ICRP 1991). For all alternatives, the probability of developing fatal cancer for any individual would be low, with the maximum value of 1 y 10-5 for the involved worker. The calculated incidence of fatal cancer for the total number of workers for each alternative and the offsite population would be less than 1.

Table 5.12-4 summarizes the 40-year projection of fatal cancer incidence associated with the worker and offsite populations. The highest involved worker and offsite population incidence, 0.1 and 0.01, respectively, would be associated with Alternative 5b.

Radiation doses associated with construction activities would be as low as reasonably achievable and no greater than 2 rem per year to any worker. Historical offsite doses associated with the INEL are summarized in the Idaho National Engineering Laboratory Historical Dose Evaluation (DOE 1991). The Centers for Disease Control and Prevention is conducting a more comprehensive reconstruction of doses from INEL operations.

5.12.2 Nonradiological Exposure and Health Effects

The air quality data listed in Tables 5.7-1 and 5.7-2 were used to evaluate health impacts associated with potential exposure to two compound classes, criteria pollutant and toxic. Table 5.7-1 lists five pollutant criteria and Table 5.7-2 lists six toxic air pollutant compounds. The toxic compounds were classified as noncarcinogens or carcinogens, consistent with EPA designations published in the Integrated Risk Information System (IRIS) data base. However, the IRIS data base does not include sufficient data to perform a quantitative inhalation cancer risk assessment.

Nonradiological health effects (hazard indices) for the INEL worker or maximally exposed individual were estimated by summing the ratios of the appropriate pollutant concentrations and their applicable standards presented in Table 5.7-1 and Table 5.7-2. Table 5.7-1 presents criteria pollutant concentrations at public access roads, which are the maximum of those calculated at the INEL site boundary, public access roads inside the INEL site boundary, and the Craters of the Moon Wilderness Area. The hazard index for the five criteria pollutants is less than 1 (0.2) for the workers or the maximally exposed individual, based on concentrations for the longest averaging times presented in **Table 5.7-1.** Table 5.7-2 presents toxic air pollutant concentrations at the public access roads, which are the maximum when compared with concentrations at the INEL site boundary and the Craters of the Moon Wilderness Area. The hazard index for the toxic air pollutants is also less than 1 (0.8) for the workers or the maximally exposed individual, based on concentrations with annual averaging time consideration. Accordingly, health effects are unlikely for either the criteria pollutants or the toxic air pollutants from spent nuclear fuel-related activities. The hazard index is not a statistical probability; therefore, it cannot be interpreted as such.

5.12.3 Industrial Safety

This section describes the following measures of impact for workplace hazards: (1) total reportable injuries and illness and (2) fatalities in the work force. This analysis considered injury and fatality rates for construction workers only since the alternatives do not result in incremental changes in operations employment. Table 5.12-5 lists the maximum annual number of projected injuries and illnesses and fatalities for construction workers by alternatives based on the maximum employment levels for any year between 1995-2035.

5.13 Idaho National Engineering Laboratory Services

This section discusses the potential impacts from spent nuclear fuel management on utilities and energy at the INEL. It considers the consumption of water, electrical energy, fossil-based fuels, and wastewater discharge at the INEL site.

5.13.1 Construction

Table 5.13-1 summarizes estimates of annual requirements for electricity, water, wastewater, and diesel fuel for construction activities associated with each alternative and compares them to projected 1995 use levels for these resources. In general, the smallest increase in the demand for site services would result from Alternatives 4b(2) and 5a [Regionalization by Geography (Elsewhere) and Centralization at Other DOE Sites] and the largest increase would be associated with Alternatives 4b(1) and 5b [Regionalization by Geography (INEL) and Centralization at INEL].

Table 5.13-1. Estimated increase in annual electricity, water, wastewater treatment, and fuel requirements for construction activities associated with each alternative.

Service	Projected 1995 usage w/o Alternative	Estimated additional demand construction			
		Alternatives 1 and 2	Alternatives 3 and 4a	Alternatives 4b(1) and 5b	Alternatives 4b(2) and 5a
Electricity (MWHa per year)	208,000	71	150	2,100	10
Water (millions of liters per year)b	6,450	No increase	2.1	2.2	0.5
Sanitary wastewater (millions of liters per year)	540	No increase	1.5	4.5	0.5
Diesel fuel (liters per year)	5,830,000	6,400	8,500	14,000	1,500

a. MWH = megawatt hours.
b. To convert liters to gallons, multiply by 0.264.
Source: Hendrickson (1995).

Under Alternatives 4b(1) and 5b, the estimated annual increases in utility and energy usage rates from construction activities would be 2,100 megawatt-hours of electricity, 2.2 million liters (580,000 gallons) of water, 4.5 million liters (1,200,000 gallons) of wastewater discharge, and 14,000 liters (3,700 gallons) of diesel fuel. These changes represent modest increases ranging from near zero percent to 1.0 percent above projected 1995 usage levels and are well within current system capabilities and usage limits (see Section 4.13). The other alternatives would result in smaller increases in energy usage and would have no adverse impact on utility services at the INEL.

5.13.2 Operations

Table 5.13-2 summarizes estimates of annual requirements for electricity, water, wastewater, and fuel for operations activities associated with each alternative and compares them to project 1995 INEL usage of these resources. In general, the smallest increase in the demand for site services would result from Alternatives 1 and 2 (No-Action and Decentralization) and the largest would be associated with Alternatives 4b(1) and 5b [Regionalization by Geography (INEL) and Centralization at INEL].

Table 5.13-2. Estimated increase in annual electricity, water, wastewater treatment, and fuel requirements for operations activities associated with each alternative.

Service	Projected 1995 usage w/o Alternative	Estimated additional demand operation			
		Alternatives 1 and 2	Alternatives 3 and 4a	Alternatives 4b(1) and 5b	Alternatives 4b(2) and 5a
Electricity (MWHa per year)	208,000	180	2,200	11,000	2,000
Water (millions of liters per year)b	6,450	No increase	No increase	48	No increase
Sanitary wastewater (millions of liters per year)c	540	No increase	No increase	0.3	No increase
Fuel oil (liters per year)	11,100,000	28,000	330,000	1,100,000	300,000

a. MWH = megawatt hours.
b. To convert liters to gallons, multiply by 0.264.
c. Some industrial wastewater, such as steam condensate, is also discharged to evaporation ponds and injection wells.
Sources: Hendrickson (1995).

Under Alternatives 4b(1) and 5b, the estimated annual increases in utility and energy usage rates from operations activities would be 11,000 megawatt-hours of electricity, 48 million liters (13 million gallons) of water, 0.3 million liters (79,000 gallons) of wastewater, and 1,100,000 liters (290,000 gallons) of fuel oil. These changes represent modest increases ranging from near zero percent to 10 percent and are well within current system capabilities and usage limits (see Section 4.13). The other alternatives would result in smaller increases in energy usage and would have no adverse impact on utility services at the INEL.

5.14 Materials and Waste Management

This section discusses the impacts to the management of materials and wastes at the INEL site and Idaho Falls facilities as a result of the implementation of the spent nuclear fuel management alternatives. Alternatives 4b(1), and 5b, both with the spent fuel processing option, each establish the upper bound of potential impacts on projected rates of generation, treatment, storage, and disposal inventories of materials and wastes. Table 5.14-1 and 5.14-2 summarize waste generation projections for each alternative. The tables present average generating rates over the life cycle of each alternative and maximum annual increments over peak generation periods.

5.14.1 Alternative 1 - No Action

Under the No Action Alternative, 9 cubic meters of industrial solid waste would be generated during construction of the Alternate Fuel Storage Facility for the TAN Pool Fuel Transfer Project at the Idaho Chemical Processing Plant. At the completion of this project in 1998, there would be 485 cubic meters of non-fuel solid low-level waste consisting of Three Mile Island hardware and metals that would be removed and dispositioned in a separate project. These impacts apply also to the description of impacts for the other spent nuclear fuel management alternatives with the exception of Alternatives 4b(2) and 5a. The non-fuel solid low-level waste is already existing; therefore, it is not included in Table 5.14-1 as an increase in low-level waste generation.

5.14.2 Alternative 2 - Decentralization

In general, the character of the impacts to materials and waste management would be similar to those under the No Action Alternative.

5.14.3 Alternative 3 - 1992/1993 Planning Basis

Industrial solid waste would be generated from construction and operation of the various SNF projects under Alternative 3. This nonradioactive waste would be disposed of in the Central Facilities Area landfill. Landfill space is nonrestrictive for industrial solid waste disposal. Construction phase activities would generate a cumulative total of 620 cubic meters of industrial and commercial solid

Table 5.14-1. Average annual waste generation projections for selected SNF management alternatives at INEL.

waste. The Fuel Receiving, Canning, Characterization, and Shipping Facility will generate the most industrial waste of any of the projects, 490 cubic meters per year from 2005 through 2035.

In addition, the Fuel Receiving, Canning, Characterization, and Shipping Facility will generate 220 cubic meters per year of low-level waste during the same period. The Dry Storage Facility would generate an additional 5 cubic meters of low-level waste annually from 2005 through 2035. Including liquid low-level waste, the Increased Rack Capacity and Additional Increased Rack Capacity projects would increase generation rates by 570 cubic meters annually during construction from 1995 through 1997. Low-level waste would decrease to approximately 160 cubic meters per year from 1997 through 1999 with the completion of the Increased Rack Capacity project. Liquid low-level waste would be disposed in existing liquid waste processing systems at the Idaho Chemical Processing Plant. Solid radioactive wastes would be packaged and disposed of at the Radioactive Waste Management Complex, or incinerated at the Waste Experimental Reduction Facility, whichever is appropriate. Low-level waste from reracking fuel racks for the Increased Rack Capacity Project will be decontaminated and dispositioned by a licensed commercial vendor.

Experimental Breeder Reactor-II Blanket Treatment will generate 7 cubic meters of low-level waste for 1 year from 1997 to 1998.

The storage of low-level waste for incineration is not considered to be restrictive between 1995 through 2005. However, beyond 2005, low-level waste storage capacity may become strained. Use of commercial facilities to incinerate the backlog of low-level waste is under consideration in order to reduce or prevent the accumulation of low-level waste, but no firm commitment or contract has yet been established (EG&G 1993a).

The Radioactive Waste Management Complex appears to have adequate disposal capacity for low-level waste between 1995 and 2005. However, beyond 2005, additional capacity may be required. Excess capacity would be provided with the development of the proposed Low-Level Waste/Mixed Low-Level Waste Disposal Facility (EG&G 1993a).

The Electrometallurgical Process Demonstration Project will generate high-level, mixed low-level, low-level, transuranic, and industrial wastes from the demonstration and testing of new spent fuel management processes from 1996 through 2024.

Experimental Breeder Reactor-II Blanket Treatment will also generate high-level, mixed low-level, and transuranic wastes.

High-level waste would be immobilized after 2005, and may eventually be transported to a Federal high-level waste and spent nuclear fuel repository for disposal. Transuranic waste meeting waste acceptance criteria to be developed could be shipped to a potential Federal repository for disposal should one be selected (EG&G 1993a).

5.14.4 Alternative 4a - Regionalization by Fuel Type

In general, the character of the impacts to materials and waste management would be similar to those under Alternative 3.

5.14.5 Alternative 4b(1) - Regionalization by Geography (INEL)

The character and intensity of impacts on waste management activities at the INEL are similar to those under Alternatives 3 and 4a for some of the SNF management projects including the TAN Pool Fuel Transfer Project at the Idaho Chemical Processing Plant; the Increased Rack Capacity and Additional Increased Rack Capacity projects; the Experimental Breeder Reactor-II Blanket Treatment facility; and the Electrometallurgical Process Demonstration Project. Under Alternative 4b(1), the Dry Fuel Storage Facility is expanded and Fuel Receiving, Canning/Characterization, and Shipping Facility waste streams decrease relative to Alternatives 3 and 4a; however, the net effect of these differences on industrial/commercial solid waste generation and low-level waste generation for both construction and operation results in waste generation rates similar to those under Alternatives 3 and 4a.

The increase in average and peak generation rates over Alternatives 3 and 4a (Tables 5.14-1 and 5.14-2) is due to the Spent Fuel Processing option included under Alternative 4b(1), which accounts for the relative increase in generation rates over Alternatives 3 and 4a. Fuel processing would be done in order to stabilize the spent nuclear fuel and remove risks associated with storage and disposal, and to manage the resultant high-level waste in a cost-effective manner. If this alternative were pursued aggressively, the generated high-level waste residual resulting from segregating fissile material from the spent nuclear fuel may require additional high-level waste tankage. This increase in capacity would be covered by the High-Level Tank Farm New Tanks project described in Volume 2 of the EIS.

Capacity discussions for industrial/commercial solid waste and low-level waste under Alternative 3 apply to Alternative 4b(1).

5.14.6 Alternative 4b(2) - Regionalization by Geography (Elsewhere)

Construction phase activities would generate a cumulative total of 50 cubic meters of industrial and commercial solid waste. Overall, waste generation would be lower than all of the SNF management alternatives, with the exceptions of the No Action and Decentralization Alternatives.

5.14.7 Alternative 5a - Centralization at Other DOE Sites

In general, the character of the impacts to materials and waste management would be similar to those under Alternative 4b(2).

5.14.8 Alternative 5b - Centralization at the INEL

In general, the character of the impacts to materials and waste management would be similar to those under Alternative 4b(1).

5.15 Accidents

5.15.1 Introduction

Activities associated with the transportation, receipt, handling, stabilization, and storage of spent nuclear fuel at the INEL involve substantial quantities of radioactive materials and limited quantities of toxic chemicals. Under certain circumstances, the potential exists for accidents involving these materials to occur, which would result in exposure to INEL workers or members of the public, or contamination of the surrounding environment. Accidents can be categorized as follows:

- Abnormal events such as minor spills
- Design-basis events, which a facility is designed to withstand
- Beyond-design-basis events, which a facility is not designed to withstand (but whose consequences it may nevertheless mitigate)

This section summarizes postulated radiological and toxic material accidents in each accident category and describes their estimated consequences to workers, members of the public, and the environment. The scope of this section is limited to accidents within facilities; transportation accidents between facilities are addressed in Section 5.11. [Further information on the accidents summarized in this section, as well as information on other "lower consequence" accidents analyzed, is provided in Slaughterbeck et al. (1995)].

An accident is a series of unexpected or undesirable "initiating" events that lead to a release of radioactive or toxic materials within a facility or to the environment. This analysis defines initiating events that can lead to a spent nuclear fuel-related facility accident in three broad categories: external initiators, internal initiators, and natural phenomena initiators. External initiators (e.g., aircraft crashes, and nearby explosions or toxic material releases) originate outside the facility and can affect the ability of the facility to maintain confinement of radioactive or hazardous material. Internal initiators originate within a facility (e.g., equipment failures or human error) and are usually the result of facility operation. Sabotage and terrorist activities (i.e., intentional human initiators) might be either external or internal initiators. Natural phenomena initiators include weather-related (e.g., floods and tornadoes) and seismic events. This analysis defines initiators in terms of events that cause, directly or indirectly, a release of radioactive or hazardous materials within a facility or to the environment by failure or bypass of confinement.

Tables 5.15-1 through 5.15-4 summarize the radiological results of the analyses described in this section. Section 5.15.2 summarizes historic accidents at the INEL associated with spent nuclear fuel-related activities. Section 5.15.3 describes the methodology used to identify and evaluate potential radiological accidents associated with spent nuclear fuel receipt, handling, storage, and intra-area transportation activities. Sections 5.15.4 and 5.15.5 evaluate the postulated maximum reasonably foreseeable radiological and toxic material accidents, respectively.

5.15.2 Historic Perspective

Many of the actions proposed under the different spent nuclear fuel management alternatives considered in this EIS are continuations or variations of past practices at the INEL. DOE has analyzed consequences to the public from historic INEL accidents in detail and has determined them to be low (DOE 1991).

Consequences of accidents can involve fatalities, injuries, or illness. Fatalities can be prompt (immediate), such as in construction accidents, or latent (delayed), such as cancer caused by radiation exposure. While public comments received in scoping meetings for this EIS included many concerns about potential accidents at the INEL, the historic record demonstrates that DOE facilities, including the INEL, have a very good safety record, particularly in comparison to commercial industries (e.g., agriculture and construction). Figure 5.15-1 shows the rate of worker fatalities at the INEL and other DOE sites (DOE 1993b) compared to national-average rates that the National Safety Council compiled over a 10-year period for various industry groups (NSC 1993) and State of Idaho average rates (Hendrix 1994). While past accident occurrence rates are not necessarily indicative of future rates, the historic record reflects the DOE emphasis on safe operations.

There have been no prompt fatalities and no known latent fatalities to members of the public from accidental releases of radioactive or hazardous materials associated with spent nuclear fuel management activities in the 40-year history of INEL facilities, although some accidents associated

a. The radiological accident results for Alternative 4b(1), "Regionalization by Geography (INEL)," are conservatively assumed to be the same as those presented for Alternative 5b, as discussed in Section 5.15.4.4. The radiological accident results for Alternative 4b(2), "Regionalization by Geography (Elsewhere)," are identical to those presented for Alternative 5a, as discussed in Section 5.15.4.4.

b. HFEF = Hot Fuel Examination Facility.

c. Consequences are presented in terms of latent fatal cancers based on conservative (95 percentile) meteorological conditions. Consequences are calculated by multiplying the estimated exposure (i.e., dose) by an International Commission on Radiological Protection conversion factor of 4.0 y 10-4 cancer per rem for an adult worker (or 8.0 y 10-4 cancer per rem if the estimated exposure is greater than 20 rem).

d. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from Accident 1 could be less than the consequences from Accidents 2 through 4. However, given the high frequency for Accident 1 compared to Accidents 2 through 4, the risk could actually be greater than for Accidents 2 through 4.

e. This attribute is equal to consequences y frequency (events per year). The information is based on conservative (95 percentile) meteorological conditions.

f. ICPP = Idaho Chemical Processing Plant.

g. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

h. Resuming processing at the INEL under this alternative is not considered.

a. The radiological accident results for Alternative 4b(1), "Regionalization by Geography (INEL)," are conservatively assumed to be the same as those presented for Alternative 5b, as discussed in Section 5.15.4.4. The radiological accident results for Alternative 4b(2), "Regionalization by Geography (Elsewhere)," are identical to those presented for Alternative 5a, as discussed in Section 5.15.4.4.

b. HFEF = Hot Fuel Examination Facility.

c. Consequences are presented in terms of latent fatal cancers based on conservative (95 percentile) meteorological conditions. Consequences are calculated by multiplying the estimated exposure (i.e., dose) by an International Commission on Radiological Protection conversion factor of 5.0 y 10-4 cancer per person-rem for the offsite population (or 1.0 y 10-3 cancer per rem if the estimated population exposure is greater than 20 rem for any individual member of the public).

d. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from this accident could be less than the consequences from Accidents 2 through 4. However, given the high frequency for this accident compared to Accidents 2 through 4, the risk could actually be greater than for Accidents 2 through 4.

e. This attribute is equal to consequences y frequency (events per year). The information is based on conservative (95 percentile) meteorological conditions.

f. ICPP = Idaho Chemical Processing Plant.

g. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

h. Resuming processing at the INEL under this alternative is not considered.

a. The radiological accident results for Alternative 4b(1), "Regionalization by Geography (INEL)," are conservatively assumed to be the same as those presented for Alternative 5b, as discussed in Section 5.15.4.4. The radiological accident results for Alternative 4b(2), "Regionalization by Geography (Elsewhere)," are identical to those presented for Alternative 5a, as discussed in Section 5.15.4.4.

b. HFEF = Hot Fuel Examination Facility.

c. Consequences are presented in terms of latent fatal cancers based on conservative (95 percentile) meteorological conditions. Consequences are calculated by multiplying the estimated exposure (i.e., dose) by an International Commission on Radiological Protection conversion factor of 5.0 y 10-4 cancer per person-rem for the offsite population (or 1.0 y 10-3 cancer per rem if the estimated population exposure is greater than 20 rem for any individual member of the public).

d. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from this accident could be less than the consequences from Accidents 2 through 4. However, given the high frequency for this accident compared to Accidents 2 through 4, the risk could actually be greater than for Accidents 2 through 4.

e. This attribute is equal to consequences y frequency (events per year). The information is based on conservative (95 percentile) meteorological conditions.

f. ICPP = Idaho Chemical Processing Plant.

g. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

h. Resuming processing at the INEL under this alternative is not considered.

Figure 5.15-1. Comparison of fatality rates among workers in various industry groups. with spent nuclear fuel management activities have occurred. In 1958, filters in the Idaho Chemical Processing Plant CPP-601 Fuel Element Cutting Facility failed during decontamination operations. An estimated 100 curies of particulate radioactivity were released over an area of approximately 200 acres (0.809 square kilometers) in the vicinity of the Idaho Chemical Processing Plant. Approximately 39 curies became airborne, resulting in an estimated dose of 0.11 millirem to a hypothetical offsite individual located at the nearest site boundary (DOE 1991).

Three inadvertent nuclear chain reactions (i.e., nuclear criticalities) occurred at the Idaho Chemical Processing Plant in 1959, 1961, and 1978. The 1959 criticality occurred in a process waste and cell floor drain collection tank. Available evidence indicates that the critical solution resulted from an accidental transfer of concentrated uranyl nitrate solution to the waste collection tank through a line normally used to transfer decontaminating solutions to the waste tank. The estimated airborne release from this incident was 3,700 curies, and the estimated dose to the maximally exposed hypothetical individual located at the nearest site boundary was 1.1 millirem (DOE 1991). The 1961 and 1978 nuclear criticalities resulted from spent nuclear fuel dissolution and reprocessing activities. Estimated releases to the environment as a result of these accidents were 120 curies and 620 curies for the 1961 and 1978 accidents, respectively, and the calculated radiation doses at the nearest site boundary were less than 0.1 millirem for both releases (DOE 1991).

The INEL Fluorinel and Storage (FAST) facility (CPP-666), which historically performed spent nuclear fuel-related reprocessing activities, is currently shut down. Activities are under way to place this facility in a permanent shutdown mode. Restart of this facility and the potential for an inadvertent nuclear criticality resulting from operating this facility are considered in Sections 5.15.4.4 and 5.15.4.5 [Alternatives 4b(1) and 5b, respectively]. Because DOE has no current plans to resume spent nuclear fuel reprocessing activities at the Idaho Chemical Processing Plant, events similar to the three historic nuclear criticalities discussed above will be unlikely in future INEL spent nuclear fuel-related activities. Additional information regarding the historical accidents summarized above is provided in Slaughterbeck et al. (1995).

In the site's 40-year history, three prompt fatalities of INEL workers have occurred by accidents involving radiation exposure. In 1961, a steam explosion resulting from an unplanned nuclear criticality in an experimental reactor (Stationary Low-Power Reactor No. 1) killed these workers, who were manually moving reactor control elements. The estimated dose from this accident to a hypothetical individual located at the nearest site boundary was approximately 3 millirem (DOE 1991). All the accidents discussed above have caused contamination that has led to secondary impacts, such as the contamination of facility equipment and land inside the site boundary, and have required cleanup.

Twenty workers at the Argonne National Laboratory-West facility area were injured in early 1994 when, in an accident involving toxic material exposure, approximately 9 kilograms (20 pounds) of chlorine gas used to treat potable (i.e., drinking) water were accidently released to the environment. Although an investigation into this incident by the DOE was still ongoing at the time this analysis was performed, the accident is presumed to have occurred while a vendor was removing and replacing a nearly empty chlorine cylinder. A maintenance employee assisting in the activity apparently disconnected the nearly empty in-service chlorine gas cylinder from the potable water system with the cylinder valve in the open position, resulting in the remaining tank contents being discharged to the environment. As a result of the accidental release, 20 workers were sent to a local hospital. Eighteen workers reported for treatment of minor respiratory distress, one worker reported symptoms of more serious respiratory problems, and one worker reported back injuries as a result of falling while responding to the accident. (ANL 1994 and DOE 1994b).

5.15.3 Methodology for Determining the Maximum Reasonably Foreseeable Radiological Accidents

5.15.3.1 Selection of Spent Nuclear Fuel Facilities and Operations Requiring

Accident Analyses. The accident analyses performed to support this EIS considered all INEL nonreactor nuclear facilities that support spent nuclear fuel-related activities with the exception of those at the Naval Reactors Facility (NRF) area. Appendix D of this EIS discusses each of the spent nuclear fuel management alternatives and postulated accident scenarios associated with the Naval Reactors Facility and other naval spent nuclear fuel facilities.

DOE Order 5480.23 (DOE 1992a) defines nonreactor nuclear facilities as those activities or operations that involve radioactive or fissionable materials in such form and quantity that a nuclear hazard potentially exists to the workers or the general public. This analysis considered spent nuclear fuel facilities designed and constructed as direct support to reactor facilities (e.g., Advanced Test Reactor Storage Canal, which stores spent nuclear fuel and irradiated fuels) as nonreactor spent nuclear fuel facilities.

DOE manages spent nuclear fuel at the following INEL facility areas: Idaho Chemical Processing Plant, Naval Reactors Facility, Test Reactor Area, Auxiliary Reactor Area/Power Burst Facility, Argonne National Laboratory-West, and Test Area North. For further information regarding the activities conducted in these areas, refer to Chapter 2. After identifying all the nonreactor nuclear facilities within these facility areas that stabilize, handle, or store spent nuclear fuel, this analysis ranked the facilities according to potential hazards using preexisting facility "hazard classifications." DOE Order 5480.23 requires contractors operating nonreactor nuclear facilities to perform a hazard classification of a facility to assess the consequences of an unmitigated release of radioactive or hazardous material in one of the following categories(1):

- Category 1. The hazard analysis shows the potential for significant offsite consequences.
- Category 2. The hazard analysis shows the potential for significant onsite consequences.
- Category 3. The hazard analysis shows the potential for only significant localized consequences.

The classification of nonreactor nuclear facilities in one of these three categories was in accordance with DOE Standard DOE-STD-1027-92 (DOE 1992b). This standard provides guidance for the hazard categorization of nuclear facilities based on facility inventories of radionuclides and the potential for those radionuclides to affect workers or the public if released to the environment.

This analysis used these categories as a screening threshold to identify those facilities of interest (i.e., those spent nuclear fuel-related facilities with sufficient quantities of radionuclides to present the potential for significant impacts to workers or the public if released to the environment). The analysis excluded (screened out) Category 3 (low hazard) facilities if they present possible worker consequences enveloped by postulated accidents at Category 2 facilities. Facilities with a hazard classification of 2 or greater (or Category 3 facilities that were not screened out) were evaluated further, as discussed in the next section.

5.15.3.2 Determination of Maximum Reasonably Foreseeable Radiological

Accidents. After determining spent nuclear fuel-related facilities with sufficient quantities of radionuclides to present radiological consequences to workers or the public (as discussed in Section 5.15.3.1), the analysis generated potential accident scenarios for each of these INEL facilities by performing the following activities:

- Reviewing historic spent nuclear fuel-related accidents that have occurred during the 40-year history of the INEL.
- Reviewing existing accident analyses and safety analysis reports for spent nuclear fuel-related activities and facilities.

---

1. These categories were formerly labeled "high", "moderate," and "low" in accordance with DOE Order 5480.23 for nonreactor nuclear facilities.

- Identifying potential internal, external, and natural phenomena events that could initiate spent nuclear fuel-related accidents other than those previously analyzed.
- Performing additional accident analyses for those accidents considered to present the greatest consequences to workers or the public, as necessary.

The analysis considered internal and external initiators associated with a wide range of activities (e.g., research and development and construction or modification of facilities) not necessarily covered in existing safety analyses. For example, potential radiological accident scenarios initiated by construction activities associated with constructing new spent nuclear fuel-related facilities or modifying existing spent nuclear fuel-related facilities (as proposed under the various alternatives) were postulated. Typically, events involved in the construction of new spent nuclear fuel-related facilities would act as external initiators to existing facilities, while events involved in modifying existing spent nuclear fuel facilities would act as internal initiators. Examples of construction or industrial-type events that could initiate a radiological accident included fires, confinement impacts or puncture events, equipment failure, and human error.

Additional considerations used to determine potential internal and external initiators that could lead to spent nuclear fuel-related radiological accidents included vulnerabilities associated with handling, stabilizing, and storing severely degraded spent nuclear fuel and equipment. For example, in November 1993, DOE issued a report (DOE 1993c) discussing vulnerabilities associated with various spent nuclear fuel-related facilities across the DOE complex. The report identified one INEL facility, the CPP-603 Underwater Fuel Storage Facility, as requiring immediate management attention to avoid unnecessary increases in worker exposures, cleanup costs, and postulated accident frequencies. Activities have begun to stabilize spent nuclear fuel inventories in the CPP-603 facility and relocate them to another facility (CPP-666); these activities will continue for several years after the scheduled 1995 Record of Decision for this EIS. Therefore, the analysis considered postulated accident scenarios associated with stabilizing and relocating CPP-603 spent nuclear fuel inventories to be potential accident initiators in developing the radiological accidents summarized in this EIS. Examples of accident scenarios considered as a result of degraded spent nuclear fuel or facility equipment included inadvertent nuclear criticalities, physical damage of spent nuclear fuel and spent nuclear fuel facilities, and radionuclide releases resulting from handling and stabilizing degraded spent nuclear fuel. For postulated accident scenarios at facilities other than the CPP-603 Underwater Fuel Storage Facility, the analysis also considered the potential for long-term degradation of facility structures, equipment, and spent nuclear fuel inventories that could lead to an increased probability for radiological accidents.

To compare the various possible spent nuclear fuel-related accident scenarios and to identify those maximum reasonably foreseeable accidents that present the greatest consequences to workers and the public, the analysis divided each postulated spent nuclear fuel-related accident into the appropriate frequency category (abnormal events, design-basis accidents(2), or beyond-design-basis accidents), according to its estimated frequency of occurrence. Table 5.15-5 lists the frequency ranges associated with the abnormal event, design-basis accident, and beyond-design-basis accident categories discussed in Section 5.15.1.

The estimated frequency of each postulated accident was based on an identification of the physical basis for the accident and the events required for the accident to occur. Because many of the postulated accidents or their constituent events (initiators or precursors) have rarely or never occurred, frequency data based on historic experience were not available. Therefore, in many instances, it was necessary to develop a frequency estimate on the basis of events for which experience existed and engineering judgment. More than 40 sources of frequency data for the accident events postulated were reviewed, including analyses and reports prepared for the DOE, U.S. Nuclear Regulatory Commission (NRC), Electric Power Research Institute, and private industry. [For further information regarding the development of estimated accident frequencies, refer to Slaughterbeck et al. (1995).]

After the division of the postulated spent nuclear fuel-related accidents into the frequency ranges defined in Table 5.15-5, the analysis identified the postulated nonprocessing-related accident within each frequency range determined to present the maximum offsite consequences as a maximum reasonably foreseeable radiological accident to be further analyzed for this EIS. Potential nonprocessing-related accident scenarios were chosen as maximum reasonably foreseeable accidents because of the shutdown status of the INEL facility (CPP-666) that historically processed spent nuclear fuel. However, because existing inventories of spent nuclear fuel at the INEL would substantially increase under Alternatives 4b(1) and 5b [Regionalization by Geography (INEL) and Centralization at the INEL, respectively], there could be a need to resume processing operations to stabilize degraded spent nuclear fuel operations and assure adequate storage space for spent nuclear fuel received from other sites(3). Therefore, in addition to the maximum reasonably foreseeable nonprocessing-related accident scenarios, this analysis considers the three postulated processing-related accidents that present the maximum offsite consequences as additional maximum reasonably foreseeable accidents under Alternatives 4b(1) and 5b.

Table 5.15-5. Accident frequency categories.

Frequency Category	Accident Frequency Range (accidents per year)
Abnormal events	frequency > 1y10-3 per year
Design-basis accidents	1y10-3 per year > frequency > 1y10-6 per year
Beyond-design-basis accidents	1y10-6 per year > frequency > 1y10-7 per year

In addition, a postulated inadvertent nuclear criticality accident at the CPP-603 Underwater Storage Facility was considered for further analysis because significant vulnerabilities associated with its spent nuclear fuel inventories have been identified (DOE 1993b) and postulated criticality accidents have been addressed in virtually all nonreactor DOE EISs and safety analysis reports where the accidents are reasonably foreseeable because of public concerns regarding their potential. As a result, the seven radiological accidents summarized in Section 5.15.4 were determined to be the maximum reasonably foreseeable radiological accidents (i.e., greatest consequences). Further discussion and analysis information for each of these accidents, as well as other accidents analyzed, is provided in Slaughterbeck et al. (1995). Appendix D identifies maximum reasonably foreseeable accidents associated with transporting, receiving, handling, and storing naval spent nuclear fuel at the INEL.

The postulated accidents summarized in this section considered with the INEL facilities analyzed in Appendix D provide a basis for characterizing the potential risks and consequences associated with managing spent nuclear fuel at the INEL over the next 40 years.

Seismic events were the only identified common-cause initiators with the potential to initiate radioactive material releases to the environment at more than one spent nuclear fuel-related facility at the INEL. However, a seismic event resulting in significant damage and radioactive releases from facilities in more than one facility area (e.g., Idaho Chemical Processing Plant and Test Area North) is considered beyond reasonably foreseeable (frequency less than one in ten million years), because of the physical distance and isolation between facility areas. In accordance with DOE guidance (DOE 1994a), a seismic event initiating multiple-facility releases in more than one facility area on the site was screened from further consideration because of its extremely low frequency of occurrence.

Analyses were performed that evaluated the potential consequences and risks associated with multiple-facility releases within a single INEL facility area resulting from a severe seismic event

---

2. For facilities where design-basis accident analyses were unavailable, evaluation basis accident scenarios (postulated accident scenarios used where documented design basis accident analyses do not exist) were considered in accordance with DOE-DP-STD-3005-YR (DOE 1994a).

3. Processing would be performed in the Flourinel and Storage (FAST) facility (CPP-666) and a new facility to be constructed, the Fuel Processing Restoration (FPR) facility (CPP-691). Processing would consist of dissolving spent nuclear fuel to immobilize radionuclides for final waste disposal.

(Slaughterbeck et al. 1995). For example, within a 500-meter radius in the Idaho Chemical Processing Plant facility area, there are several spent nuclear fuel facilities, the primary facilities being the CPP-749 dry storage facilities and the CPP-666 and CPP-603 underwater fuel storage facilities. An analysis was performed (Slaughterbeck et al. 1995) to determine whether simultaneous releases from these facilities could result from a severe seismic event. Because the CPP-666 and CPP-749 facilities were designed and qualified to withstand a severe seismic event, they are not expected to contribute to the consequences and risks resulting from a severe seismic event impacting the Idaho Chemical Processing Plant. However, because of known structural deficiencies and vulnerabilities with the spent nuclear fuel at the CPP-603 facility, the CPP-603 facility is expected to be significantly damaged following a severe seismic event, resulting in one or more criticalities and the leakage of contaminated basin water to the surrounding environment. While the consequences from these simultaneous multiple-release mechanisms (one or more criticalities and water drainage) would be greater than the single criticality analyzed for CPP-603 facility (Section 5.15.3.3.2), the consequences and risk of such releases are expected to be bounded by the other accidents analyzed in the EIS--primarily, a seismic event that causes fuel melting at the Argonne National Laboratory-West Hot Fuel Examination Facility (highest consequence accident), and a fuel handling accident in the same facility (highest risk accident, where risk = consequence x frequency). Similar analyses (DOE 1993a) for the Test Area North and Argonne National Laboratory-West also demonstrate that potential multiple-facility releases or multiple-release mechanisms from a single facility resulting from a severe seismic event would also be bounded by accidents postulated for the Hot Fuel Examination Facility. Based on this conclusion and the accident selection methodology described 5.15.3.1, the consequences and risks associated with multiple-facility releases were screened from further consideration since they do not represent the bounding accident scenarios within the frequency categories defined in Table 5.15-5.

In addition, the screening methodology did not specifically include potential accident scenarios associated with operating new spent nuclear fuel handling and storage facilities proposed under the various alternatives considered in this EIS because postulated accident scenarios for existing facilities would bound the consequences associated with potential accidents at new facilities. This assumption is appropriate for two primary reasons. First, the missions of new spent nuclear fuel facilities would be similar to the missions of existing spent nuclear fuel-related DOE facilities, which implies that DOE would consider the same types of accident scenarios for the new facilities it considered for the existing facilities. Second, DOE would design and build new facilities that would incorporate modern preventive and mitigative features to reduce the frequency and potential consequences associated with postulated accidents.

To compare the consequences of the same accident scenario at an identical hypothetical facility constructed at each DOE site included in this EIS (based on local geological and meteorological conditions), Appendix D summarizes postulated accident scenarios for a new Expended Core Facility at Oak Ridge, Hanford Site, Savannah River Site, or Nevada Test Site.

To determine the radiological and toxicological consequences presented throughout Section 5.15 associated with the postulated accidents and with spent nuclear fuel-related activities, the analysis used the following definitions:

- Worker. An individual 100 meters (328 feet) downwind of the facility location where the release occurs.[4]
- Nearest Public Access. The nearest point of public access to the location where the release occurs, sometimes inside the site boundary.

---

[4] The worker is defined as the individual located at 100 meters because reliable safety analyses quantifying the impacts (e.g., dose and health effects) to workers at distances less than 100 (i.e., "close-in" workers) meters fram an accidental release of radionuclides are unavailable. The effects on and risks to workers closer in than 100 meters are recognized and discussed in Section 5.15.3.3. Each of the maximum reasonably forseeable accidents considered in this EIS, particularly the design-basis and beyond-design-basis accidents, contains some risk of worker

injury or death at distances closer than 100 meters.

- Maximally Exposed Offsite Individual. A hypothetical resident at the site boundary nearest to the facility where the release occurs.
- Offsite Population. The collective total of individuals within an 80-kilometer (50-mile) radius of the INEL.
- Environment. The area outward from 100 meters (328 feet) downwind of the facility where the release occurs.

5.15.3.3 Impact of Accidents on Close-In Workers. An evaluation has been made on the

radiological impact to close-in workers from the selected accident scenarios. Injuries or fatalities that might occur due to an external event, such as a severe seismic disturbance or airplane crash into the structure, are not considered in this evaluation since they are not attributable to direct radiological consequences. Seven accident scenarios for nonprocessing-related and processing-related activities are considered maximum reasonably foreseeable accidents.

5.15.3.3.1 Mechanical Handling Accident at the Argonne National Laboratory

West Hot Fuel Examination Facility - This accident is assumed to result in fuel pin breach and venting of noble gases and iodine. No fatalities to workers are expected from this event. However, a substantial iodine dose to the thyroid could cause radiation-induced hypothyroidism or a similar disorder.

5.15.3.3.2 Criticality Accident at the Idaho Chemical Processing Plant -

CPP-603 - This event is an unplanned nuclear criticality associated with underwater spent nuclear fuel storage at the CPP-603 facility. Based on shielding provided by the pool water, it is likely that no fatalities would occur. To the extent water is expelled due to the energy of the event, close-in workers could receive substantial radiation exposure. Worker presence in the area above the pool or very close to the edge of the pool is not routine. The impact of the event would likely be isolated to nearby equipment operators if the criticality were initiated by a handling error.

5.15.3.3.3 Seismic Event Leading to Fuel Melt at the Argonne National

Laboratory West Hot Fuel Examination Facility - A seismic event is postulated to result in a breech of the main cell used for examination of the fuel, which is assumed to lead to a failure of the fuel cooling system. It is likely that the release of radioactive materials from fuel melting would occur slowly enough to allow evacuation of all workers before any appreciable exposure. Therefore, no radiation-induced fatalities would be expected.

5.15.3.3.4 Airplane Crash and Fire at Argonne National Laboratory West Hot

Fuel Examination Facility - An airplane crash and subsequent fire sustained by airplane fuel could result in a major breach of the confinement barriers and could lead to a substantial atmospheric release of radionuclides. Workers unaffected by the airplane crash or fire would not be expected to remain in the area long enough to receive substantial radiation exposure. It is assumed the buoyancy of the radioactive material due to the fire would mitigate the direct radiological impacts to close-in workers, substantially reducing the likelihood of radiation induced worker fatalities.

5.15.3.3.5 Criticality Accident During Processing at the Idaho Chemical

Processing Plant - CPP-666 - This is the first of three evaluated accidents that could occur only if processing were resumed at the Fluorinel and Storage Facility (FAST). Three inadvertent nuclear criticalities have occurred in INEL processing facilities and none has resulted in worker fatalities. In each event, radioactive material was released to the atmosphere and close-in workers received direct exposure. If processing were resumed, the techniques and controls implemented to prevent recurrence of processing-related criticalities would be employed again. Due to the cell wall shielding provided by concrete walls that are several feet thick, it is expected that no workers would receive substantial radiation exposure.

5.15.3.3.6 Hydrogen Explosion at the Idaho Chemical Processing Plant - A

hydrogen explosion in the dissolver off-gas system of the Flourinel and Storage (FAST) Facility would result in release of radioactive material to the facility. If workers were near the dissolver off-gas system, they could receive substantial radiation exposure from the explosion. No fatalities would be expected, but radiation-induced health detriments could occur.

5.15.3.3.7 Dissolution of Short-Cooled Fuel at the Idaho Chemical Processing

Plant - An explosion in the dissolver tank could occur if fuel that has not cooled for at least 30 days was inadvertently shipped to the dissolver at the Flourinel and Storage Facility (FAST). This energetic event would likely breach the dissolver off gas system and could breach the dissolver tank. Workers in the areas closely associated with the dissolver tank could receive substantial radiation exposure, but it is likely that no radiation-induced fatalities would occur.

5.15.3.4 Analysis of Radiological Accident Consequences. The quantities of

radioactive materials and the ways these materials interact with human beings are important factors in determining health effects. The ways in which radioactive materials reach human beings, their absorption and retention in the body, and the resulting health effects have been studied in great detail. The International Commission on Radiological Protection (ICRP) has made specific recommendations for quantifying these health effects (ICRP 1991). This organization is the recognized body for establishing standards for the protection of workers and the public from the effects of radiation exposure. Health effects can be classified into two categories: prompt (also referred to as acute) and latent. Prompt health effects are those experienced immediately after exposure and include damage to the body up to and including death. Latent health effects are those experienced some time after exposure and include cancers and hereditary symptoms. An INEL-developed computer code, Radiological Safety Analysis Computer Program-5 (RSAC-5), estimates potential radiation doses to maximally exposed individuals or population groups from accidental releases of radionuclides. This code, which is customized to specific INEL conditions, uses well-established and generally accepted scientific engineering principles as the basis for its various calculational steps. The code is based on guidance provided in NRC Guide 1.145 (NRC 1983) and has been validated to comply with accepted standards for such software. [For a detailed description of RSAC-5, refer to Slaughterbeck et al.

(1995).]

The RSAC-5 code determined estimated consequences to the worker, an individual assumed to be stranded at the nearest point of public access, the maximally exposed hypothetical individual at the nearest site boundary, and the offsite population within 80 kilometers (50 miles) of the radiological accidents postulated under Alternative 1, No Action. Postulated frequencies and consequences analyzed under Alternative 1 are based on (1) the approximate amount of spent nuclear fuel currently at the INEL [measured in Metric Tons Heavy Metal (MTHM)], (2) the estimated increases in inventories resulting from spent nuclear fuel generated by operating INEL reactors (i.e., fuel recently removed from a reactor that has not had sufficient time to cool), and (3) the estimated number of fuel handling activities associated with stabilizing or relocating spent fuel inventories inside the INEL site boundary. Although the four nonprocessing-related maximum reasonably foreseeable radiological accident scenarios identified for Alternative 1 are also considered under Alternatives 2 through 5, proposed changes in INEL spent nuclear fuel inventories and the number of fuel handling activities associated with these changes could affect the estimated frequencies and consequences expected for Alternatives 2 through 5. Therefore, to reasonably estimate the frequencies and consequences associated with activities proposed under Alternatives 2 through 5, the frequencies and consequences for the accidents presented under Alternative 1 require appropriate "adjustment" or "scaling."

To be conservative, the analysis assumed that the increase in the annual frequency of mechanical handling accidents would be equal to the estimated increase in the annual number of handling events proposed under Alternatives 2 through 5. However, the consequences associated with a mechanical handling accident would not vary with a change in the number of handling events because the amount of material involved in each event would not change. To determine potential changes in annual mechanical handling accident frequencies between the different spent nuclear fuel management alternatives, the analysis based its estimates of the annual number of fuel handling events under each alternative on spent fuel shipment rates anticipated for the next 40 years, as discussed in Appendix I.

Estimates of long-term (40-year) and short-term (5-year) shipments at the INEL were considered in determining the annual shipment rates for each alternative. The basis for the number of long-term shipments include spent nuclear fuel the INEL will continue to receive from operating reactors such as DOE, Naval Nuclear Propulsion Program, university, and research reactors. Short-term shipments consist of shipments that would be required to relocate existing spent fuel inventories between sites under the various alternatives. Table 5.15-6 summarizes the estimated annual shipment rate to and from the INEL under each alternative, and within INEL site boundaries. The estimates provided in Table 5.15-6 consider both onsite and offsite shipments.

Table 5.15-6. Determination of accident frequency adjustment factors for Alternatives 2 through 5 based on estimated number of annual spent nuclear fuel shipments under each alternative.

Alternative	Estimated Shipment Rate (per year)a	Adjustment Factor (shipment rate/baseline)
1. No Action	41	Baseline
2. Decentralization	50	1.2
3. 1992/1993 Planning Basis	128	3.1
4a. Regionalization by Fuel Type	195	4.8
4b(1) Regionalization by Geography (INEL)	824	20.0
4b(2) Regionalization by Geography (Elsewhere)	351	8.6
5a. Centralization at Other DOE Sites	351	8.6
5b. Centralization at the INEL	824	20.0

a. Data presented for the estimated annual shipment rate is based on information tabulated in Appendix I. The annual shipment rate for the No-Action Alternative (baseline) is derived from Table 3 of Wichmann 1994.

Based on the number of annual shipments estimated for Alternatives 2 through 5, as listed in Table 5.15-6, the analysis calculated multiplication factors by dividing the estimated shipment rates **under Alternatives 2 through 5 by the baseline (Alternative 1) shipment rate.** To determine the estimated frequency for the maximum reasonably foreseeable mechanical handling accidents under each alternative, the frequency identified for Alternative 1 was multiplied by the appropriate adjustment factor. The same approach determined estimated frequencies for Accident 1 (fuel pin breach and noble gases and iodine release from the Hot Fuel Examination Facility) under Alternatives 2 through 5. For Accident 2 (inadvertent criticality in the CPP-603 Underwater Fuel

Storage Facility resulting from a handling accident associated with degraded spent nuclear fuel), the estimated frequency considered under Alternative 1 (1 y 10-3 event per year) is based on the number of handling activities associated with relocation of the CPP-603 spent nuclear fuel inventories to the CPP-666 facility. Because proposed changes in INEL inventories under the different alternatives would not affect handling events associated with relocating spent fuel from the CPP-603 facility to the CPP-666 facility, the estimated frequency for this mechanical handling event would not change. As a result of this approach and the fact that 3 of the 4 accident scenarios that present the greatest consequences are not handling accidents, Accident 1 is the only accident requiring "adjustment" for each alternative.

Variable source-term-sensitive accidents would have consequences that depended on the amount of spent nuclear fuel in storage. One example is the accidental drainage of a spent fuel storage canal that results in the release of corrosion products in the canal to the environment. The larger the spent fuel inventory in the canal, the larger the release of corrosion products to the environment resulting from draining the canal. (Drainage of a water canal completely filled with spent nuclear fuel was considered in the determination of the maximum reasonably foreseeable accidents and was determined to present lower consequences than other accident scenarios analyzed.) Variable source-term sensitive accidents depend only on spent nuclear fuel inventories and do not require adjustment of their estimated frequencies of occurrence. Because none of the postulated accidents summarized under Alternative 1 is source-term sensitive (e.g., spent nuclear fuel inventories in the Hot Fuel Examination Facility are not likely to increase), adjustment of the estimated consequences calculated under Alternative 1 is not required for Alternatives 2 through 5.

5.15.4 Impacts from Postulated Maximum Reasonably Foreseeable Radiological Accidents

Section 5.15.4.1 summarizes impacts (e.g., exposures and health effects) from the four nonprocessing-related maximum reasonably foreseeable radiological accidents postulated under Alternative 1 (No Action). Sections 5.15.4.4.2.1 through 5.15.4.5.2 describe changes in these postulated accident impacts resulting from changes in spent nuclear fuel inventories and handling activities under the other alternatives. Sections 5.15.4.4.2.1 and 5.15.4.5.2 also summarize impacts from three additional maximum reasonably foreseeable accidents associated with resumption of processing activities at the INEL. Section 5.15.6 provides more information about the assumptions and analyses performed for each of the radiological accidents discussed under each alternative.

5.15.4.1 Alternative 1: No Action. Based on the quantity of spent nuclear fuel at the INEL

(excluding naval fuel at Naval Reactors Facility, which is analyzed in Appendix D), its storage configuration (wet versus dry), the amount of time the spent fuel has been allowed to cool, and consideration of various internal, external, and natural phenomena initiators (as discussed in Section 5.15.3), the postulated accidents listed in Table 5.15-7 would have the greatest radiological consequences within the abnormal event, design-basis accident, and beyond-design-accident categories under this alternative. For each accident, Table 5.15-7 also lists estimated accident frequencies; radiation exposures to the offsite population within 80 kilometers (50 miles), a member of the public stranded at the nearest point of public access inside the INEL site boundary, a hypothetical maximally exposed individual (MEI) at the nearest site boundary, and a worker; point estimates of the annualized risk of the maximally exposed individual contracting a fatal cancer during his/her lifetime as a result of the radiation exposure; and point estimates of risk of the expected number of fatal cancers (annualized and total) in the offsite population. The estimates of the consequences and risk to the offsite population are based on conservative (95 percentile) and average (50 percentile) meteorological conditions(5). The estimates of the consequences and risk to the maximally exposed individual are based on conservative (95 percentile) meteorological conditions. The postulated accidents listed in Table 5.15-7, in conjunction with the maximum reasonably foreseeable spent nuclear fuel accidents identified for the INEL Naval Reactors Facility in Appendix D, characterize the potential consequences and risks associated with the proposed spent fuel management activities at the INEL under this alternative.

Atmospheric transport of radionuclides from the postulated accidents could result in some **secondary impacts, such as contamination of the environment or impacts to national defense.** To

---

5. Conservative (95 percentile) meteorological conditions are defined as the meteorlogical conditions that, for a given release, the concentration at a fixed receptor location will not be exceeded 95 percent of the time. Average (50 percentile) meteorological conditions are defined as the meteorological conditions that, for a given release, the concentration at a fixed receptor location will not be exceeded 50 percent of the time.

Table 5.15-7. Impacts from selected maximum reasonably foreseeable radiological accidents - Alternative 1, No Action (50 and 95 percentile meteorological conditions).

Accident	Frequency (events per year)	Worker Dosea (rem)	Nearest Public Accessb (rem)	Dose to MEIc (rem)	Offsite Population Dose (95%) (person-rem)	Point estimates of risk of fatal cancers (per year)		
						MEI	Offsite Population	
						95%d	50%	95%
1. Fuel handling accident, fuel pin breach, venting of noble gases and iodine at HFEFe	1.0y10-2	(f)	(f)	2.0y10-3	(f)	1.0y10-8	(f)	(f)
2. Inadvertent criticality in ICPPg CPP-603 storage facilityh	1.0y10-3	9.7y10-2	1.4y10-3	1.0y10-3	5.9y10-1	5.0y10-10	6.5y10-9 (6.5y10-6)d	3.0y10-7 (3.0y10-4)d
3. Fuel melting of small number of assemblies at HFEF resulting from seismic event and cell breach	1.0y10-5	6.2y10-1	6.5y10-1	5.0y100	1.4y104	2.5y10-8	4.5y10-7 (4.5y10-2)d	7.0y10-5 (7.0y100)d
4. Material release from HFEF resulting from aircraft crash and ensuing fire	1.0y10-7(i)	4.6y100	3.2y10-1	5.0y100	2.0y103	2.5y10-10	3.6y10-8 (3.6y10-1)d	1.0y10-7 (1.0y100)d

a. A worker is defined as a worker located 100 meters (328 feet) from the point of release.
b. Public individual assumed to be stranded at the nearest point of public access inside the site boundary.
c. MEI = Maximally exposed hypothetical offsite individual, located at the nearest site boundary.
d. Maximally exposed individual and offsite population fatal cancer risk = dose y accident frequency y 5.0 y 10-4 fatal cancer per rem (ICRP-60 conversion factor) if dose is less than 20 rem. For doses 20 rem or more the ICRP-60 conversion factor is doubled, or 1.0 y 10-3. Numbers in parentheses indicate the total number of fatal cancers in the population if the accident occurred.
e. HFEF - Hot Fuel Examination Facility.
f. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from this accident could be less than the consequences from Accidents 2 through 4.
g. ICPP = Idaho Chemical Processing Plant.
h. Although three nuclear criticalities associated with spent nuclear fuel reprocessing activities have occurred at the INEL during its 40-year operating history, the estimated frequency for an inadvertent criticality is not based on historic reprocessing data because reprocessing is not considered under this alternative. Nominal frequency estimates vary from 1.0 y 10-4 (CPP-666 underwater storage facility) to 1.0 y 10-3 (CPP-603

underwater storage facility) event per year.

i. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

prevent these radionuclides from increasing any potential safety concerns, DOE would initiate cleanup activities if an accident occurred, and no irreversible environmental impacts would be likely. Table 5.15-8 summarizes postulated secondary impacts resulting from the postulated radiological accidents listed in Table 5.15-7.

This analysis takes limited credit for emergency response actions in determining the consequences **listed in Table 5.15-7.** DOE would initiate INEL emergency response programs, as appropriate, following the occurrence of an accident to prevent or mitigate potential consequences. These emergency response programs, implemented in accordance with 5500-DOE series Orders, typically involve emergency planning, emergency preparedness, and emergency response actions. Each emergency response plan utilizes resources specifically dedicated to assist a facility in emergency management. These resources include but are not limited to the following:

- INEL Warning Communications Center
- INEL Fire Department
- Facility Emergency Command Centers
- DOE Emergency Operations Centers
- County and State Emergency Command Centers
- Medical, health physics, and industrial hygiene specialists
- Protective clothing and equipment (respirators, breathing air supplies, etc.)
- Periodic training exercises and drills within and between the organizations involved in implementing the response plans

5.15.4.2 Alternative 2: Decentralization. Adjustments in estimated accident frequencies

and point estimates of risk presented for Alternative 1 would be related to (1) the receipt, handling, and storage activities associated with the additional spent nuclear fuel inventories; and (2) the increase in overall spent nuclear fuel-related storage, relocation, and handling activities not allowed under Alternative 1. Because no changes in the accident consequences estimated for Alternative 1 are likely to occur under this alternative from increased fuel inventories (i.e., the same amount of radioactive material would accidentally be released to the environment as discussed in Section 5.15.3.3), no changes are likely in the postulated secondary impacts listed in Table 5-15-8. Table 5.15-9 summarizes the four postulated accidents with the greatest radiological impacts under this alternative.

Table 5.15-8. Estimated secondary impacts resulting from the maximum reasonably foreseeable accidents postulated under Alternative 1, No Action, assuming conservative (95 percentile) meteorological conditions.

Radiological Accident Summary	Environmental or Social Impacts (Assuming 88 millirem per year limit with 24-hour-per-day exposure)a							
	Biotic Resources	Water Resources	Economic Impacts	National Defense	Environmental Contamination	Endangered Species	Land Use	Treaty Rights & Tribal Resources
1. Fuel handling accident, fuel pin breach, venting of noble gases and iodine at HFEFb (1x10-2 per year)	Limited adverse effects expected to vegetation or wildlife.	Limited adverse effects expected to surface water or groundwater.	Limited economic impacts expected. Any cleanup required would be localized and could be accomplished with existing workforce and equipment.	No effects on national defense expected.	Local contamination requiring cleanup expected around site accident.	No impacts exptected to endangered or threatened species.	No change in land use or irreversible impacts expected.	No irreversible impacts to Native Americans or public lands expected.
2. Uncontrolled chain reaction (criticality) at ICPPc (1x10-3	Limited adverse effects expected to vegetation or wildlife.	Limited adverse effects expected to surface water or groundwater.	No economic impacts expected. Any cleanup required would be	No effects on national defense expected.	Local contamination requiring cleanup expected around	No impacts exptected to endangered or threatened species.	No change in land use or irreversible impacts expected.	No irreversible impacts to Native American or public lands

per year)			localized and could be accomplished with existing workforce and equipment.		site accident.			expected.
3. Fuel melting of small number of assemblies at HFEF resulting from seismic event and cell breach (1x10-5 per year)	Limited adverse effects expected to vegetation or wildlife.	Limited adverse effects expected to surface water or groundwater.	Potential interdiction of affected agricultural products on nearby lands. Local cleanup in the vicinity of HFEF.	No effects on national defense expected.	Local contamination requiring cleanup expected around site accident (on and off the INEL site).	No impacts exptected to endangered or threatened species.	Potential for 1 year of agricultural land withdrawal of up to 10,000 acresd	Potential for temporary restricted access to affected public land (less than 10,000 acres).d
4. Material release from HFEF resulting from aircraft crash and ensuing fire (1x10-7 per year)	Limited adverse effects expected to vegetation or wildlife.	Limited adverse effects expected to surface water or groundwater.	Potential interdiction of affected agricultural products on nearby lands. Local cleanup in the vicinity of HFEF.	No effects on national defense expected.	Local contamination requiring cleanup expected around site accident (on and off the INEL site).	No impacts exptected to endangered or threatened species.	Potential for 1 year of agricultural withdrawal of up to 10,000 acresd	Potential for temporary restricted access to affected public land (less than 10,000 acres).d

a. Postulated secondary impacts based on 10-microrem-per-hour exposure (88 millirem per year with 24-hour-per-day exposure) from ground contamination resulting from radionuclide deposition from the plume. This approach in estimated secondary impacts is conservative because DOE Order 5400.5 states that the public dose limit for exposure to residual contamination and natural background radiation is 100 millirem per year.

b. HFEF = Hot Fuel Examination Facility.

c. ICPP = Idaho Chemical Processing Plant.

d. To convert acres to square kilometers, multiply by 0.004.

Table 5.15-9. Impacts from selected maximum reasonably foreseeable accidents - Alternative 2, Decentralization (50 and 95 percentile meteorological conditions).

a. Numbers in parentheses indicate multiplication factor used to scale or adjust estimated accident frequencies under Alternative 1, as described in Section 5.15.3.3.

b. A worker is defined as a worker located 100 meters (328 feet) from the point of release.

c. Public individual assumed to be stranded at the nearest point of public access inside the site boundary.

d. MEI = Maximally exposed hypothetical offsite individual located at the nearest site boundary.

e. Maximally exposed individual and offsite population fatal cancer risk = dose y accident frequency y 5.0 y 10-4 fatal cancer per rem (ICRP-60 conversion factor) if dose is less than 20 rem. For doses of 20 rem or more, the ICRP-60 conversion factor is doubled, or 1.0 y 10-3. Numbers in parentheses indicate total number of fatal cancers in the population if the accident occurs.

f. HFEF = Hot Fuel Examination Facility.

g. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from this accident could be less than the consequences from Accidents 2 through 4.

h. ICPP = Idaho Chemical Processing Plant.

i. Although three nuclear criticalities associated with spent nuclear fuel reprocessing activities have occurred at the INEL during its 40-year operating history, the estimated frequency for an inadvertent criticality is not based on historic reprocessing data since reprocessing is not considered under this alternative. Nominal frequency estimates vary from 1.0 y 10-4 (CPP-666 underwater storage facility) to 1.0 y 10-3 (CPP-603 underwater storage facility) events per year.

j. Refer to Sections 5.15.3.3 and 5.15.6.2 for details on why this frequency was not adjusted under this alternative.

k. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

5.15.4.3 Alternative 3: 1992/1993 Planning Basis. Under this alternative, the INEL could receive the following spent nuclear fuel:

- Spent nuclear fuel from domestic DOE and university reactors and foreign research test reactors
- All Training Reactor Isotopics General Atomics (TRIGA) spent nuclear fuel from foreign and Hanford reactors
- Fort St. Vrain spent nuclear fuel from Public Service Company of Colorado
- Special case commercial pressurized water reactor and boiling water reactor spent nuclear fuel from West Valley, New York
- Naval spent nuclear fuel from sites such as the Norfolk or Puget Sound Naval Shipyard.

Adjustments in estimated accident frequencies and point estimates of risk presented for Alternative 1 would be related to (1) the receipt, handling, and storage activities associated with the additional spent nuclear fuel inventories; and (2) the increase in overall spent fuel-related storage, relocation, and handling activities not allowed under Alternative 1. Because no changes in the accident consequences estimated for Alternative 1 are likely to occur under this alternative from increased fuel inventories (i.e., the same amount of radioactive material would accidentally be released to the environment as discussed in Section 5.15.3.3), no changes are likely in the postulated secondary impacts listed in Table 5.15-8. Table 5.15-10 summarizes the postulated accidents with the greatest radiological impacts under this alternative.

5.15.4.4 Alternative 4: Regionalization. Under this alternative, there are two primary Regionalization alternatives: (1) Alternative 4a (Regionalization by Fuel Type), where existing and spent nuclear fuel inventories will be distributed between the DOE sites based primarily on the similarity of fuel types, although DOE would also consider transportation distances, available stabilization capabilities, available storage capacities, or a combination of these factors; or (2) Alternative 4b (Regionalization by Geography), where existing and new spent nuclear fuel inventories in the western region of the country will be centralized at a single western site, and existing and new spent nuclear fuel inventories in the eastern region of the country will be centralized at a single eastern site.

a. Numbers in parentheses indicate multiplication factor used to scale or adjust estimated accident frequencies under Alternative 1, as described in Section 5.15.3.3.

b. A worker is defined as a worker located 100 meters (328 feet) from the point of release.

c. Public individual assumed to be stranded at the nearest point of public access inside the site boundary.

d. MEI = Maximally exposed hypothetical offsite individual located at the nearest site boundary.

e. Maximally exposed individual and offsite population fatal cancer risk = dose y accident frequency y 5.0 y 10-4 fatal cancer per rem (ICRP-60 conversion factor) if dose is less than 20 rem. For doses of 20 rem or more, the ICRP-60 conversion factor is doubled, or 1.0 y 10-3. Numbers in parentheses indicate total number of fatal cancers in the population if the accident occurs.

f. HFEF = Hot Fuel Examination Facility.

g. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from this accident could be less than the consequences from Accidents 2 through 4. However, given the high frequency for this accident compared to Accidents 2 through 4, the risk could actually be greater than for Accidents 2 through 4.

h. ICPP = Idaho Chemical Processing Plant.

i. Although three nuclear criticalities associated with spent nuclear fuel reprocessing activities have occurred at the INEL during its 40-year operating history, the estimated frequency for an inadvertent criticality is not based on historic reprocessing data since reprocessing is not considered under this alternative. Nominal frequency estimates vary from 1.0 y 10-4 (CPP-666 underwater storage facility) to 1.0 y 10-3 (CPP-603 underwater storage facility) events per year.

j. Refer to Sections 5.15.3.3 and 5.15.6.2 for details on why this frequency was not adjusted under this alternative.

k. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

5.15.4.4.1 Alternative 4a - Regionalization By Fuel Type - Adjustments in the estimated

accident frequencies and point estimates of risk presented for Alternative 1 would be related to

(1) the receipt, handling, and storage activities associated with the additional spent nuclear fuel inventories; and (2) the increase in overall spent nuclear fuel-related storage, relocation, and handling activities not allowed under Alternative 1.

Because no changes in the accident consequences estimated for Alternative 1 are likely to occur under this alternative from increased fuel inventories (i.e., the same amount of radioactive material would accidentally be released to the environment as discussed in Section 5.15.3.3), no changes are likely in the postulated secondary impacts listed in Table 5.15-8.

Table 5.15-11 summarizes the postulated accidents with the greatest radiological impacts under this alternative.

5.15.4.4.2 Alternative 4b - Regionalization by Geography - Under this alternative, spent

nuclear fuel inventories in the western region of the country would be centralized at either the INEL, Hanford Site, or Nevada Test Site.

Alternative 4b(1) considers regionalization at the INEL.

Alternative 4b(2) considers regionalization at the Hanford Site or Nevada Test Site.

5.15.4.4.2.1 Alternative 4b(1) - Regionalization by Geography (INEL) - Under

this alternative, existing and new spent nuclear fuel inventories in the western region of the country would be centralized at the INEL. Fuel stabilization would be performed in the Fluorinel and Storage (FAST) facility (CPP-666) and a new facility to be constructed, the Fuel Processing Restoration facility (CPP-691), to dissolve spent nuclear fuel and stabilize (i.e., immobilize) radionuclides.

Because the volume of spent nuclear fuel considered under this alternative is only slightly lower than that considered under Alternative 5b, adjustments in the estimated accident frequencies and point estimates of risk for the four accidents presented under Alternative 1 were conservatively considered equivalent to the adjustments required under Alternative 5b (i.e., centralization of all the DOE, Naval Nuclear Propulsion Program, university, and research reactor spent nuclear fuel in the country at the INEL). Adjustments in the estimated accident frequencies and point estimates of risk for the four accidents presented under Alternative 1 would be related to (1) the receipt, handling, and storage activities associated with the additional spent nuclear fuel inventories; and (2) the increase in overall spent nuclear fuel-related storage, relocation, and handling activities not allowed under Alternative 1.

Because no changes in the accident consequences estimated for Alternative 1 are likely to occur under this alternative from increased fuel inventories (i.e., the same amount of radioactive material would accidentally be released to the environment as discussed in Section 5.15.3.3), no changes are likely in the postulated secondary impacts listed in Table 5.15-8.

h. ICPP = Idaho Chemical Processing Plant.

i. Although three nuclear criticalities associated with spent nuclear fuel reprocessing activities have occurred at the INEL during its 40-year operating history, the estimated frequency for an inadvertent criticality is not based on historic reprocessing data since reprocessing is not considered under this alternative. Nominal frequency estimates vary from 1.0 y 10-4 (CPP-666 underwater storage facility) to 1.0 y 10-3 (CPP-603 underwater storage facility) events per year.

j. Refer to Sections 5.15.3.3 and 5.15.6.2 for details on why this frequency was not adjusted under this alternative.

k. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

Because the option exists to restart processing activities, three additional processing-related maximum reasonably foreseeable accidents are considered under this alternative (as discussed in Section 5.15.3.2). Since the amount of radioactive material that would accidentally be released to the environment from these accidents is expected to be lower than in Accidents 3 and 4 (i.e., small fuel melt and aircraft crash at the Hot Fuel Examination Facility, respectively), potential secondary impacts associated with these additional processing-related accidents would be less severe than those presented for the nonprocessing-related accidents in Table 5.15-8.

Table 5.15-12 summarizes the postulated accidents with the greatest radiological impacts under this alternative.

5.15.4.4.2.2 Alternative 4b(2) - Regionalization by Geography (Elsewhere) - Under this

alternative, existing and new spent nuclear fuel inventories in the western region of the country would be centralized at either the Hanford Site or Nevada Test Site. Similar to Alternative 5a, which considers centralization of existing INEL spent nuclear fuel inventories at another DOE site, the inventory of spent nuclear fuel at the INEL would be reduced substantially so that the only spent nuclear fuel at the INEL would consist of fresh fuel generated from operating INEL reactors that had not cooled sufficiently for relocation to the regionalized or centralized site. Therefore, this alternative considers the same amount of material considered under Alternative 1 until the regionalized site could accept existing inventories of INEL spent nuclear fuel and freshly generated spent nuclear fuel that has sufficiently cooled.

Table 5.15-13 summarizes the postulated accidents with the greatest radiological impacts under this alternative.

5.15.4.5 Alternative 5: Centralization. Under this alternative, DOE would collect all current and future spent nuclear fuel inventories from both DOE and the Naval Nuclear Propulsion Program at one site. For the INEL, there are two possibilities: (1) Alternative 5a, in which most spent fuel inventories and activities would take place at the Hanford Site, Savannah River Site, Nevada Test Site, or Oak Ridge Reservation; or (2) Alternative 5b, in which all spent fuel inventories and activities would be centralized at the INEL.

5.15.4.5.1 Alternative 5a: Centralization at Other DOE Sites - This alternative would consider approximately the same amount of material considered under Alternative 1 until the centralized site could accept existing INEL spent nuclear fuel inventories and freshly generated spent

h. ICPP = Idaho Chemical Processing Plant.

i. Although three nuclear criticalities associated with spent nuclear fuel reprocessing activities have occurred at the INEL during its 40-year operating history, the estimated frequency for an inadvertent criticality is not based on historic reprocessing data since reprocessing is not considered under this alternative. Nominal frequency estimates vary from 1.0 y 10-4 (CPP-666 underwater storage facility) to 1.0 y 10-3 (CPP-603 underwater storage facility) events per year.

j. Refer to Sections 5.15.3.3 and 5.15.6.2 for details on why this frequency was not adjusted under this alternative.

k. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

fuel that had cooled sufficiently. On demonstration of the centralized site's capability to receive INEL spent nuclear fuel, the inventory of spent fuel at the INEL would be reduced substantially so that the only spent nuclear fuel at the INEL would consist of fresh fuel generated from operating INEL reactors that had not cooled sufficiently for relocation to the centralized site.

Adjustments in estimated accident frequencies and point estimates of risk presented for Alternative 1 would be related to (1) the receipt, handling, and storage activities associated with the additional spent nuclear fuel inventories; and (2) the increase in overall spent fuel-related storage, relocation, and handling activities not allowed under Alternative 1. Because no changes in the accident consequences estimated for Alternative 1 are likely to occur under this alternative from increased fuel inventories (i.e., the same amount of radioactive material would accidentally be released to the environment as discussed in Section 5.15.3.3), no changes are likely in the postulated secondary impacts presented in Table 5.15-8. Table 5.15-14 summarizes the postulated accidents with the greatest radiological impacts under these alternatives.

5.15.4.5.2 Alternative 5b: Centralization at the INEL - Adjustments in estimated

accident frequencies and point estimates of risk presented for Alternative 1 would be related to (1) the receipt, handling, and storage activities associated with the additional spent nuclear fuel inventories; and (2) the increase in overall spent nuclear fuel-related storage, relocation, and handling activities not allowed under Alternative 1.

Because no changes in the accident consequences estimated for Alternative 1 are likely to occur under this alternative from increased fuel inventories (i.e., the same amount of radioactive material would accidentally be released to the environment as discussed in Section 5.15.3.3), no changes are likely in the postulated secondary impacts presented in Table 5.15-8.

Table 5.15-15 summarizes the postulated accidents with the greatest radiological impacts under this alternative.

Because the option exists to restart processing activities, three additional processing-related maximum reasonably foreseeable accidents are considered under this alternative (as discussed in **Section 5.15.3.2).** Since the amount of radioactive material that would accidentally be released to the environment from these accidents is expected to be lower than Accidents 3 and 4 (i.e., small fuel melt and aircraft crash at the Hot Fuel Examination Facility, respectively), potential secondary impacts associated with these additional processing-related accidents would be less severe than those presented for the nonprocessing-related accidents in Table 5.15-8.

a. Numbers in parentheses indicate multiplication factor used to scale or adjust estimated accident frequencies under Alternative 1, as described in Section 5.15.3.3.

b. A worker is defined as a worker located 100 meters (328 feet) from the point of release.

c. Public individual assumed to be stranded at the nearest point of public access inside the site boundary.

d. MEI = Maximally exposed hypothetical offsite individual located at the nearest site boundary.

e. Maximally exposed individual and offsite population fatal cancer risk = dose y accident frequency y 5.0 y 10-4 fatal cancer per rem (ICRP-60 conversion factor) if dose is less than 20 rem. For doses of 20 rem or more, the ICRP-60 conversion factor is doubled, or 1.0 y 10-3. Numbers in parentheses indicate total number of fatal cancers in the population if the accident occurs.

f. HFEF = Hot Fuel Examination Facility.

g. The safety analysis report utilized for this accident analysis does not provide this information because it was developed prior to DOE Orders requiring this information. As demonstrated by the dose to the maximally exposed individual, consequences to the public from this accident could be less than the consequences from Accidents 2 through 4. However, given the high frequency for this accident compared to Accidents 2 through 4, the risk could actually be greater than for Accidents 2 through 4.

h. ICPP = Idaho Chemical Processing Plant.

i. Although three nuclear criticalities associated with spent nuclear fuel reprocessing activities have occurred during the 40-year operating history of CPP-666, the estimated frequency for an inadvertent criticality in this facility is based on existing spent nuclear conditions and fuel vulnerabilities. Nominal estimates vary from 1.0 y 10-4 (CPP-666 underwater storage facility) to 1.0 y 10-3 (CPP-603 underwater storage facility) events per year.

j. Refer to Sections 5.15.3.3 and 5.15.6.2 for details on why this frequency was not adjusted under this alternative.

k. This frequency is a qualitative bounding estimate for a potential aircraft crash, as discussed in Section 5.15.6.4.

l. The Idaho Chemical Processing Plant has experienced three inadvertent nuclear criticalities during its operating history, the last one 14 years ago. This frequency is based on modern facility conditions and safeguards that exist at CPP-666.

m. The safety analysis report utilized for this accident does not provide this information because it was developed prior to DOE Order 5480.23 requiring this information. However, a comparison of the data presented for this accident to the other accidents provides a relative measure of the impacts to this receptor.

5.15.5 Impacts from Postulated Maximum Reasonably Foreseeable Toxic Material Accidents

Like radioactive materials, toxic materials (e.g., chemicals) are involved in a variety of operations, including spent nuclear fuel-related activities, at the INEL. As a result of these operations and activities, the potential exists for releases of toxic materials to the environment from the same types of initiators considered in determining the radiological accident scenarios discussed in Section 5.15.4. This section summarizes analyses of postulated accident scenarios associated with spent nuclear fuel activities that could result in the release of toxic materials from their confinements.

5.15.5.1 Identification of Toxic Chemicals at the INEL. The facilities at the INEL use

many types and quantities of chemically toxic materials. To determine the spent fuel-related chemicals that exist in sufficient quantities to present health effects to workers or the offsite population, DOE performed an initial screening of the chemical inventories at the INEL. This screening consisted of identifying those hazardous chemicals at the INEL listed in the Superfund Amendments and Reauthorization Act of 1986 (SARA) 312 Report for 1992 (Priestly 1992) that (1) exist in bulk quantities [assumed to be greater than 227 kilograms (500 pounds)]; or (2) exceed reportable quantities [usually 0.45 kilogram (1 pound)] on the EPA Title III List of Lists (EPA 1990), which includes hazardous chemicals defined in the following:

- SARA Section 302, Extremely Hazardous Substances (40 CFR Part 355, Appendixes A and B, List of Extremely Hazardous Substances and Their Threshold Planning Quantities) (CFR 1993)
- Comprehensive Environmental Response, Compensation, and Liability Act Hazardous

Substances (40 CFR Part 302, Table 302.4, Lists of Hazardous Substances and Reportable Quantities) (CFR 1992a)

- SARA Section 313, Toxic Chemicals (CFR 1992b)
- Federal Register list of 100 extremely hazardous chemicals (FR 1994)

5.15.5.2 Selection of Spent Nuclear Fuel-Related Toxic Chemicals Requiring

Accident Analysis. As indicated by the screening methodology discussed above, toxic chemical inventories are located throughout INEL facilities in varying quantities and are involved in nearly all operations and activities performed by INEL facilities, including spent nuclear fuel-related activities. The screening identified no toxic chemicals associated with the dry storage of spent nuclear fuel. Except for processing-related activities that could be performed under the Regionalization and Centralization at INEL alternatives [i.e., Alternatives 4b(1) and 5b, respectively], the screening identified activities associated with the underwater storage of spent nuclear fuel (e.g., maintaining water chemistry) as the only spent nuclear-fuel related activities that might utilize toxic chemicals in sufficient quantities to present a potential for health effects to workers or the offsite population, or potential contamination of the environment. For Alternatives 4b(2) and 5a, in which DOE would relocate INEL spent nuclear fuel inventories and related activities to other DOE sites, the existing toxic chemical inventories at the INEL would be expected to slightly decrease. For Alternatives 4b(1) and 5b, in which the INEL could potentially resume processing activities, a substantial increase in existing chemical inventories, primarily hydrofluoric acid and anhydrous ammonia, would be expected. No substantial changes in existing spent nuclear fuel-related toxic chemical inventories would be expected under Alternatives 1, 2, or 3.

To demonstrate how the consequences of the same accident at an identical hypothetical facility constructed at the Hanford Site or the Savannah River Site under this alternative would compare to the INEL (based on local geological and meteorological conditions), Appendix D summarizes postulated accident scenarios for a new Expended Core Facility that DOE could construct at any of the sites considered in this EIS.

To determine potential accident scenarios associated with handling or storing toxic chemicals at the various spent nuclear fuel-related facilities, DOE performed an extensive review of existing safety analyses and walkdowns of various facilities. This review identified two nonprocessing-related toxic chemicals at the Idaho Chemical Processing Plant - nitric acid and chlorine - as requiring further evaluation to determine potential health effects to workers and the offsite population. Additionally, two toxic chemicals that would be required to support the resumption of processing activities at the Idaho Chemical Processing Plant - hydrofluoric acid and anhydrous ammonia - were identified as requiring further evaluation(6). Although spent fuel-related facilities at the Idaho Chemical Processing Plant use several other toxic chemicals (e.g., oxalic acid), the quantities of these chemicals are not sufficient to present an impact to workers or the environment from accidental releases to the environment. (For postulated accident scenarios involving Naval spent nuclear fuel-related activities at the INEL, refer to Appendix D.)

Because DOE determined that it needed to evaluate postulated toxic chemical accidents at the Idaho Chemical Processing Plant as part of this EIS, it did not consider postulated toxic chemical

---

6. Although bulk quantities of nitric acid would be required to perform processing activities that could be resumed Alternatives 4b(1) and 5b, the consequences of processing-related accidents involving nitric acid would be bounded by the hydrofluoric acid and anhydrous accidents analyzed in Sections 5.15.3.3. and 5.15.3.4., respectively. Therefore, this analysis focuses on a potential nitric acid accident resulting from the nonprocessing spent nuclear fuel-related activities considered under the other alternatives.

accidents at the Advanced Test Reactor Storage Canal and the Hot Fuel Examination Facility that could be involved in spent fuel-related activities(7) for further evaluation in this EIS for the following reasons:

- In general, quantities of spent nuclear fuel-related chemicals at the Idaho Chemical Processing Plant are substantially greater than those at the Advanced Test Reactor Storage Canal and Hot Fuel Examination Facility.
- The Idaho Chemical Processing Plant is located approximately 1,000 meters (1,094 yards) closer to the nearest site boundary than the Advanced Test Reactor.

Based on a review of safety documentation for the Test Area North spent nuclear fuel underwater storage facility and discussions with facility personnel, DOE determined that none of the toxic chemicals identified in the screening (Section 5.15.5.1) is related to spent fuel handling or storage activities.

5.15.5.3 Toxic Chemical Accident Analysis. For chemically toxic materials, several government agencies recommend quantifying health effects that cause short-term effects as threshold values of concentrations in air or water. The long-term health consequences of human exposure to toxic materials are not as well understood as the long-term health consequences related to radiation exposure. Thus, the potential health effects for exposures to toxic chemicals are more subjective than those for radioactive materials. Factors such as receptor locations, terrain, meteorological conditions, release conditions, and characteristics of chemical inventories are required parameters for determinations of airborne concentrations of toxic chemicals at various distances from a postulated point of release.

EPICodeTM was used to estimate airborne concentrations resulting from spent nuclear fuel-related toxic chemical releases at the INEL. [For a detailed description of EPICodeTM, refer to Slaughterbeck et al. (1995).]

To determine the potential health effects from accidental releases of toxic chemicals, this analysis compared the concentrations determined by EPICodeTM against Emergency Response Planning Guideline values, where available. These values, which are specific for each substance, are related to three general severity levels:

- Exposure to concentrations greater than Emergency Response Planning Guideline-1 values for a period of time greater than 1 hour results in an unacceptable likelihood that a person would experience mild transient adverse health effects, or perception of a clearly defined objectionable odor.
- Exposure to concentrations greater than Emergency Response Planning Guideline-2 values for a period of time greater than 1 hour results in an unacceptable likelihood that a person would experience or develop irreversible or other serious health effects, or symptoms that could impair one's ability to take protective action.
- Exposure to concentrations greater than Emergency Response Planning Guideline-3 values for a period of time greater than 1 hour results in an unacceptable likelihood that a person would experience or develop life-threatening health effects.

If there were no Emergency Response Planning Guideline values for a toxic substance, the analysis substituted other chemical toxicity values, as follows:

- Threshold limit values/time-weighted average values (ACGIH 1988) substituted for Emergency Response Planning Guideline-1. This is the time-weighted average concentration for a normal 8-hour workday and a 40-hour workweek to which nearly all workers could be repeatedly exposed, day after day, without adverse effect.
- Level of concern values (equal to 0.1 of the immediately dangerous to life or health values - see below) substituted for Emergency Response Planning Guideline-2. The level of concern value is the concentration of a hazardous substance in the air above which there might be

---

7. The scope of this analysis has been restricted to the Advanced Test Reactor fuel storage canal. Everything inside the reactor gas-tight boundary and associated with reactor operations has been excluded from consideration because reactor operations are not related to the spent nuclear fual activities considered in this EIS.

serious irreversible health effects or death as a result of a single exposure for a relatively short period of time.

- Immediately dangerous to life or health values are substituted for Emergency Response Planning Guideline-3. The immediately dangerous to life or health value is the maximum concentration from which a person could escape within 30 minutes without a respirator and without experiencing any impairment of escape or irreversible side effects (NIOSH 1990).

As stated in the above section, four toxic chemicals - chlorine, nitric acid, hydrofluoric acid, and anhydrous ammonia - at the Idaho Chemical Processing Plant were identified as requiring further evaluation to estimate potential health effects to workers and the public. The following sections summarize the analyses performed for these chemicals.

5.15.5.3.1 Accidental Chlorine Release - Chlorine, while not directly associated with spent nuclear fuel-related activities at the INEL, is used to treat drinking water supplies at the various spent fuel facilities. Therefore, an analysis of a postulated accidental chlorine release at the Idaho Chemical Processing Plant was performed to determine potential impacts on workers operating the spent fuel-related facilities.

At the Idaho Chemical Processing Plant, chlorine is contained in two pressurized bottles [65 atmospheres at 20yC (68yF)], a 68-kilogram (150-pound) bottle and a 55-kilogram (120-pound) bottle, totaling 123 kilograms (270 pounds). To be conservative, DOE assumed that a breach of the drain line causes an instantaneous release of the total inventory of both tanks. The highest chlorine concentrations at the receptor locations would result from the largest release over the shortest time period. Therefore, the release duration was assumed to be approximately 5 minutes.

An accidental chlorine release from one of the chlorine tanks could be initiated by one of several events, such as a handling event, piping or valve rupture, or human error. Because the two tanks are physically separated, an accidental simultaneous release from both tanks would require a common initiator such as a delivery accident, a common maintenance failure, or a natural phenomena event (e.g., seismic) that damaged or punctured both tanks. The frequency of an accidental release from one pressurized tank is 1.0 y 10-4 event per year (EPA/FEMA/DOT 1987). A common cause failure resulting in the release of chlorine from two separated tanks is assumed to be no greater than 5 percent of the time given for the first tank failure. Therefore, the estimated frequency of an accidental release from both tanks is 5.0 y 10-6 events per year (with no credit taken for pressure vessel management and training).

Table 5.15-16 summarizes the concentrations of the subject chlorine release at the following receptor locations: a facility worker, a member of the public stranded at the nearest point of public access inside the INEL boundary, and a maximally exposed hypothetical member of the public located at the nearest site boundary. As listed in Table 5.15-10, the peak chlorine concentrations for facility workers could result in life-threatening health effects (i.e., Emergency Response Planning Guideline-3 values are exceeded) for both conservative (95 percentile) and average (50 percentile) meteorological conditions.

Table 5.15-16. Summary of chemical concentrations for postulated nonprocessing-related accidental releases at the Idaho Chemical Processing Plant under Alternatives 1 through 5.

Receptor Location	Chemical Concentrations (milligrams per cubic meter)a			
	95% Meteorologyb		50% Meteorologyc	
	Chlorine	Nitric Acide	Chlorine	Nitric Acide
	ERPG-1d = 3 (1)	TWA = 5.2 (2)	ERPG-1 = 3 (1)	TWA = 5.2 (2)
	ERPG-2 = 9 (3)	LOC = 25.5 (10)	ERPG-2 = 9 (3)	LOC = 25.5 (10)
	ERPG-3 = 60 (20)	IDLH = 255 (100)	ERPG-3 = 60 (20)	IDLH = 255 (100)
1. Worker located at 100 meters (325 feet).	84,000 (28,000)	250 (95)	1,620 (540)	33 (13)

2. Nearest point of public access where a member of the public is assumed stranded at the time of the release.f	19.5 (6.5)	0.32 (0.12)	1.89 (0.63)	0.049 (0.019)
3. Maximally exposed hypothetical individual located at the nearest site boundary.g	4.2 (1.4)	0.12 (0.047)	0.42 (0.14)	0.016 (0.006)

a. Numbers in parentheses reflect concentrations in parts per million.
b. The 95 percentile meteorology is based on Class F (unfavorable) meteorological conditions with 0.5 meter per second (1.1 miles per hour) wind speed for receptors located within 2 kilometers (1.2 miles) of the release and 2 meters per second (4.5 miles per hour) for receptors beyond 2 kilometers of the release.
c. The 50 percentile meteorology is based on Class D (typical) meteorological conditions with 4.5 meters per second (10 miles per hour) wind speed for all receptors.
d. ERPG = Emergency Response Planning Guidelines.
e. Because Emergency Response Planning Guideline values are not available for nitric acid, time-weighted average values are substituted for ERPG-1 values, level of concern values are substituted for ERPG-2 values, and immediately dangerous to life or health values are substituted for Emergency Response Planning Guideline-3 values. Refer to Section 5.15.5.3 for further information regarding the use of these values.
f. The nearest point of public access from this postulated release is 5,870 meters (6,419 yards).
g. The nearest site boundary is located at 14,000 meters (15,310 yards).

Peak chlorine concentrations estimated at the nearest point of public access can exceed the Emergency Response Planning Guideline-2 value assuming 95 percentile meteorological conditions, as listed in Table 5.15-10. Symptoms associated with exposure to these concentrations could include burning of the eyes, nose, and throat, coughing, choking, and possibly skin burns.

As listed in Table 5.15-16, the estimated peak averaged chlorine concentration at the nearest site boundary would be above the Emergency Response Planning Guideline-1 value for 95 percentile meteorological conditions. However, due to the nature of the release, this concentration probably would not last for more than a few minutes. Therefore, it would be likely that individuals at this distance would experience no more than mild transient adverse health effects.

This analysis took limited credit for emergency response actions following a chlorine release in calculating the concentrations listed in Table 5.15-16. To mitigate the consequences of a chlorine release to the environment, the same emergency response programs and actions described for radiological accident scenarios (Section 5.15.4.1) would be initiated following the release. Therefore, actual health effects experienced by persons inside the site boundary would realistically be less than the values listed in Table 5.15-16.

Because the estimated airborne concentration of chlorine at 100 meters (328 feet) substantially exceeds the guidelines listed in Table 5.15-16, workers could be fatally injured or could receive long-term or permanent health effects. Potential secondary impacts associated with the chlorine accident scenario would involve economic impacts such as workers' compensation, medical bills, and potential lawsuits. No other secondary impacts, such as impacts on national defense or biotic resources, were identified.

5.15.5.3.2 Accidental Nitric Acid Release - Nitric acid is used at various spent

nuclear fuel-related storage facilities for maintaining the chemistry of the water used in underwater storage facilities(8).
Based on the toxic chemical screening discussed in Section 5.15.5.1, review of existing safety analyses, walkdowns of spent nuclear fuel-related facilities, and interviews with INEL

---

8. Although bulk quantities of nitric acid would be required to perform processing activities that

could be resumed under Alternatives 4b(1) and 5b, the consequences of processing-related accidents
involving nitric acid would be bounded by the hydrfluoric acid and anhydrous accidents analyzed in Sections 5.15.5.3.3. and 5.15.5.3.4., respectively. Therefore, this analysis focuses on a potential nitric acid accident resulting from the non-processing spent nuclear fuel-related activities considered under the other alternatives.

---

personnel, DOE determined that the potential exists for an accidental release of nitric acid from one of two 1,135 liters (300-gallon) storage tanks used to support spent nuclear fuel-related water treatment activities at the Idaho Chemical Processing Plant. Because one of the tanks is usually empty, the two tanks have separate valves, and they are physically separated, DOE could not identify a reasonably likely initiator that could cause an accidental simultaneous release from both tanks.

The quantity of nitric acid assumed available for release from a single initiator would be (1,135 liters) 300 gallons. The following assumptions were made for this analysis:

- An initiating event causes severe structural damage (e.g., large puncture) to one of the tanks.
- The entire inventory of nitric acid is released into the containment wall surrounding the storage tank.
- The area of the containment wall is approximately 28 square meters (300 square feet).
- The total release of nitric acid [i.e., 1.135 liters (300 gallons)] evaporates into the atmosphere before the implementation of emergency response procedures can recover the nitric acid.

Table 5.15-16 summarizes the concentrations of the nitric acid release at the following receptor locations for both conservative (95 percentile) and average (50 percentile) meteorological conditions:
a facility worker, a member of the public stranded at the nearest point of public access inside the INEL boundary, and a maximally exposed hypothetical member of the public at the nearest site boundary. The estimated frequency for this event is 1 y 10-5 events per year.

This analysis took limited credit for emergency response actions following a nitric acid release in calculating the concentrations listed in Table 5.15-16. To mitigate the consequences of a release to the environment, the same emergency response programs and actions described for radiological accident scenarios (Section 5.15.4.1) would be initiated following a nitric acid release. Therefore, actual health effects experienced by persons inside the site boundary would realistically be less than the values listed in Table 5.15-16.

Other than limited economic secondary impacts, no other secondary impacts would be likely if this accident occurred.

5.15.5.3.3 Accidental Hydrofluoric Acid Release - To resume spent nuclear fuel

processing activities at the Fluorinel and Storage (FAST) facility (CPP-666), which is currently shutdown and being placed in a permanent shutdown mode, bulk quantities of hydrofluoric acid would be required to support the dissolution process.
A hydrofluoric acid storage tank with an operating capacity of approximately 30,283 liters (8,000 gallons) is located in the Idaho Chemical Processing Plant facility area to support processing activities, although only 11,356 liters (3,000 gallons) of hydrofluoric acid remain in the tank, and efforts are currently underway to remove the remaining hydrofluoric acid in the tank from the INEL site.

Table 5.15-17 summarizes the potential impacts upon a maximally exposed hypothetically offsite individual located at the nearest site boundary [14,000 meters (15,310 yards)] resulting from a potential hydrofluoric acid release at the Idaho Chemical Processing Plant assuming 95 percentile meteorological conditions. Slaughterbeck et al. (1995) provides further details and discussion regarding this postulated accident scenario. Although Slaughterbeck et al. (1995) presents impacts to only the maximally exposed offsite hypothetical individual resulting from this postulated accident for 95 percentile meteorological conditions, a comparison of the airborne concentration of hydrofluoric acid at 14,000 meters (15,310 yards) to the airborne concentrations from other postulated chemical accident scenarios (as presented in Table 5.15-16) at the same receptor distance provides meaningful perspective on the significance of this accident.

Table 5.15-17. Summary of chemical concentrations for postulated processing-related accidental releases at the Idaho Chemical Processing Plant under Alternatives 4b(1) and 5b.

	Chemical Concentrations (milligrams per cubic meter)a	
	95% Meteorologyb	
	Hydrofluoric Acid	Anhydrous Ammonia
Receptor Location	ERPG-1c = 4 (5) ERPG-2 = 17 (20) ERPG-3 = 43 (50)	ERPG-1 = 17 (25) ERPG-2 = 136 (200) ERPG-3 = 680 (1000)
Maximally exposed hypothetical individual located at the nearest boundaryd	0.078 (0.09)	82 (120.6)

a. Numbers in parentheses reflect concentrations in parts per million.
b. The 95 percentile meteorology is based on Class F (unfavorable) meteorological conditions with 0.5 meter per second (1.1 miles per hour) wind speed for receptors located within 2 kilometers (1.2 miles) of the release and 2 meters per second (4.5 miles per hour) for receptors beyond 2 kilometers of the release.
c. ERPG = Emergency Response Planning Guidelines.
d. The nearest site boundary is located at 14,000 meters (15,310 yards).

The estimated frequency for this event is 1 y 10-5 events per year. It should be noted that this potential accident applies only to Alternatives 4b(1) and 5b, and is in addition to the potential chlorine and nitric acid release accidents described in Sections 5.15.5.3.1 and 5.15.5.3.2, respectively.

This analysis took limited credit for emergency response actions following a hydrofluoric acid release in calculating the concentrations listed in Table 5.15-17. To mitigate the consequences of a release to the environment, the same emergency response programs and actions described for radiological accident scenarios (Section 5.15.4.1) would be initiated following a hydrofluoric acid release. Therefore, actual health effects experienced by persons inside the site boundary would realistically be less than the values listed in Table 5.15-17.

Other than limited economic secondary impacts, no other secondary impacts would be likely if this accident occurred.

5.15.5.3.4 Accidental Anhydrous Ammonia Release - To resume spent nuclear

fuel processing activities at the Fluorinel and Storage (FAST) facility (CPP-666), bulk quantities of anhydrous ammonia would be required to support operation of the NOx-Abatement Facility (CPP-1670), a facility that would be constructed to treat airborne effluents from the INEL processing facilities before being released to the environment.

The NOx-Abatement Facility would be expected to utilize two anhydrous ammonia tanks, each with a storage capacity of 68,000 liters (18,000 gallons). Table 5.15-17 summarizes the potential impacts upon the maximally exposed hypothetical offsite individual located at the nearest site boundary [14,000 meters (15,310 yards)] resulting from a short-term release of the contents of both storage tanks [i.e., 136,000 liters (36,000 gallons)] at the Idaho Chemical Processing Plant assuming 95 percentile meteorological conditions. Slaughterbeck et al. (1995) provides further details and discussion regarding this postulated accident scenario. Although Slaughterbeck et al. (1995) presents only impacts to the maximally exposed offsite hypothetical individual resulting from this postulated accident for 95 percentile meteorological conditions, a comparison of the airborne concentration of anhydrous ammonia at 14,000 meters (15,310 yards) to the airborne concentrations from other postulated chemical accident scenarios (as presented in Table 5.15-16) at the same distance provides meaningful perspective on the significance of this accident.

The estimated frequency for this event is 5 y 10-6 events per year. The basis for this estimated frequency is identical to that described for an accidental chlorine release from two separate tanks, as described in Section 5.15.5.3.1. It should be noted that this potential accident applies only to Alternatives 4b(1) and 5b, and is in addition to the potential chlorine and nitric acid release accidents described in Sections 5.15.5.3.1 and 5.15.5.3.2, respectively.

This analysis took limited credit for emergency response actions following an anhydrous ammonia release in calculating the concentrations listed in Table 5.15-17. To mitigate the consequences of a release to the environment, the same emergency response programs and actions described for radiological accident scenarios (Section 5.15.4.1) would be initiated following a hydrofluoric acid release. Therefore, actual health effects experienced by persons inside the site boundary would realistically be less than the values listed in Table 5.15-17.

Other than limited economic secondary impacts, no other secondary impacts would be likely if this accident occurred.

5.15.6 Maximum Reasonably Foreseeable Radiological Accident Scenario Descriptions

The purpose of this section is to summarize the different accident scenarios identified in Section 5.15.4. The Facility Safety Report for the Argonne National Laboratory-West Hot Fuel Examination Facility (ANL 1975) contains further details and discussions for Accident 1, discussed below. Slaughterbeck et al. (1995) provides further details, discussions, and references for Accidents 2 through 7, discussed below. Additional discussions and references regarding the processing-related accidents summarized in this section are also provided in a study performed to determine the potential impacts spent nuclear fuel processing-related accidents could have on the siting of a new production reactor at the INEL (EG&G 1993b). These documents contain additional information, such as release fractions, source terms, and other assumptions used in the accident analyses. Appendix D describes postulated accident scenarios associated with Naval spent nuclear fuel-related facilities and activities at the INEL.

5.15.6.1 Accident 1: Fuel Pin Breach and Venting of Noble Gases and Iodine to

the Environment from a Mechanical Handling Accident at the Argonne National Laboratory-West Hot Fuel Examination Facility. The accident screening methodology discussed in Section 5.15.3 identified a mechanical handling event at the Argonne National Laboratory-West Hot Fuel Examination Facility as an initiator to the maximum reasonably foreseeable accident within the abnormal event frequency range. This event would result in a fuel pin breach and venting of noble gases and iodine to the environment. The identification of this accident as a maximum reasonably foreseeable accident is based on the estimated radiological consequences to the maximally exposed hypothetical offsite individual at the nearest site boundary presented in the Hot Fuel Examination Facility Safety Report (ANL 1975). Other postulated accidents associated with handling spent nuclear fuel in the Hot Fuel Examination Facility before the identification of the fuel pin breach accident as the maximum reasonably foreseeable accident included an inadvertent criticality and a sodium fire. A fuel pin breach accident was chosen as the maximum reasonably foreseeable accident because the estimated frequencies for an inadvertent criticality and a sodium fire in the facility are extremely low (ANL 1975).

The analyses defined in the Facility Safety Report (ANL 1975) made the following assumptions:

- The fuel subassemblies and experimental capsules being examined in the facility were cooled for at least 15 days to ensure that the short-lived fission products had decayed.
- The noble gases and iodines that could be released from this accident scenario were immediately released.
- One hundred percent of the noble gases, 25 percent of the iodines, and 1 percent of particulates were available for escape to the atmosphere.
- The building containment structure, including the building ventilation system, and the Main Cell, including the argon ventilation system, remained operational following the handling accident. This assumption is considered appropriate because the mechanical handling accident scenario under consideration would not initiate a failure in these systems. (Accident 3 considers the simultaneous failure of all these systems in conjunction with the melting of fuel assemblies stored in the facility).

The Facility Safety Report (ANL 1975) contains specific information on the source terms associated with breaching the fuel section of a pin. Because that report does not provide an estimated frequency of occurrence for the subject mechanical handling accident scenario, the analysis used historic information and engineering judgment to determine the conservatively estimated frequency for this accident of 1.0 y 10-2 event per year.

For determining the impacts from this postulated accident scenario, the nearest point of public access is equivalent to the nearest site boundary, which is 5,240 meters (5,730 yards) from the point of the release. Although the Facility Safety Report (ANL 1975) does not estimate consequences to the offsite population resulting from this accident scenario, this analysis reasonably estimated that the exposures (i.e., dose) to the offsite population would be less than the offsite population dose calculated for Accidents 2 through 4 because the dose to the maximally exposed hypothetical individual at the nearest site boundary from this accident would be less than that estimated for Accidents 2 through 4.

5.15.6.2 Accident 2: Inadvertent Nuclear Chain Reaction in Wet Spent Nuclear

Fuel Storage (1 y 1019 fissions, 8-hour release) at the Idaho Chemical Processing Plant CPP-603 Underwater Fuel Storage Facility. The accident screening methodology discussed in Section 5.15.3 identified an inadvertent nuclear criticality associated with underwater spent nuclear fuel storage at the CPP-603 Underwater Fuel Storage Facility as an accident requiring further evaluation.

Other postulated accidents that were considered before the identification of an inadvertent criticality accident as a maximum reasonably foreseeable accident included pool leaks, fuel damage events, and loss of cooling events. This analysis selected an inadvertent nuclear criticality for evaluation in this EIS over the other accidents for the following reasons:

- Postulated inadvertent nuclear criticality accidents have been addressed in virtually all DOE nonreactor EISs and safety analysis reports in which such accidents were reasonably foreseeable because of public concerns regarding the potential for these accidents.
- The Idaho Chemical Processing Plant has experienced three inadvertent nuclear criticality accidents. Although none of these accidents involved a fuel storage facility, they demonstrate the potential and concern for such events.
- The consequences of water leakage from a pool-draining event would present lower prompt consequences to workers than a criticality because the INEL could implement emergency response plans to evacuate workers before the risk to these workers could substantially increase. In addition, a pool drain was considered to be an initiator to a criticality accident.
- Mechanical fuel damage events are less impacting than a nuclear chain reaction scenario because some degree of fuel damage is part of the criticality accident scenario and analysis.

Of the different Idaho Chemical Processing Plant facility areas that store spent nuclear fuel, the CPP-603 Underwater Fuel Storage Facility was selected for analysis of a criticality accident for the following reasons:

- CPP-603 facility storage includes most types of spent nuclear fuel stored elsewhere on the site. Fuel stored at reactor basins is an exception (but was considered in the determination of other reasonably foreseeable accident scenarios) because of its much shorter cooling times after removal from a reactor.
- CPP-603 facility spent nuclear fuel storage quantities are comparable to or exceed the spent nuclear fuel inventories stored elsewhere on the site.
- The CPP-603 facility is an older facility that does not contain all the preventive or mitigative design features found in more modern facilities, such as the CPP-666 Fuel Storage Area.

The analysis selected the underwater fuel storage portion of the CPP-603 facility rather than the Irradiated Fuels Storage Facility portion of the CPP-603 facility because accidents involving graphite fuels in dry storage probably would have less severe potential consequences because they had been removed from reactors for a much longer period of time and, because of their design, would prevent most of the remaining fission products from being released if a criticality accident occurred.

Initiating events that the analysis considered possible to lead to an inadvertent nuclear criticality included operator error, hanger corrosion, equipment failure, an earthquake, pool drain, and an aircraft crash. The scenario discussed in this EIS assumes a postulated criticality scenario that could be initiated by human error, equipment failure, or earthquake. Heat generated from the chain reaction would easily dissipate and thereby avoid fuel melting but would still cause the release of fission products associated with 1 y 1019 fissions over an 8-hour period.

Between 1945 and 1980, 40 known inadvertent criticalities occurred worldwide, none of which involved the handling or storage of spent nuclear fuel in an underwater fuel storage facilities. In addition, between 1975 and 1980, there were 160 nuclear power reactor facilities with underwater fuel storage facilities worldwide. None of these facilities ever had a nuclear criticality associated with its underwater storage facilities. Therefore, it is generally assumed that the likelihood for such an event in a modern underwater storage facility is unlikely, with a frequency estimated at 1 y 10-4 event per year. This estimated frequency is supported by information in the safety analysis report for the CPP-666 underwater storage facility, which is a modern facility (e.g., 1980s vintage) at the INEL used to store various types of spent nuclear fuel. In the CPP-603 Underwater Fuel Storage Facility, however, where spent nuclear fuel inventories have substantially corroded or degraded (DOE 1993c), and where the design of the facility and its supporting equipment do not meet current design specifications, activities associated with handling and storing spent nuclear fuel present an increase in the likelihood for an inadvertent nuclear criticality accident by as much as an order of magnitude. Therefore, this analysis conservatively assumes the estimated frequency for an inadvertent nuclear criticality associated with handling spent nuclear fuel in the CPP-603 Underwater Fuel Storage Facility to be 1 y 10-3 event per year for this analysis.

The handling activities associated with stabilizing CPP-603 facility spent nuclear fuel inventories would occur under each of the five alternatives considered in this EIS. The estimated frequency for an inadvertent criticality at the CPP-603 facility is an order of magnitude larger than that of any other INEL facility (e.g., 1 y 10-3 event per year), and is considered a "worst-case" frequency that bounds changes in estimated criticality frequencies at other INEL facilities resulting from increased handling activities associated with changes in spent nuclear fuel inventories. Therefore, using the estimated criticality frequency related to the CPP-603 as the estimated frequency under each alternative provides a conservative bound on the estimated criticality frequencies for other spent nuclear fuel-related handling and storage facilities.

To determine the accident impacts from this postulated accident scenario, the analysis assumed the worker to be located 100 meters (328 feet) from the event, the nearest point of public access (U.S. Route 20/26) is 5,870 meters (6,420 yards), and the nearest site boundary is located at 14,000 meters (15,310 yards).

5.15.6.3 Accident 3: Earthquake-Induced Breach and Fuel Melt at the Argonne

National Laboratory-West Hot Fuel Examination Facility. The accident screening methodology discussed in Section 5.15.3 identified an earthquake-induced breach and fuel melt at the Argonne National Laboratory-West Hot Fuel Examination Facility as a maximum reasonably foreseeable accident that would present higher radiological consequences to facility workers or the offsite population than other postulated accidents analyzed in the same accident frequency range. The postulated events leading to atmospheric release of radionuclides are as follows:

- The earthquake results in a peak horizontal ground acceleration of sufficient magnitude to cause structural damage to the building structure and a large breach in the main cell.9
- Coincident with the breach, a failure of the fuel subassembly cooling system occurs, resulting in the melting of fresh assemblies.
- Radionuclides from the melting fuel subassemblies are released to the atmosphere.

The estimated probability of an earthquake in the Argonne National Laboratory-West facility area resulting in a peak horizontal acceleration of sufficient magnitude to damage the facility structure and breach the cell is 1 y 10-5 event per year. This analysis conservatively assumes the probability of failure of the building structure, Main Cell, and subassembly cooling to be 1.0, given that the earthquake has occurred. A preliminary assessment of the seismic integrity of the Hot Fuel Examination Facility, as discussed in Slaughterbeck et al. (1995), indicates that, given the current state of analysis, significant failures could result at the Hot Fuel Examination Facility from this earthquake.

In determining the number of fuel assemblies that would be affected during this scenario, the analysis assumed that 20 fuel subassemblies would melt due to failure of the forced cooling in this accident. Although 40 storage positions are available for fuel that would require forced cooling, current plans do not estimate the need to use more than 20 of these positions. The release duration for this scenario is 30 days. To prevent doses greater than 5 rem to the public from this scenario, the analysis assumed intervention by evacuation or prevention of contaminated food consumption, with the calculated doses reflecting this assumption.

To determine the impacts from this postulated accident scenario, the analysis assumed the worker to be located 100 meters (328 feet) from the event, and the nearest point of public access (U.S. Route 20) and the nearest site boundary at 5,240 meters (5,730 yards).

5.15.6.4 Accident 4: Radiological Material Release from the Argonne National

Laboratory-West Hot Fuel Examination Facility Resulting from an Aircraft Crash and Ensuing Fire. The accident screening methodology discussed in Section 5.15.3 identified a radioactive material release from the Argonne National Laboratory-West Hot Fuel Examination Facility resulting from an aircraft crash as the maximum reasonably foreseeable accident in the beyond-design-basis accident frequency range. Of externally initiated events, an aircraft crash into the Hot Fuel Examination Facility is a maximum reasonably foreseeable accident because it could (1) cause a major breach of confinement barriers, (2) involve a large portion of the material at risk, and (3) have a high-energy release mechanism (physical impact followed by a sustained fire). The analysis eliminated other accident scenarios considered in this frequency range because they would not have sufficient energy sources to cause a large breach of confinement and release to the atmosphere. Although the facility contains little combustible material to sustain a fire, a fire caused by aircraft fuel involved in the crash could increase potential consequences over other beyond-design-basis accidents. The major events of an aircraft crash scenario are as follows:

- A large or high-velocity aircraft (e.g., commercial or military) crashes directly into the Hot Fuel Examination Facility.
- The impact has sufficient force to cause catastrophic failure of the building structure, breach of the Main Cell, and loss of forced cooling to subassemblies in the cell.
- The fuel in the aircraft is released to the facility and is ignited.
- The ensuing fire involves the contents of the Main Cell, Decontamination Cell, High Bay Area, and Hot Repair Area, resulting in atmospheric release of radionuclides.

To determine aircraft crash probability, the analysis limited this scenario to large or high-velocity jet airplanes. High-velocity military jets from the U.S. Air Force Base at Mountain Home in southwestern Idaho could enter the airspace of the INEL. In addition, large jet aircraft have been flown at low altitudes in landing configurations over portions of the INEL for vortex tests. The likelihood of a large aircraft crash directly in the Hot Fuel Examination Facility is remote, but possible. Analyses of jet aircraft crashes at specific facilities, such as the Idaho Chemical Processing Plant, have resulted in predicted frequencies on the order of 1.0 y 10-7 event per year. Because specific analyses have not determined the likelihood of an aircraft crash into the Hot Fuel

---

9. As discussed in Slaughterbeck et al. (1995), accelerations with any of several potential seismic events with a combined estimated frequency of 1 * 10(-5) per year are beyond the design of the Hot Fuel Examination Facility and were determined to compromise the ability of the structure to maintain confinement. Events this rare are beyond the requirements of DOE Order 5480.28 and DOE-ID Architechtural Engineering Standards for Category 1 (high hazard) facilities.

Examination Facility (although it is expected that fewer flights occur over the Argonne National Laboratory-West facility area than the Idaho Chemical Processing Plant), the analysis conservatively assumed that the frequency for an aircraft crashing into the Hot Fuel Examination Facility is 1.0 y 10-7 per year.

For determining impacts from this postulated accident scenario, the analysis assumed the worker was located 100 meters from the event; and the nearest point of public access (U.S. Route 20) and the nearest site boundary were both at 5,240 meters (5,730 yards).

5.15.6.5 Accident 5: Inadvertent Nuclear Chain Reaction During Spent Nuclear

Fuel Processing (1 x 1019 fissions) at the Idaho Chemical Processing Plant CPP-666 Fluorinel and Storage (FAST) Facility. The accident screening methodology discussed in Section 5.15.3 identified an inadvertent nuclear criticality resulting from spent nuclear fuel reprocessing in the CPP-666 Fluorinel and Storage Facility as a maximum reasonably foreseeable processing accident. Although the CPP-666 Fluorinel and Storage Facility, which historically reprocessed spent nuclear fuel to recover fissionable radionuclides (e.g., uranium-235), is currently shutdown, there may be a need to resume processing operations to dissolve spent nuclear fuel and to stabilize the radionuclides in a waste form. Therefore, while the potential for this accident does not currently exist, the potential would exist if processing-related activities are resumed under Alternatives 4b(1) and 5b (Regionalization and Centralization at the INEL, respectively).

Initiating events that the analysis considered possible to lead to an inadvertent nuclear criticality during processing included human error, equipment failure, an earthquake, an aircraft crash, excessive fissionable radionuclides in the spent nuclear fuel being processed, and reduced neutron poison concentrations. Consistent with the inadvertent criticality scenario associated with underwater storage of spent nuclear fuel described in Section 5.15.6.2, the fission yield associated with this criticality was assumed to be 1 y 1019 fissions. Further information and references regarding this postulated accident scenario are provided in Slaughterbeck et al. (1995) and EG&G (1993b).

As discussed in Section 5.15.2, three inadvertent nuclear criticalities have occurred in INEL processing facilities during the 40-year history of the INEL. The last of these criticalities occurred 14 years ago. As a result of these accidents, administrative controls and facility modifications were implemented to reduce the potential for inadvertent nuclear criticality accidents resulting from processing-related activities. If the decision is made to resume processing operations, these same controls would be utilized. Therefore, the estimated frequency for a potential inadvertent nuclear criticality is assumed to be 1 y 10-3 events per year, which is consistent with assumptions made regarding the potential for an inadvertent criticality resulting from underwater storage and handling of severely degraded spent nuclear fuel (as discussed in Section 5.15.6.2).

Limited credit was taken for mitigative features, such as emergency response programs, in determining worker and public exposures resulting from this postulated accident scenario. However, credit was taken for shielding walls placed in the facility to reduce potential personnel exposures resulting from an inadvertent nuclear criticality.

To determine the accident impacts from this postulated accident scenario, the analysis assumed the worker to be located 100 meters (328 feet) from the event, the nearest point of public access (U.S., Route 20/26) is 5,870 meters (6,420 yards), and the nearest site boundary is located at 14,000 meters (15,310 yards).

5.15.6.6 Accident 6: Radionuclide Release During Spent Nuclear Fuel Processing

at the Idaho Chemical Processing Plant CPP-666 Fluorinel and Storage (FAST) Facility Resulting from a Hydrogen Explosion in the Dissolver Off-Gas System. The accident screening methodology discussed in Section 5.15.3 identified a hydrogen explosion in the CPP-666 Fluorinel and Storage Facility dissolver off-gas system as a maximum reasonably foreseeable processing accident. Despite CPP-666's current shutdown status, there may be a need to resume processing operation to dissolve spent nuclear fuel and stabilize the radionuclides in a waste form.

Therefore, while the potential for this accident does not currently exist, the potential would exist if processing-related activities are resumed under Alternatives 4b(1) and 5b (Regionalization and Centralization at the INEL, respectively).

Initiating events that the analysis considered possible to lead to a hydrogen explosion in the dissolver off-gas system included human error, equipment failure, and an earthquake. Further information and references regarding this postulated accident scenario are provided in Slaughterbeck et al. (1995) and EG&G (1993b).

Limited credit was taken for mitigative features, such as emergency response programs, in determining worker and public exposures resulting from this postulated accident scenario. To determine the accident impacts from this postulated accident scenario, the analysis assumed the worker to be located 100 meters (328 feet) from the event, the nearest point of public access (U.S., Route 20/26) is 5,870 meters (6,420 yards), and the nearest site boundary is located at 14,000 meters (15,310 yards).

5.15.6.7 Accident 7: Radionuclide Release During Spent Nuclear Fuel Processing

at the Idaho Chemical Processing Plant CPP-666 Fluorinel and Storage (FAST) Facility Resulting from the Inadvertent Dissolution of 30-Day Cooled Spent Nuclear Fuel. The accident screening methodology discussed in Section 5.15.3 identified a radionuclide release resulting from the inadvertent dissolution of 30-day cooled spent nuclear fuel in the CPP-666 Fluorinel and Storage Facility as a maximum reasonably foreseeable accident. There may be a need to resume processing operation at CPP-666 to dissolve spent nuclear fuel and stabilize the radionuclides in a waste form. Therefore, while the potential for this accident does not currently exist, the potential would exist if processing-related activities are resumed under Alternatives 4b(1) and 5b (Regionalization and Centralization at the INEL, respectively).

Upon removal from a nuclear reactor, spent nuclear fuel is placed in an underwater storage canal (e.g., Advanced Test Reactor Storage Canal in the Test Reactor Area) to allow the fuel temperature to cool and short-lived radionuclides to decay. Inadvertent processing of spent nuclear fuel that has not had the opportunity to sufficiently cool presents the potential for accidents during dissolution of the fuel. Examples of accidents that could potentially occur are explosions in the dissolver tank and an inadvertent criticality. An explosion resulting from inadvertent dissolving spent nuclear fuel that has not sufficiently cooled (i.e., 30-day cooled fuel) is considered for this analysis since an inadvertent criticality is already considered (as discussed in Section 5.15.6.6).

The potential initiating event considered for this accident involves several operator errors that result in the wrong spent nuclear fuel assemblies being dissolved. First, fuel cooled 30 or fewer days would have to be shipped to and received by the Fluorinel and Storage Facility. Second, operators at the CPP-666 Fluorinel and Storage Facility would have to inadvertently dissolve the 30-day (or fewer) cooled fuel. Based on the individual probability of these events, and the probability that the dissolved fuel would accidentally release radionuclides to the environment, the estimated frequency for this event is 1 y 10-6 events per year. Further information and references regarding this postulated accident scenario are provided in Slaughterbeck et al. (1995) and EG&G (1993b).

Limited credit was taken for mitigative features, such as emergency response programs, in determining worker and public exposures resulting from this postulated accident scenario. To determine the accident impacts from this postulated accident scenario, the analysis assumed the worker to be located 100 meters (328 feet) from the event, the nearest point of public access (U.S., Route 20/26) is 5,870 meters (6,420 yards), and the nearest site boundary is located at 14,000 meters (15,310 yards).

5.16 Cumulative Impacts and Impacts from

Connected or Similar Actions

The INEL already contains major DOE facilities unrelated to spent nuclear fuel that would continue to operate throughout the life of the spent nuclear fuel management program. The activities associated with these existing facilities produce environmental consequences that this EIS has included in the baseline environmental conditions (Chapter 4) against which it has assessed the consequences of the spent nuclear fuel alternatives. In addition, the cumulative impacts assessed in this section include other past, present, and reasonably foreseeable future actions that DOE expects to occur at the INEL, such as spent nuclear fuel management, Naval Nuclear Propulsion Program activities, environmental restoration and waste management activities, as well as any known offsite projects conducted by government agencies, businesses, or individuals. Onsite projects include decontamination and decommissioning, repair, and upgrades of existing facilities. Offsite projects include residential and commercial development, and changes in manufacturing plants.

Consistent with the DOE sliding scale approach and the programmatic aspects of this EIS, cumulative impacts are discussed commensurate with the degree of impact. Therefore, not every area of analysis from Chapter 5 is represented in this section. DOE used information and analyses from Volume 2 of this EIS as input for this section. Section 5.15 of Volume 2 provides a more detailed discussion of cumulative impacts.

Tables 5.16-1 and 5.16-2 list the cumulative impacts identified for each alternative. DOE made necessary adjustments to accommodate the differences between Volume 1 and Volume 2 alternatives. Cumulative impacts from Alternatives 3 and 4a are nominally the same, as are cumulative impacts from Alternatives 1 and 2, 5a and 4b(2), and 5b and 4b(1).

5.16.1 Land Use

Implementation of any of the alternatives would contribute to the cumulative loss of land with open-space land use. However, the cumulative amount of land that would no longer be open space or available for other land uses would be small compared to the size of INEL or regional land uses. As discussed in Section 5.2, Land Use, the maximum land disturbance, 31 acres (0.12 square kilometer) would occur under Alternative 4b(l) [Regionalization by Geography (INEL)] and 5b (Centralization at INEL). While exact maximum figures are not available, over 200 acres (0.81 square kilometer) of vacant land in nearby communities are scheduled for development. Projects that would potentially

	Routine workplace safety hazards	Estimated fatalities	3	3	3	3	Estimates differ only slightly between alternatives due to changes in number of workers. Total workplace safety hazards are fewer than those encountered by the average worker in private industry.

a. Approximate numbers. See Volume 2, Section 5.12 and Volume 2, Appendix F for detailed discussion and analyses.
b. Estimated excess fatal cancers calculated from dosimeter measurements.

disturb previously disturbed land are scheduled to take place on about 270 acres (1.0 square kilometer) at the INEL. An additional 1,060 acres (4.3 square kilometers) of open space INEL land may also be disturbed by potential projects.

5.16.2 Socioeconomics

Any of the spent fuel management alternatives would cause minimal cumulative impacts on socioeconomic resources of the INEL region when combined with known onsite or offsite projects. The implementation of any of the alternatives would create temporary additional employment during construction; the upper bound of potential impact would occur under Alternatives 3, 4a, 4b(1), and 5b. In the long term, the expected future decrease in employment at the INEL would more than offset this increase, as well as any increases from known offsite projects. Therefore, the cumulative effect on employment would be an overall decrease. Potential population declines associated with the cumulative effect on regional employment are estimated to represent less than 2 percent of the total regional population. It is unlikely that a change in population of this size would generate any notable long-term adverse impacts to housing, community services, or public finance in the region.

5.16.3 Cultural Resources

The types of cumulative impacts on cultural resources are the same for all alternatives. Each of the alternatives, when combined with associated onsite and offsite activities, could potentially impact cultural resources. However, surveying, recording, and stabilizing archeological and historic sites and structures at the INEL would increase scientific knowledge of the region's cultural resources, although stabilizing resources may adversely affect their significance to Native American groups. The unchecked deterioration of both structures and historic documents on nuclear facilities at the INEL could have a long-term adverse impact on these resources. Long-term effects may also occur to traditional resources that may not be mitigated through scientific studies. Cumulative impacts associated with Alternatives 3 and 4a (see 1992/1993 Planning Basis and Regionalization by Fuel Type) and Alternatives 5b and 4b(1) [Centralization at INEL and Regionalization by Geography (INEL)] have the greatest potential for impacts. Alternatives 1 and 2 (No Action and Decentralization) would have the least potential for impacts.

5.16.4 Air Quality

For radiological emissions, all cumulative impacts at onsite and offsite locations are well below applicable standards and are a small fraction of the dose received from natural background sources. The highest dose to a maximally exposed member of the public would be caused by Alternatives 4b(l) and 5b and would be about 0.05 millirem per year. When added to the projected dose from other INEL proposed projects of approximately 0.7 millirem per year and the maximum baseline dose of 0.05 millirem per year, this dose would be well below the National Emissions Standards for Hazardous Air Pollutants limit of 10 millirem per year (CFR 1992c). The National Council on Radiation Protection and Measurements has identified a dose rate below 1 millirem per year as negligible (NCRP 1987).

Cumulative nonradiological impacts were analyzed in terms of concentrations of criteria and toxic air pollutants in ambient air. At site boundary locations, the highest potential concentrations of criteria pollutants remain well below applicable National Ambient Air Quality Standards (CFR 1991). Concentrations at public road locations within the INEL boundary could increase significantly from current levels, but would remain well below applicable standards.

5.16.5 Occupational and Public Health and Safety

Work activities and the exposure to radiological and chemical hazards under each of the alternatives would be similar to those at present. Therefore, average radiation dose, exposure to toxic chemicals, and associated health effects would be related to the number of site workers under each alternative. Because the cumulative impacts of any alternative would be a decrease in the number of workers, the cumulative impact of any alternative on occupational health would be a decrease in health effects to the levels listed in Table 5.16-2. The incidence of expected health effects would be similar for all alternatives because the relative difference in employment effects (and therefore the effects on the health of those employed) is very small. While air emissions present the only calculable pathway for public radiation exposure due to spent nuclear fuel management, groundwater and biotic pathways are included in Table 5.16-2 due to Volume 2 analyses of environmental restoration and waste management activities.

Occupational health data concerning historic accidents are incomplete and not readily available. Though historical records of accidents at the INEL are available, occupational doses were not always known and reported. Worker dose data are currently being collected and analyzed under a National Institute of Occupational Safety and Health program. Historical offsite doses associated with the INEL are summarized in the Idaho National Engineering Laboratory Historical Dose Evaluation (DOE 1991). The Centers for Disease Control and Prevention is conducting a more comprehensive reconstruction of doses from INEL operations. An assessment of the cumulative impacts of accidents at the Site to the health of INEL workers is not available at this time.

Cumulative transportation impacts are addressed in Volume 1, Appendix I.

5.16.6 Materials and Waste Management

The total volumes of waste existing and projected to be generated or shipped to the INEL from spent nuclear fuel management, as well as known onsite and offsite projects over a 10-year period, are presented by waste stream for each alternative in Table 5.16-1. The storage of low-level waste for incineration is not considered to be restrictive between 1995 and 2005; however, beyond 2005 additional capacity may be required. Although spent nuclear fuel management would not cause permitted storage capacity to exceed its limits without available treatment or disposal under the No Action and Decentralization Alternatives, it is anticipated that the permitted storage capacity for mixed low-level waste will be exceeded during the first year of a 10-year timeframe. All other alternatives include facility construction for storage of, or shipping of, mixed low-level waste; therefore, storage capacity is accounted for.

5.17 Adverse Environmental Effects That Cannot Be Avoided

The construction and operation of any of the alternatives at the INEL could result in adverse impacts to the environment. Changes in project design and other measures would avoid or otherwise mitigate most of these impacts to minimal levels. This section identifies only adverse impacts that mitigation could not reduce to minimal levels or avoid altogether.

Under each alternative, the continued deterioration of structures with historic preservation potential and historic documents on nuclear facilities could have a long-term adverse impact on these resources at the INEL. However, DOE would avoid potentially adverse impacts by preserving the historic value of the property through appropriate research, or by conducting limited rehabilitation on these structures. This impact is discussed in Section 5.4.

As discussed in Section 5.2, the maximum loss of habitat would involve the conversion to industrial use of about 31 acres (0.12 square kilometers) of previously disturbed habitat that is of low quality and limited use to wildlife; conversion would occur under Alternatives 4b(1) and 5b.

The amount of radiation exposure from normal operation of the spent nuclear fuel facilities would be a small fraction of the existing natural background at the INEL and would be well below applicable regulatory standards. In all cases, the number of estimated additional cancers is a small fraction of 1 per year of site operation through 2035. This effect is discussed in Section 5.12.

With the exception of the unavoidable temporary increase in noise due to construction activities, any impact of noise from activities under any of the alternatives would be minor and highly unlikely.

An unavoidable adverse impact of the proposed activities with any of the alternatives would be an accident either at the involved facilities or during the transportation of construction materials or dismantled components. Accidents are discussed in Section 5.15; transportation is discussed in Section 5.11.

Spent nuclear fuel management supports the continuation of beneficial activities such as radiopharmaceutical and other research. An unavoidable adverse impact of the No-Action Alternative would be a reduction in the support of such activities.

As discussed in Section 5.14, the increased generation of industrial solid waste that would occur under all alternatives is an unavoidable adverse impact. However, the amount generated under each alternative would be a very small percentage increase from the projected 1995 baseline levels.

5.18 Relationship Between

Short-Term Use of the Environment and the Maintenance and Enhancement of Long-Term Productivity

Under all alternatives, short-term use of the environment is generally associated with resource demands for spent nuclear fuel management activities. Resources demands also include those required for upgrade, construction, and operation of facilities. These short-term demands and uses provide a foundation and direction for the long-term productivity of INEL; they also have an effect on the success of future INEL missions. A brief discussion of the influence proposed actions would have on the long-term productivity of the INEL follows. The INEL missions, including spent nuclear fuel, are discussed in Section 2.1.

The No-Action Alternative would provide few long-term benefits and would not allow DOE-Idaho Operations Office to fulfill its missions regarding the disposition and management of spent nuclear fuel. The activities proposed in this alternative would not support future proposals for disposal technology development. Further, the No-Action Alternative could bring enforcement actions because it would not meet all the requirements of existing DOE regulatory commitments such as those outlined in the Federal Facility Agreement and Consent Order.

To a varying degree, Alternatives 2, 3, and 4(a) would provide more flexibility than other alternatives for fulfilling existing or future missions and actions at INEL. Near- and long-term actions under these alternatives ensure compliance with regulatory requirements and protection of the environment. Furthermore, these alternatives would provide a diverse decisionmaking platform for future actions concerning disposition of DOE spent nuclear fuel. Facilities constructed and technologies developed under these alternatives could be used for a wide range of activities such as interim treatment and storage or preparation and packaging for transportation offsite.

The approach that would be taken for spent nuclear fuel under Alternatives 4b(2) and 5a could confine and hinder long-term productivity at INEL. Efforts would focus on shipment of spent nuclear fuel to other locations. No emphasis would be placed on solving particular spent nuclear fuel disposal problems or increasing the understanding of how certain spent nuclear fuels react over time.

Alternatives 4b(1) and 5b would direct INEL's future mission and development primarily toward large-scale canning and characterization, storage, and disposal of all INEL and DOE regional or complex-wide spent nuclear fuel. These alternatives could limit INEL's flexibility in redirecting or enhancing future INEL-specific missions.

5.19 Irreversible and Irretrievable Commitment of Resources

The irreversible and irretrievable commitment of natural and manmade resources resulting from the construction and operation of facilities related to the spent nuclear fuel alternatives would involve materials and resources that could not be recovered or recycled or that would be consumed or reduced to unrecoverable forms. Some of these commitments would be irretrievable because of the nature of the commitment or the cost of reclamation. For example, the construction and operation of spent nuclear fuel facilities at the INEL would consume irretrievable amounts of electrical energy, fuel, concrete, steel, aluminum, copper, plastics, lumber, sand, gravel, groundwater, and miscellaneous chemicals.

Alternatives 4b(1) and 5b are each estimated to require approximately 11,000 megawatt-hours per year of electricity, 1,100,000 liters (290,000 gallons) per year of fuel oil, and 48 million liters (13 million gallons) per year of water above the projected baseline (1995) usage of these resources (see Section 5.13). These changes would represent a modest increase of 5.3 percent, 9.9 percent, and 0.7 percent respectively, and are well within current system capabilities and usage limits. All other alternatives would place smaller demands on these resources, commensurate with the level of construction and operation activities proposed.

Alternatives 4b(1) and 5b would also commit 31 acres (0.12 square kilometer) of previously disturbed land to industrial use; the conversion of this acreage would result in the commitment of poor quality wildlife habitat and natural resource services. Alternatives 4b(1) and 5b would involve the greatest irretrievable consumption of other resources, such as construction materials and operating supplies. However, this demand would not constitute a permanent drain on local resources or involve any material that is in short supply in the region.

Other commitments would be irreversible because the construction or operation of facilities related to the spent nuclear fuel alternatives would consume the resource. Proposed activities would also require an expenditure of labor that would be irretrievable.

5.20 Potential Mitigation Measures

This section summarizes measures that DOE would use to avoid or reduce impacts to the environment caused by spent nuclear fuel management activities at the INEL. The potential mitigation measures for each aspect of the affected environment described below are the same under each alternative. Section 5.7 of Volume 1 discusses other generalized measures DOE could use.

5.20.1 Pollution Prevention

DOE is committed to comply with Executive Order 12856, Federal Compliance with Right-to-Know Laws and Pollution Prevention Requirements; Executive Order 12873. Federal Acquisition, Recycling and Waste Prevention; and applicable DOE Orders and guidance documents in planning and implementing pollution prevention at the INEL. The DOE views source reduction as the first priority in its pollution prevention program, followed by an increased emphasis on recycling. Waste treatment and disposal are considered only when prevention or recycling is not possible or practical.

5.20.2 Cultural Resources

The lack of detailed specifications associated with the proposed construction at the INEL under various alternatives precludes identifying specific project impacts and potential mitigation measures for particular structures and facilities. Basic compliance under cultural resource law involves five steps that would be essentially the same under all alternatives. These steps are (a) identification and evaluation of resources in danger of impact, (b) assessment of effects to these resources in consultation with the State Historic Preservation Office and representatives of the Shoshone-Bannock Tribes, (c) development of plans and documents to minimize any adverse effects. (d) consultation with the Advisory Council on Historic Preservation and tribal representatives as to the appropriateness of mitigation measures, and (e) implementation of potential mitigation measures. Therefore, if a cultural resource survey has not been performed in an area planned for ground disturbance under one of the proposed alternatives, consultation would be initiated with the Idaho State Historic Preservation Office and the survey would be conducted prior to any disturbance. If cultural resources were discovered, they would be evaluated according to National Register criteria. Wherever possible. important resources would be left undisturbed. If the impacts are determined to be adverse and it is not feasible to leave the resource undisturbed, then measures would be initiated to reduce impacts. All mitigation plans would be developed in consultation with the State Historic Preservation Office and the Advisory Council on Historic Preservation and would conform to appropriate standards and guidelines established for historic preservation activities by the Secretary of the Interior.

Some actions may affect areas of religious, cultural, or historic value to Native Americans. DOE has implemented a Working Agreement (DOE 1992d) to ensure communication with the Shoshone-Bannock Tribe, especially relating to the treatment of archeological sites during excavation, as mandated by the Archeological Resources Protection Act (ARPA 1979); the protection of human remains, as required under the Native American Graves Protection and Repatriation Act (NAGPRA 1990); and the free exercise of religion as protected by the American Indian Religious Freedom Act (AIRFA 1978). In keeping with DOE Native American policy (DOE 1990), DOE Order 1230.2 (DOE 1992c), and procedures to be defined in the final Cultural Resources Management Plan for the INEL, DOE would conduct Native American consultation during the planning and implementation of all proposed alternatives. Procedures for dealing with the inadvertent discovery of human remains would be consistent with the Native American Graves Protection and Repatriation Act (NAGPRA 1990). If human remains are discovered, DOE will notify all tribes that have expressed an interest in the repatriation of graves as required under NAGPRA, including the Shoshone-Bannock, Shoshone, Painte, and the Northwestern band of the Shoshone Nation. These tribes will then have an opportunity to claim the remains and associated artifacts in accordance with the requirements of NAGPRA. Procedures for the repatriation of "cultural items" in accordance with NAGPRA will be described in a curation agreement that will be finalized by June 1996.

In addition to consultation, other measures would mitigate potential adverse effects to Native American Resources, in particular effects to air, water, plants, animals, and visual setting. These measures include avoidance of sensitive areas, placement of facilities within existing areas of construction, revegetation with native plants of areas with ground disturbance, monitoring of plants and animals within hunting and gathering areas for radiological contamination, reducing noise and night lights outside of existing facilities, monitoring tanks, ponds and runoff for contaminants, minimizing ground disturbance, use of dust suppressers during construction, and use of filters and other air pollutant control equipment to reduce air contaminants.

5.20.3 Traffic and Transportation

All onsite shipments of spent nuclear fuel would be in compliance with ID Directive 5480.3, "Hazardous Materials Packaging and Transportation Safety Requirements." These requirements provide assurance that, under normal conditions, the INEL would meet as-low-as-reasonably-achievable conditions, reasonably foreseeable accident situations (those with probability of occurrence greater than 1x10^-7 per year) would not result in a loss of shielding or containment or a criticality, and an unintentional release of radioactive material would result in a timely response.

DOE would approve the type packages used for onsite shipments or would obtain a Nuclear Regulatory Commission or DOE certificate of compliance. If the onsite package did not have Nuclear Regulatory Commission or DOE certification, the user of the package would have to establish how administrative controls or other potential mitigating measures would ensure that the package would maintain containment and shielding integrity. The administrative and emergency response considerations would provide sufficient control so that accidents would not result in loss of containment or shielding, in criticality, or in an uncontrolled release of radioactive material that would create a hazard to the health and safety of the public or workers. Accident mitigation is described below.

5.20.4 Accidents

The DOE would initiate INEL emergency response programs, as appropriate, following the occurrence of an accident to prevent or mitigate consequences. These emergency response programs, implemented in accordance with 5300-DOE series Orders, typically involve emergency planning, emergency preparedness, and emergency response actions. Participating government agencies with plans that are interrelated with the INEL Emergency Plan for Action include the State of Idaho, Bingham County, Bonneville County, Butte County, Clark County, Jefferson County, the Bureau of Indian Affairs, and Fort Hall Indian Reservation. When an emergency condition exists at a facility, the Emergency Action Director is responsible for recognition, classification, notification, and protective action recommendations. Each emergency response plan utilizes resources specifically dedicated to assist a facility in emergency management. These resources include but are not limited to the following:

- INEL Warning Communications Center
- INEL Fire Department
- Facility Emergency Command Centers
- DOE Emergency Operations Centers
- County and State Emergency Command Centers
- Medical, health physics, and industrial hygiene specialists
- Protective clothing and equipment (respirators, breathing air supplies, etc.)
- Periodic training exercises and drills within and between the organizations involved in implementing the response plans

1. INTRODUCTION

The U.S. Department of Energy (DOE) is engaged in two related decisionmaking processes concerning: (1) the transportation, receipt, processing, and storage of spent nuclear fuel (SNF) at the DOE Idaho National Engineering Laboratory (INEL) which will focus on the next 10 years; and (2) programmatic decisions on future spent nuclear fuel management which will emphasize the next 40 years.

DOE is analyzing the environmental consequences of these spent nuclear fuel management actions in this two-volume Environmental Impact Statement (EIS). Volume 1 supports broad programmatic decisions that will have applicability across the DOE complex and describes in detail the purpose and need for this DOE action. Volume 2 is specific to actions at the INEL. This document, which limits its discussion to the Savannah River Site (SRS) spent nuclear fuel management program, supports Volume 1 of the EIS. Other documents supporting Volume 1 focus on spent nuclear fuel management programs for the Hanford Site, INEL, Naval Nuclear Propulsion Program, and other sites.

As part of its planning process for this two-volume EIS, DOE issued an Implementation Plan on October 29, 1993. The organization of this document is consistent with the provisions established in the Implementation Plan and are outlined below:

- Chapter 2 contains background information related to the SRS and the framework of environmental regulations pertinent to spent nuclear fuel management.
- Chapter 3 identifies spent nuclear fuel management alternatives that DOE could implement at the SRS, and summarizes their potential environmental consequences.
- Chapter 4 describes the existing environmental resources of the SRS that spent nuclear fuel activities could affect.
- Chapter 5 analyzes in detail the environmental consequences of each spent nuclear fuel management alternative and describes cumulative impacts. The chapter also contains information on unavoidable adverse impacts, commitment of resources, short-term use of the environment and mitigation measures.

2. BACKGROUND

The chapter contains an overview of the Savannah River Site (SRS) and a description of the regulatory framework related to the actions that this document evaluates. In addition, it discusses the U.S. Department of Energy (DOE) Spent Nuclear Fuel (SNF) Management Program as it relates to the SRS. Finally, it describes the representative sites located on the SRS that could serve as locations for spent nuclear fuel facilities.

2.1 SRS Overview

The SRS is a key DOE facility for research on and processing of special nuclear materials. The U.S. Government built the Site in the early 1950s to produce the basic materials - primarily plutonium-239 and tritium - used in the fabrication of nuclear weapons. The DOE Savannah River Operations Office manages the SRS, and Westinghouse Savannah River Company (WSRC) operates the Site under contract to DOE.

2.1.1 Site Description

The SRS occupies an area of approximately 310 square miles (800 square kilometers) in western South Carolina, in a generally rural area about 25 miles (40 kilometers) southeast of Augusta, Georgia, and 12 miles (19 kilometers) south of Aiken, South Carolina (Figure 2-1). The Savannah River forms the southwestern border of the SRS, which includes portions of Aiken, Barnwell, and Allendale Counties. The average population density (1990 census data) in the six-county region of influence around the Site is 140 people per square mile (54 per square kilometer); the largest concentration is 2,595 people per square mile (1,002 per square kilometer) in the City of Augusta (HNUS 1992). Four other population centers - Aiken, Allendale, Barnwell, and North Augusta, South Carolina - are within 22 miles (40 kilometers) of the Site. Three small towns - Jackson, New Ellenton, and Snelling, South Carolina - are adjacent to the SRS boundary to the northwest, north, and east, respectively. Based on 1990 U.S. Census Bureau data, the population within a 50-mile (80-kilometer) radius of the SRS is approximately 620,100 (Arnett et al. 1993).

The Site consists primarily of managed upland forest with some wetland areas. Facilities and roadways occupy approximately 5 percent of the SRS land area. Access to the Site is controlled, with public transportation limited to through traffic on South Carolina Highway 125 (SRS Road A), U.S. Highway 278, SRS Road 1, and the CSX Railroad corridor.

Figure 2-1. National location of SRS.

The SRS contains 15 major production, service, and research and development (R&D) areas that previously supported nuclear materials production and can support processing operations and waste management activities. Major SRS facilities include five nuclear reactors, two chemical separations plants, a fuel and target fabrication facility, the Defense Waste Processing Facility (DWPF), the Replacement Tritium Facility, a heavy-water rework plant, and the Savannah River Technology Center (SRTC), formerly called the Savannah River Laboratory. In addition, the University of Georgia Research Foundation operates the Savannah River Ecology Laboratory (SREL) on the Site under contract to DOE. Under an interagency agreement, the U.S. Forest Service operates the Savannah River Forest Station, which manages the natural resources and secondary roads on the Site. These facilities are in defined areas scattered across the Site. Each area is identified by a letter designation, as summarized in Table 2-1. Figure 2-2 shows the locations of the principal SRS facilities. The reactor, waste storage, and separations areas are at least 4 miles (6 kilometers) inside the nearest SRS boundary.

The primary SRS facilities were related to the production of nuclear materials. M-Area manufactured fuel and target components for shipment to the SRS reactors. Originally, the Site operated five reactors; at present, all are in shutdown status. Shielded railroad cars transported irradiated fuel to the F- or H-Area Canyon for the recovery of nuclear materials. The F- and H-Area separations processes dissolve irradiated components in acid, and extract and separate the desired nuclear materials. In H-Area, additional processes extract other products from irradiated components.

DOE neutralizes and stores the high-level liquid radioactive waste generated by the separations facilities in underground tanks. DOE plans to process this waste into a borosilicate glass waste form in the Defense Waste Processing Facility when that facility becomes operational, and to store this glass waste form at the SRS until an offsite geological repository is available. [DOE has prepared a Supplemental EIS related to Defense Waste Processing Facility operations (DOE 1994a).] In addition to the underground waste storage tanks, DOE has established a centrally located 196-acre (0.8-square-kilometer) site between F- and H-Areas, called E-Area, for the disposal of solid low-level radioactive waste and the storage of transuranic (TRU) radioactive waste and mixed (hazardous and radioactive) waste. The Site also has a central sanitary landfill and buildings in the Central Shops (N-Area) for the storage of nonradioactive hazardous wastes and mixed waste. DOE is preparing an EIS on waste management activities at the SRS (DOE 1995a).

Table 2-1. Description of functions and principal facilities at SRS areas.

Area	Function	Principal facilities
A	Main DOE administration area, research laboratories	Main administration building, Savannah River Technology Center, Savannah River Ecology Laboratory, powerhouse
B	Wackenhut Services, Inc., administration area (security)	Administration building, WSRC Engineering building, WSRC training buildings
C	One of five SRS reactors	C-Reactor, training facilities, cooling basin
D	Central powerhouse and heavy-water rework	Powerhouse, heavy-water rework facility
E	Waste disposal and storage	Solid Waste Disposal Facility
F	Process plutonium	F-Area Canyon, FB-Line, tank farm
G	Various support functions	Spread throughout the Site: railroad yard, U.S. Forest Service installations
H	Process uranium and tritium	H-Area Canyon, HB-Line, Effluent Treatment Facility, tank farm, Receiving Basin for Offsite Fuels, Consolidated Incineration Facility
K	One of five SRS reactors	K-Reactor, cooling basins, cooling tower
L	One of five SRS reactors	L-Reactor, cooling basins
M	Production of fuel and target assemblies	Slug and target production facilities, effluent treatment facility
N	Receiving	Central Shops
P	One of five SRS reactors	P-Reactor, cooling basins
R	One of five SRS reactors	R-Reactor, cooling basins
S	Process high-level radioactive waste	Defense Waste Processing Facility
TNX	Applied research and development	Analytical laboratory, Defense Waste Processing Technology facilities, various mockups, effluent treatment facilities
Z	Waste treatment and handling	Saltstone facility

The Site contains facilities for processing support and for research and development. These include operational coal-fired powerhouses in A-, D-, and H-Areas that generate electricity and steam. The largest powerhouse, which is in D-Area, produces electricity and sends process steam to C-, F-, H-, and S-Areas through a 7-mile (11-kilometer) steam line. D-Area also contains the heavy-water rework facility at which DOE purified the deuterium oxide (heavy water) used as the moderator and coolant in SRS reactors. TNX-Area facilities study chemical and waste processing problems and test production-scale equipment. Finally, A-Area facilities include the Savannah River Technology Center, the Savannah River Ecology Laboratory, and the DOE and Westinghouse Savannah River Company administrative offices.

Figure 2-2. Location of principal SRS facilities (see Table 2-1).

The SRS employs approximately 20,000 people. Most of these employees work for Westinghouse Savannah River Company and its subcontractors. The remainder work for DOE, the Savannah River Ecology Laboratory, Wackenhut Services, Inc., the U.S. Forest Service, and other contractors.

2.1.2 Site History

The U.S. Atomic Energy Commission (AEC), a DOE predecessor agency, selected the location for the SRS in November 1950 after a study of more than 100 prospective sites. The government selected E. I. du Pont de Nemours and Company, Inc., to build and operate the facility. Construction began in February 1951; the basic plant was completed in 1956 at a cost of $1.1 billion, including the land. On October 3, 1952, operations began with the startup of a unit of the heavy-water extraction plant. Criticality occurred in the first production reactor on December 28, 1953.

In 1972, the AEC designated the SRS as the nation's first National Environmental Research Park. Through the years, scientists have performed a wide range of investigations on the diverse habitats, flora, and fauna of the Site.

2.1.3 Mission

The historic mission of the SRS was to serve the national security interests of the United States by safely processing nuclear materials while protecting the health and safety of employees and the public and protecting the environment. The SRS was responsible for producing tritium and special nuclear materials for national defense. At present, it supports the viability of the weapons stockpile by recycling limited-life components. The SRS also produces isotopes for nonweapons applications in the nation's space program and for medical applications.
